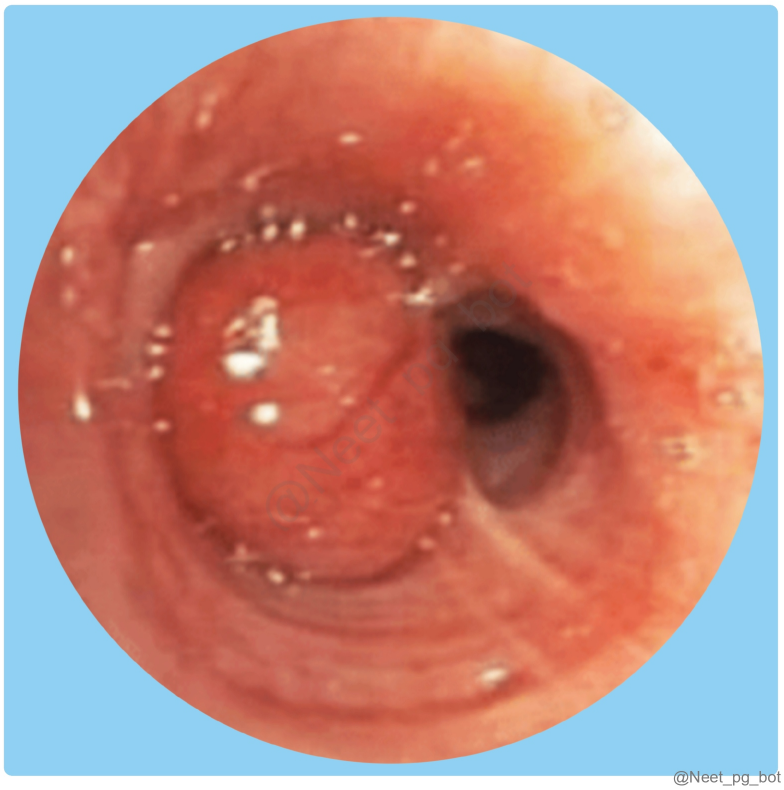
Q1: A 50-year-old female presents with a chronic cough and recurrent episodes of wheezing. Bronchoscopy reveals a "coat button lesion" within the bronchus, as shown in the image. Biopsy of the lesion shows nesting of cells with uniform round nuclei and moderate eosinophilic cytoplasm. What is the most likely diagnosis based on the described features? (Q845562)

A. Small cell lung carcinoma

B. Squamous cell carcinoma

C. Bronchial carcinoid tumor

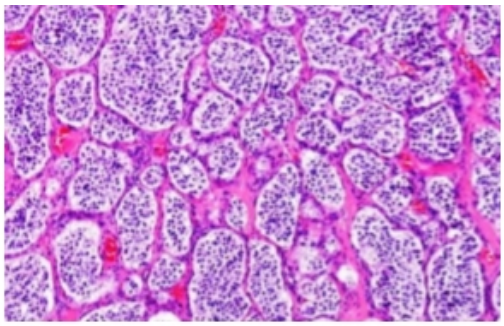
D. Adenocarcinoma



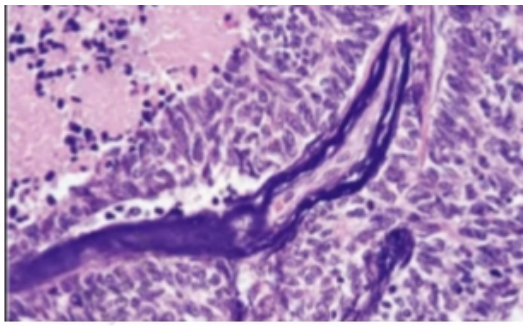
Correct Answer: C. Bronchial carcinoid tumor

- *Listen (English)*
- *Listen (Hindi)*

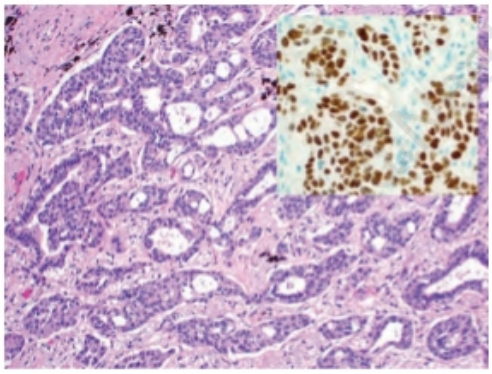
Explanation: The features described in the scenario suggest bronchial carcinoid tumour, a neuroendocrine tumour of bronchial epithelium characterised by nesting of cells with uniform round nuclei, moderate eosinophilic cytoplasm , and the characteristic "salt and pepper" appearance of chromatin within the nuclei. Typical carcinoids exhibit <2 mitoses per 10 high-power fields and lack necrosis. Atypical carcinoids may show 2-10 mitoses per 10 high-power fields and/or foci of necrosis. Characteristic Small Cell Carcinoma (Option A) Squamous Cell Carcinoma (Option B) Carcinoid Tumor (Option C) Adenocarcinoma (Option D) Origin Neuroendocrine cells of the lung. Squamous cells of the lung. Neuroendocrine cells of bronchial epithelium. Glandular cells of the lung. Cells in histopathology Small, round to oval, blue cells with scant cytoplasm and finely granular chromatin with a “salt and pepper” appearance. Sheets of polygonal cells with keratinisation and intercellular bridges Nesting (organoid) growth pattern with uniform round nuclei, moderate eosinophilic cytoplasm, and a “salt-and-pepper” chromatin pattern. Glandular or epithelial cells forming acinar, papillary, or solid patterns Mitotic rate High Variable Low to moderate Variable Electron microscopy findings Dense core neurosecretory granules. Desmosomes, tonofilaments, keratinisation Dense core neurosecretory granules. Variable organelles, sometimes containing mucin vacuoles IHC markers Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin). P63, p40, CK5/6 Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin) Variable (e.g., TTF-1, Napsin A for primary lung adenocarcinoma)



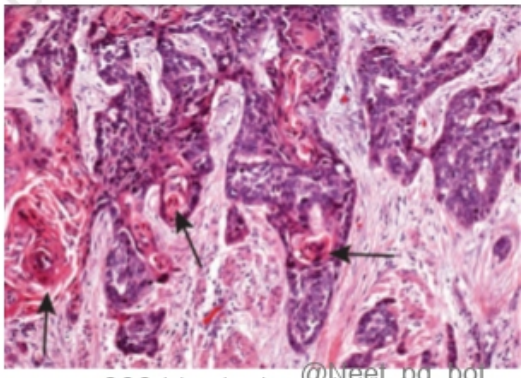
Carcinoid tumor (Nesting pattern)



Small cell cancer (showing Azzopardi effect)



Adenocarcinoma (Inset showing IHC)



SCC (showing keratinization)

@Neet_pg_bot

Q2: Which of the following lung cancer subtypes has the highest mutational burden and is the most aggressive? (Q890492)

A. Adenocarcinoma

B. Squamous cell carcinoma

C. Small cell carcinoma

D. Large cell carcinoma

Correct Answer: C. Small cell carcinoma

Explanation: Small cell carcinoma has the highest mutational burden among lung cancers and is the most aggressive subtype. Small Cell Carcinoma (Lung): Highly aggressive; strong smoking association No preinvasive

phase; early widespread metastasis Highest mutational burden TP53 inactivation, RB loss, and 3p loss are common MYC amplification frequent Histology:■ Small cells, scant cytoplasm Salt & pepper chromatin Nuclear molding High mitoses, extensive necrosis Azzopardi effect ■ Chromogranin, Synaptophysin, and CD56 positive Most common lung cancer causing ectopic hormone production Adenocarcinoma (Option A): Most common lung cancer overall, usually peripheral and associated with EGFR, ALK, KRAS mutations ; less aggressive than small cell carcinoma. Squamous cell carcinoma (Option B): Smoking-related central lung tumor showing keratinization and intercellular bridges ; aggressive but slower than small cell carcinoma. Large cell carcinoma (Option D): Poorly differentiated non-small cell carcinoma lacking glandular or squamous differentiation; not the most aggressive subtype.

@Neet_pg_bot

Q3: Which of the following is the most common presenting symptom of lung carcinoma? (Q890491)

A. Cough

B. Hemoptysis

C. Chest pain

D. Weight loss

Correct Answer: A. Cough

Explanation: Cough is the most common presenting symptom of lung carcinoma, occurring in approximately 75% of patients. It usually results from involvement or irritation of the central airways by the tumour. Common Presenting Complaints (Lung Cancer): Cough - 75% (Most common) Weight loss - 40% (Option D) Chest pain - 40% (Option C) Dyspnea - 20% Local Effects of Lung Tumour Spread: Clinical Feature Pathologic Basis Cough (50-75%) Involvement of the central airways Hemoptysis (25-50%) (Option B) Tumour haemorrhage into the airway Chest pain Extension into the mediastinum, pleura, or chest wall Pneumonia / Abscess / Lobar collapse Airway obstruction by tumor Pleural effusion Tumour spread to the pleura Hoarseness Recurrent laryngeal nerve invasion Dysphagia Esophageal invasion SVC syndrome Superior vena cava compression Horner syndrome Sympathetic ganglia invasion Pericarditis / Cardiac tamponade Pericardial involvement

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 656, 657

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following represents the most common histologic subtype of lung cancer worldwide? (Q890490)

A. Adenocarcinoma > Squamous cell carcinoma > Small cell carcinoma

B. Small cell carcinoma > Large cell carcinoma > Adenocarcinoma

C. Adenocarcinoma > Small cell carcinoma > Squamous cell carcinoma

D. Squamous cell carcinoma > Adenocarcinoma > small cell carcinoma

Correct Answer: A. Adenocarcinoma > Squamous cell carcinoma > Small cell carcinoma

Explanation: Adenocarcinoma is the most common histologic subtype of lung cancer worldwide (~50%), followed by squamous cell carcinoma (~20%), and then small cell carcinoma (~15%). Adenocarcinoma has surpassed squamous cell carcinoma globally and is also the most common subtype in never-smokers. Lung Carcinoma: Most frequently diagnosed major cancer worldwide Leading cause of cancer mortality Age Distribution: Common between 55-84 years Peak: 65-74 years Only 2% occur <40 years Major Histologic Types: Adenocarcinoma (50%) Squamous cell carcinoma (20%) Small cell carcinoma (15%) Large cell carcinoma (2%) Others (13%)

@Neet_pg_bot

Q5: What is the diagnosis for a patient who has a history of smoking 24 packs, is currently experiencing breathlessness and chest pain, and is found to have a lung tumor with positive chromogranin staining? (Q882173)

A. Adenocarcinoma

B. Squamous cell carcinoma

C. Mesothelioma

D. Small cell carcinoma

Correct Answer: D. Small cell carcinoma

Explanation: Small cell lung cancer (SCLC) is a highly aggressive type of lung cancer that is strongly associated with smoking. It tends to grow rapidly and is often diagnosed at an advanced stage. SCLC is characterized by positive staining for neuroendocrine markers, including chromogranin, which confirms its neuroendocrine origin. This cancer typically arises centrally in the lung, often in the bronchi, and can cause symptoms such as breathlessness and chest pain. Cancer Type Smoking Location Markers Genes Histopathology Notes Adenocarcinoma (Option A) Weak association Peripheral TTF-1, Napsin A EGFR, ALK, KRAS Lepidic spread Most common overall (India and World) Small cell carcinoma (Option D) Strong association Central Chromogranin, Synaptophysin, NSE, Bombensin L-myc Azzopardi effect, Salt and pepper chromatin Neuroendocrine, aggressive Squamous cell carcinoma (Option B) Strong association Central p40/p63 p53 Keratin Pearls Hypercalcemia (PTHrP) Mesothelioma (Option C) Asbestos Pleura Calretinin, Ck5/6, WT-1 BAP-1 Long and slender microvilli seen on electron microscopy Pleural tumor

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 715-722

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which of the following is not an IHC marker for small-cell lung carcinoma? (Q846630)

A. Napsin A

B. Chromogranin

C. NSE

D. CD56

Correct Answer: A. Napsin A

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: NAPSIN A, MUC 1, and TTF 1 are the IHC (immunohistochemistry) markers for adenocarcinoma of the lung. IHC markers for small cell lung carcinoma are: Synaptophysin Chromogranin (Option B) Bombesin NSE (Neuron-Specific Enolase) (Option C) INSM CD56 (Option D) CD57

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 719.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 56-year-old male presents with persistent shoulder pain radiating to the ulnar aspect of the forearm and progressive weakness in his right hand. Examination reveals muscle wasting in the right hand. Imaging of the chest shows a mass at the apex of the right lung involving nearby neurovascular structures. Which syndrome is most likely associated with this presentation? (Q845630)

A. Horner syndrome

B. Superior vena cava (SVC) syndrome

C. Caplan syndrome

D. Carcinoid syndrome

Correct Answer: A. Horner syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's presentation and the presence of a lung apex mass involving nearby neurovascular structures suggests a Pancoast tumour (superior sulcus tumour) located at the apex of the lung, typically involving nearby neurovascular structures. Compression or invasion of nearby nerves, including the sympathetic chain, can result in Horner syndrome, characterised by a combination of ptosis (drooping eyelid), miosis (constricted pupil), and anhidrosis (lack of sweating) on the affected side of the face and sometimes enophthalmos (sunken appearance

of the eyeball). Superior vena cava syndrome (Option B): SVC syndrome is characterised by symptoms related to compression or obstruction of the superior vena cava, typically by a tumour in the mediastinum leading to facial swelling, dilated veins, and other signs of venous congestion but not neurological manifestations. Caplan syndrome (Option C): Caplan syndrome is the combination of rheumatoid arthritis and pneumoconiosis (Coal workers' pneumoconiosis) with characteristic pulmonary nodules . It is not associated with any neurological symptoms. Carcinoid syndrome (Option D): Carcinoid syndrome is associated with symptoms such as flushing, diarrhoea, and wheezing due to the release of vasoactive substances from carcinoid tumours, and it has no association with neurological manifestations.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 722

↑ *Back to this question in Part A*

@Neet_pg_bot

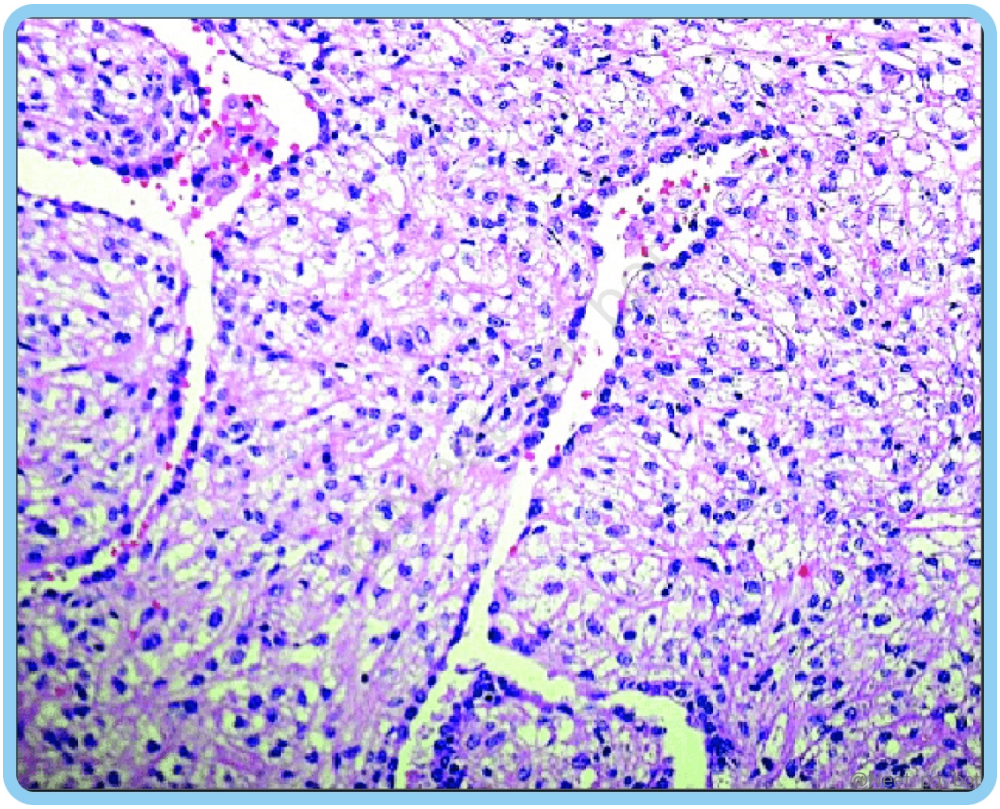
Q8: A 55-year-old woman has an incidental finding of a lung mass on imaging. CT scan reveals a well-circumscribed lesion with calcifications. Biopsy revealed spindle and epithelioid cells with an eosinophilic cytoplasm, perivascular growth, and positive HMB-45 staining. What is the most likely diagnosis? (Q845627)

A. Pulmonary hamartoma

B. Sugar tumour (PEComa)

C. Solitary fibrous tumour

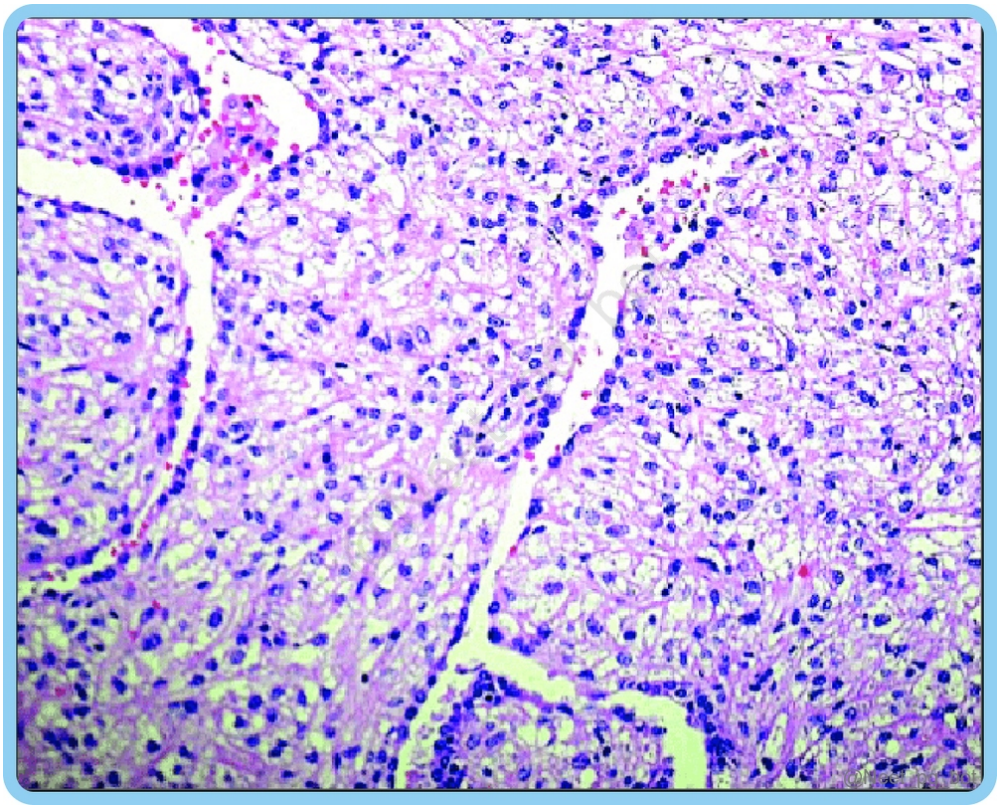
D. Carcinoid tumour

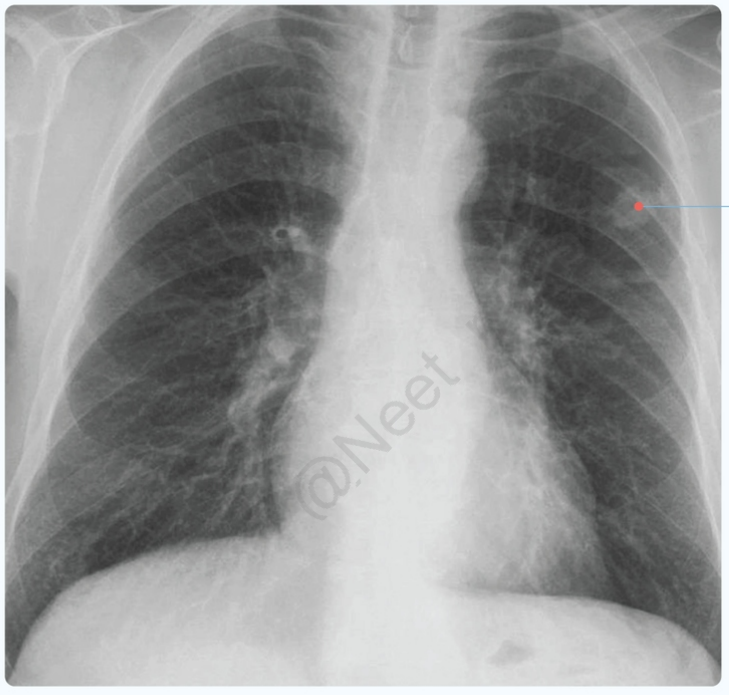


Correct Answer: B. Sugar tumour (PEComa)

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical scenario of a well-circumscribed lung mass with calcifications and histological features of spindle and epithelioid cells with eosinophilic cytoplasm, perivascular growth pattern , and positivity for HMB-45 immunostaining is highly suggestive of a sugar tumour. It is also known as a perivascular epithelioid cell tumour (PEComa). PEComa It is a rare mesenchymal tumour . It can lead to cystic, emphysema-like dilation of terminal airspaces and obstruction of lymphatic vessels . Treatment involves surgical resection, and mTOR inhibitors are considered for un-resectable or metastatic cases. Pulmonary hamartomas (Option A): Pulmonary hamartomas are benign lung tumours of mesenchymal and epithelial components like cartilage, fat, and fibrous tissue . They are often discovered incidentally on imaging scans as small, well-defined, rounded opacities (coin lesions). Microscopically, they show nodules of connective tissue with epithelial clefts, often containing cartilage and lined by ciliated or non-ciliated epithelium. Solitary fibrous tumour (Option C): Solitary fibrous tumours are rare mesenchymal tumours of the lung and are well-circumscribed masses composed of spindle and epithelioid cells . They typically stain positive for CD34 and STAT6 , with a favourable prognosis after surgical resection. Carcinoid tumor (Option D): Carcinoid tumours are neuroendocrine tumours typically manifest as polypoid masses in the bronchi. Their histopathological features include the nesting of cells with uniform round nuclei, moderate eosinophilic cytoplasm, and chromatin's characteristic 'salt and pepper' appearance within the nuclei . These tumours stain positive for neuroendocrine markers like Synaptophysin and Chromogranin.





@Neet_pg_bot

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 722-724

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 55-year-old former shipyard worker presents with progressive dyspnea and left-sided chest pain for three months. He has a history of occupational asbestos exposure. Physical examination reveals decreased breath sounds over the left lung base. Imaging shows left-sided pleural thickening and effusion. Biopsy confirms mesothelioma. Which of the following statements is not accurate about mesothelioma and adenocarcinoma following asbestos exposure? (Q845595)

A. Adenocarcinoma often has a shorter latency period compared to mesothelioma following asbestos exposure.

B. Mesothelioma under electron microscopy, reveals non-branching microvilli.

C. Mesothelioma often presents with positive staining for calretinin and WT-1.

D. Adenocarcinoma is commonly associated with EGFR mutation.

Correct Answer: B. Mesothelioma under electron microscopy, reveals non-branching microvilli.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Characteristic Malignant mesothelioma Adenocarcinoma lung Origin Arises from mesothelial cells lining the pleura. Arises from glandular epithelial cells. Association with asbestos exposure Most specific tumours due to asbestos exposure M/C carcinoma in asbestos exposure. Latency period 25-45 years after asbestos exposure 10-30 years after asbestos exposure (Option A) Specific genetic mutations NF2, BAP1, chromosome 9p deletion EGFR, ALK, KRAS (Option D) Pathological features Epithelioid, sarcomatoid, or biphasic patterns Various growth patterns, glandular differentiation Immunohistochemistry Keratin, Calretinin, WT-1 (Option C), cytokeratin 5/6, podoplanin Thyroid transcription factor-1 (TTF-1) Electron microscopy Long, slender, branching microvilli (Option B) Short and non-branching microvilli

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Pages 716-724

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 55-year-old male presents with pleuritic chest pain and a pleural-based mass observed on imaging studies. Histopathological examination of a biopsy from the mass

reveals spindle-shaped cells within a collagenous stroma. Which immunohistochemical marker would be most useful in differentiating solitary fibrous tumour (SFT) from mesothelioma? (Q845579)

A. CD34

B. Calretinin

C. WT1

D. TTF-1 (Thyroid transcription factor 1)

Correct Answer: A. CD34

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: CD34 is a marker often expressed in solitary fibrous tumours. It is most useful for identifying solitary fibrous tumours due to its high rate of positivity in SFT and its absence in mesothelioma. Characteristic Solitary Fibrous Tumor (SFT) Malignant Mesothelioma Nature of the tumour Mostly benign, rare malignant Malignant Histopathology Dense fibrous tissue, spindle cells, occasional cysts Diffuse, invasive tumour growth across the pleural surface Immunohistochemistry Positive for CD34 and STAT6. Negative for Keratin. Positive for Calretinin, WT1, cytokeratin 5/6, and podoplanin. Morphology Tumours, often pedunculated and attached to the pleural surface, may have a whorled appearance. Thick, firm, gelatinous tissue ensheathing the lung; often extensive effusion. Microscopic appearance Spindle cells are arranged in whorls among reticulin and collagen fibres. Variable : Epithelioid (tubular/papillary structures), sarcomatoid (fibrosarcoma-like), or biphasic Calretinin (Option B): Calretinin is a calcium-binding protein commonly used as a marker for mesothelioma. It is typically expressed in the epithelial and some biphasic types of mesothelioma but is not usually expressed in solitary fibrous tumours . WT1 (Wilms' tumour 1) (Option C): WT1 is another frequently positive marker in mesothelioma, particularly in epithelial mesothelioma. This marker, however, is not usually expressed in solitary fibrous tumours. TTF-1 (Thyroid transcription factor 1) (Option D): TTF-1 is primarily used to identify carcinoma of lung and thyroid origin and is not useful for distinguishing between solitary fibrous tumours and mesothelioma. TTF-1 is positive in the adenocarcinoma of the lung.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 725

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 45-year-old nonsmoking woman presents with a persistent cough and hemoptysis. Imaging reveals a solitary pulmonary nodule in the right lung. Biopsy shows cells with neuroendocrine features, including round to oval nuclei, stippled chromatin, and abundant granular cytoplasm arranged in nests and trabeculae. Which cell type is most likely involved in the origin of this patient's lung tumour? (Q845564)

A. Type II pneumocytes

B. Clara cells

C. Kulchitsky cells

D. Alveolar macrophages

Correct Answer: C. Kulchitsky cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario, along with biopsy features, suggest a Carcinoid tumour , a neuroendocrine tumour arising from Kulchitsky cells (Neuroendocrine cells) within the bronchial epithelium. These cells produce and secrete bioactive substances such as serotonin (5-HT) and other peptides that can influence smooth muscle contraction, immune responses, and other physiological processes. Type II pneumocytes (Option A): Type II pneumocytes are surfactant-producing cells in the alveoli and are associated with adenocarcinoma rather than carcinoid tumours. Clara cells (Option B): Clara cells are non-ciliated cells found in the bronchioles and are not involved in the origin of bronchial carcinoid tumours. These cells secrete proteins and lipids that maintain and protect the airway epithelium. Alveolar macrophages (Option D): Alveolar macrophages are immune cells responsible for phagocytosis within the alveoli and are not related to the development of carcinoid tumours.

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 724

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 45-year-old female presents progressive shortness of breath, especially on exertion, fatigue, and ankle swelling. Physical examination reveals elevated jugular venous pressure. Echocardiography shows right ventricular hypertrophy and elevated pulmonary artery pressure. Which of the following conditions can predispose her to this condition? (Q845467)

A. High altitude

B. Recurrent thromboembolic

C. Scleroderma

D. All the above

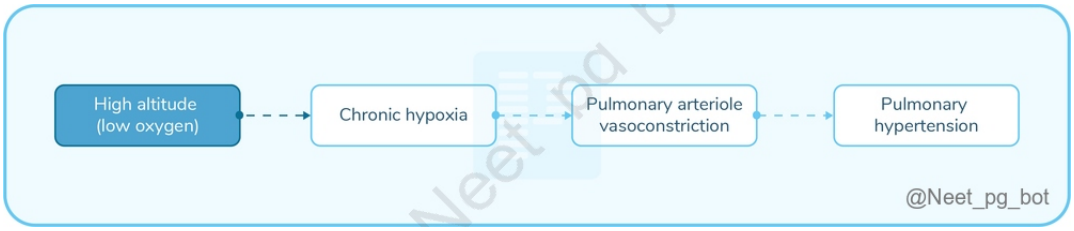
Correct Answer: D. All the above

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's clinical presentation with symptoms of exertional dyspnea, signs of right heart failure (elevated jugular venous pressure, right ventricular hypertrophy), and echocardiographic evidence of elevated pulmonary artery pressure suggest the presence of pulmonary hypertension. Pulmonary hypertension results from vascular remodelling and vasoconstriction in the pulmonary arterioles, leading to increased pulmonary vascular resistance and elevated pulmonary arterial pressure. Manifestations include exertional dyspnea, fatigue, chest pain, syncope, right heart failure with jugular venous distension, and peripheral oedema. Causes of Pulmonary

hypertension Primary Pulmonary Hypertension (Idiopathic) Secondary Pulmonary Hypertension High altitude (Chronic hypoxia) (Option A) Chronic Obstructive Pulmonary Disease (COPD) Interstitial lung disease (e.g., Pulmonary fibrosis) Left Heart Failure (e.g. Mitral stenosis, Systolic dysfunction) Recurrent thromboembolism events (Pulmonary embolism) (Option B) Autoimmune diseases (e.g. Systemic sclerosis) (Option C) Congenital Heart Disease (e.g. Atrial Septal Defect; Eisenmenger Syndrome) Obstructive Sleep apnea High altitude (Option A): Living at high altitudes with reduced oxygen can lead to pulmonary hypertension as: Recurrent thromboembolic events (Option B): Repeated pulmonary embolisms can obstruct blood vessels in the lungs, increasing pulmonary vascular resistance and causing pulmonary hypertension. Scleroderma (Option C): Scleroderma or Systemic Sclerosis can lead to lung vessel fibrosis and narrowing, raising pulmonary vascular resistance and contributing to pulmonary hypertension.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 702

↑ *Back to this question in Part A*

@Neet_pg_bot

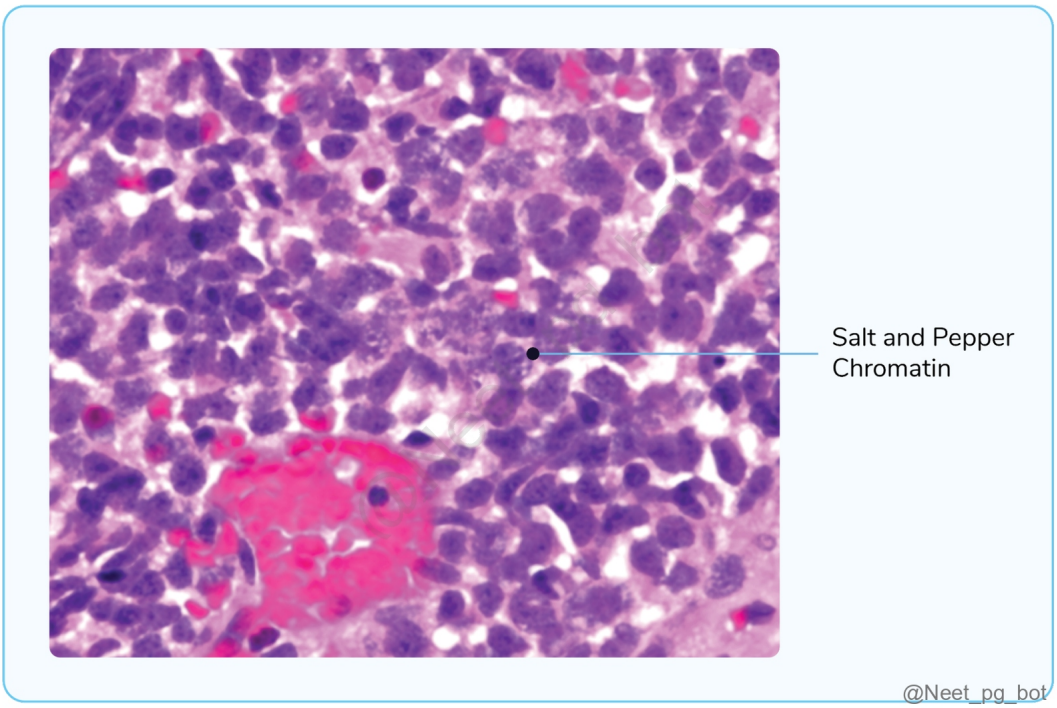
Q13: A 50-year-old heavy smoker presents with a persistent cough and unintentional weight loss. Imaging shows a right lung mass with mediastinal lymphadenopathy. Biopsy reveals small, round cells with scant cytoplasm and nuclei exhibiting a salt-and-pepper chromatin pattern. Immunohistochemistry (IHC) is positive for neuroendocrine markers. Which of the following features is incorrectly associated with this clinical condition? (Q845561)

A. Both glandular and squamous differentiation are seen

B. Encrustation of tumour cells along the blood vessels with DNA material

C. Presence of dense neurosecretory granules on electron microscopy

D. High proliferative index

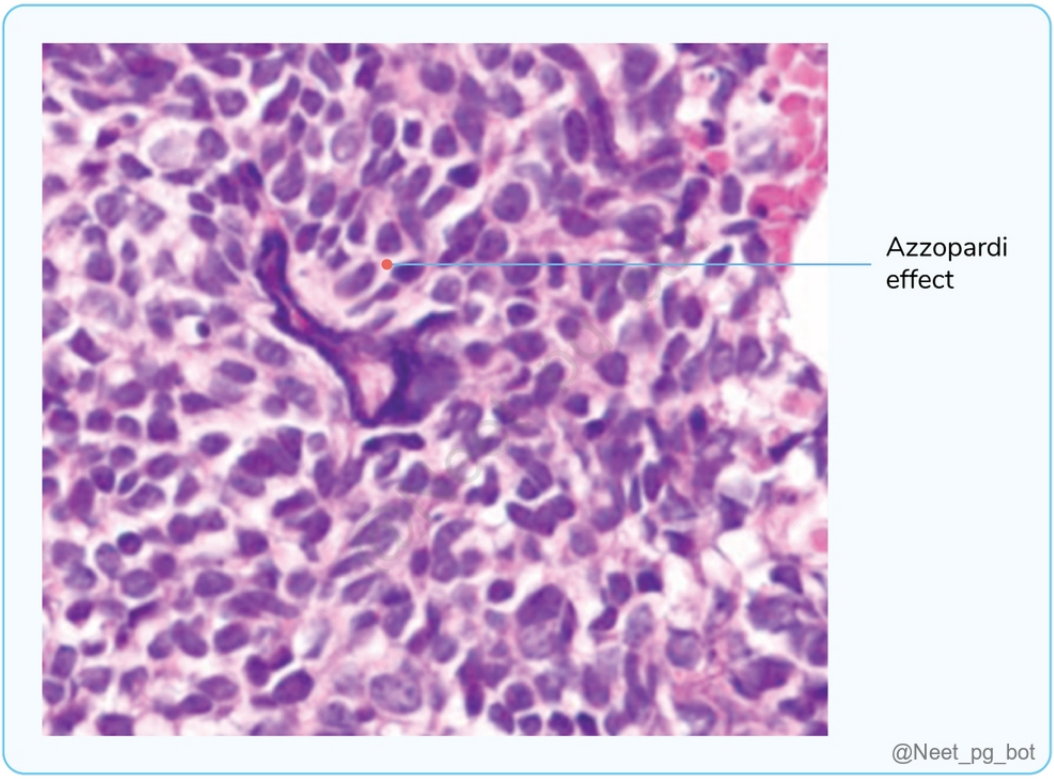


Correct Answer: A. Both glandular and squamous differentiation are seen

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and histological features described suggest small-cell lung carcinoma, a highly malignant neuroendocrine tumour with a strong relationship to cigarette smoking. Small cell lung cancer (SCLC) primarily exhibits neuroendocrine characteristics without the glandular histological features seen in adenocarcinoma or the squamous differentiation seen in squamous cell carcinoma. Encrustation of tumour cells along the blood vessels with DNA material(Option B) The encrustation of necrotic tumour cells along the blood vessels with DNA material causes basophilic staining of vascular walls . It is known as the ‘Azzopardi effect’ , a characteristic feature often observed in Small-cell lung carcinoma. Presence of dense neurosecretory granules on electron microscopy (Option C): Small-cell lung carcinoma shows neuroendocrine differentiation and dense neurosecretory granules on electron microscopy. High proliferative index (Option D): Small-cell lung carcinoma is known for its aggressive behaviour and rapid growth, both clinically and histologically. This is reflected in a high proliferative index, with many cells in active cell cycle phases.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 718

↑ *Back to this question in Part A*

@Neet_pg_bot

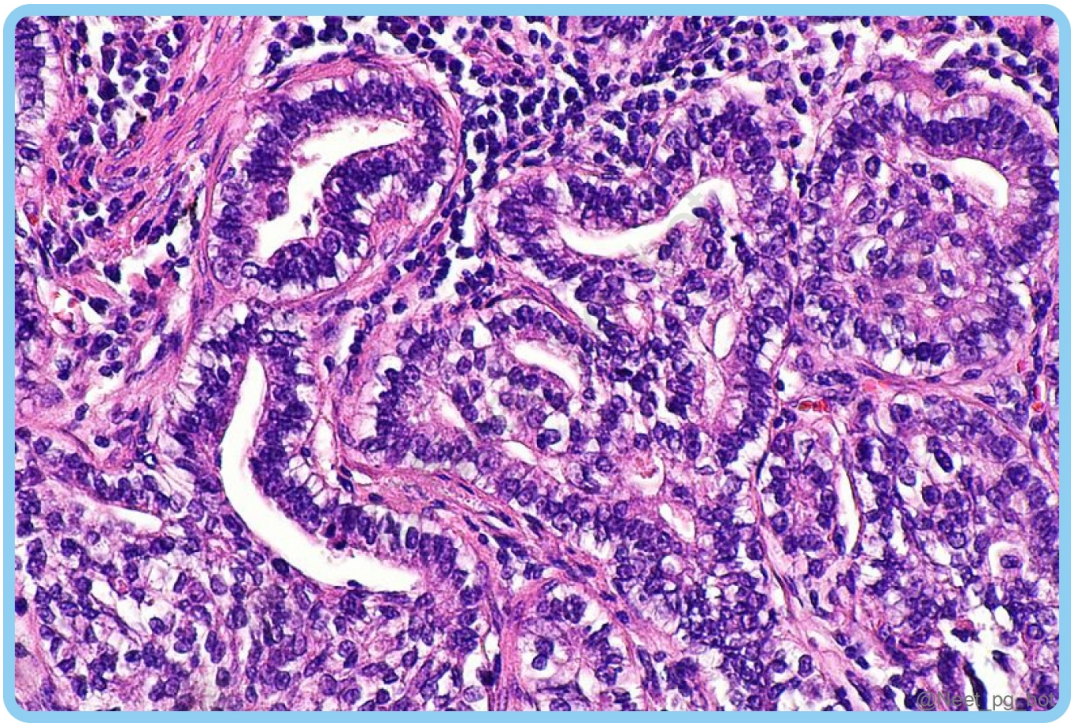
Q14: A 52-year-old male, non-smoker, presents with progressive shortness of breath, persistent dry cough, and chest pain. A CT scan reveals a peripheral mass in the lower lobe of left lung, and a biopsy of the nodule demonstrates a glandular pattern with mucinous differentiation, as shown in the image below. Which of the following markers is least likely to be positive in this patient's lung lesion? (Q845560)

A. TTF-1 (Thyroid Transcription Factor-1)

B. MUC1

C. Napsin A

D. Chromogranin



Correct Answer: D. Chromogranin

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The morphology is consistent with pulmonary adenocarcinoma, particularly mucinous adenocarcinoma. Adenocarcinomas typically express TTF-1, Napsin A, and MUC1, reflecting glandular differentiation. (Option A,B & C ruled out) Chromogranin is a neuroendocrine marker, expressed in small-cell carcinoma, carcinoid tumors, and other neuroendocrine tumors, not in conventional adenocarcinomas. Therefore, chromogranin is least likely to be positive in this lesion.

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 719

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: A 59-year-old heavy smoker presents with loss of appetite and a persistent cough for the past few months. Imaging reveals a central lung mass involving the right bronchus and mediastinal lymph nodes. Immunohistochemical staining of a lung mass biopsy is positive for chromogranin and synaptophysin. Which set of genes is most likely involved in the underlying pathology of this patient's condition? P53 RB L-myc (Q845559)

A. 1, 2

B. 1, 2, 3

C. Only 2

D. 2, 3

Correct Answer: B. 1, 2, 3

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's clinical presentation and positive staining for neuroendocrine markers such as Chromogranin and synaptophysin are highly suggestive of Small-cell lung cancer (SCLC) originating from neuroendocrine cells. It is a highly malignant form of lung cancer associated with smoking and is known for its aggressive behaviour and early metastasis. The genetic landscape of SCLC typically involves the inactivation of TP53 and RB genes. L-MYC amplification is a common feature in some SCLC cases, contributing to the tumour's rapid growth and aggressive nature.

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 717

↑ *Back to this question in Part A*

@Neet_pg_bot

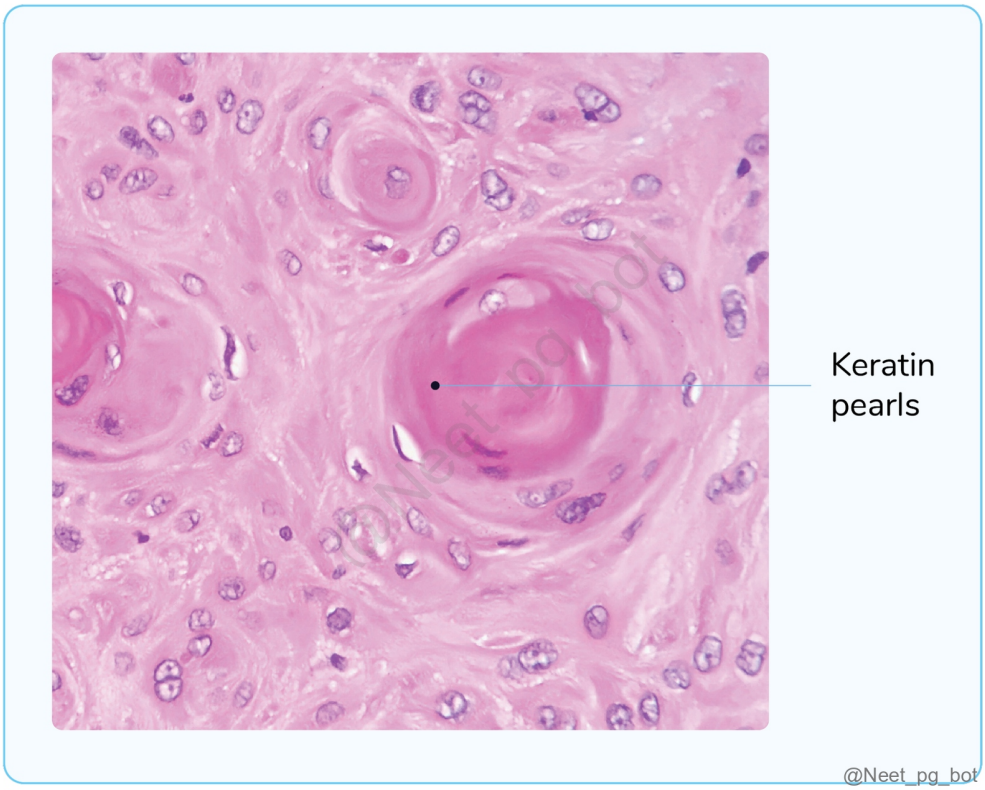
Q16: A 57-year-old male smoker with a persistent cough and weight loss is found to have a lung mass on imaging. The biopsy showed keratin pearls and intercellular bridges. Which of the following paraneoplastic syndromes is highly associated with this diagnosis? (Q845558)

A. Hypercalcemia

B. Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

C. Migratory thrombophlebitis

D. Cushing's syndrome



Correct Answer: A. Hypercalcemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical presentation and histological findings point towards the diagnosis of squamous cell carcinoma, one of the major subtypes of non-small cell lung cancer, which typically arises from the central bronchi and can cause symptoms like coughing, chest pain, and hemoptysis. Hypercalcemia is the most common paraneoplastic syndrome associated with squamous cell carcinoma of the lung. SCC of the lung can produce parathyroid hormone-related protein (PTHrP) , leading to elevated calcium levels in the blood. This condition is characterised by symptoms such as fatigue, confusion, excessive thirst and urination, and nausea. Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH) (Option B): It is more commonly associated with small cell lung cancer rather than SCC. SIADH leads to excessive release of antidiuretic hormone, causing water retention and dilutional hyponatremia, which can result in symptoms like muscle cramps, nausea, headaches, and disorientation. Migratory thrombophlebitis (also known as Trousseau’s syndrome) (Option C): While this can be seen in many types of cancers, it is typically more associated with adenocarcinoma rather than with SCC. This syndrome involves the formation of blood clots that migrate within the venous system. Cushing's syndrome (Option D): It is characterised by the ectopic production of ACTH, most frequently associated with small cell lung cancer, not SCC. Patients may experience symptoms such as weight gain, muscle weakness, and a rounded face (moon face).

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 722

↑ *Back to this question in Part A*

Q17: A 67-year-old male smoker presents with a persistent cough and weight loss. Imaging reveals a lung mass in the upper lobe of the right lung. The biopsy reveals typical features, including keratin pearls, intercellular bridges, and nests of malignant squamous cells with abundant eosinophilic cytoplasm. Based on this scenario, which of the following statements is incorrect? (Q845557)

A. Keratin pearls are not seen in poorly differentiated squamous cell carcinoma.

B. p40 is the best marker for squamous cell carcinoma.

C. Squamous dysplasia is a precursor lesion of squamous cell carcinoma

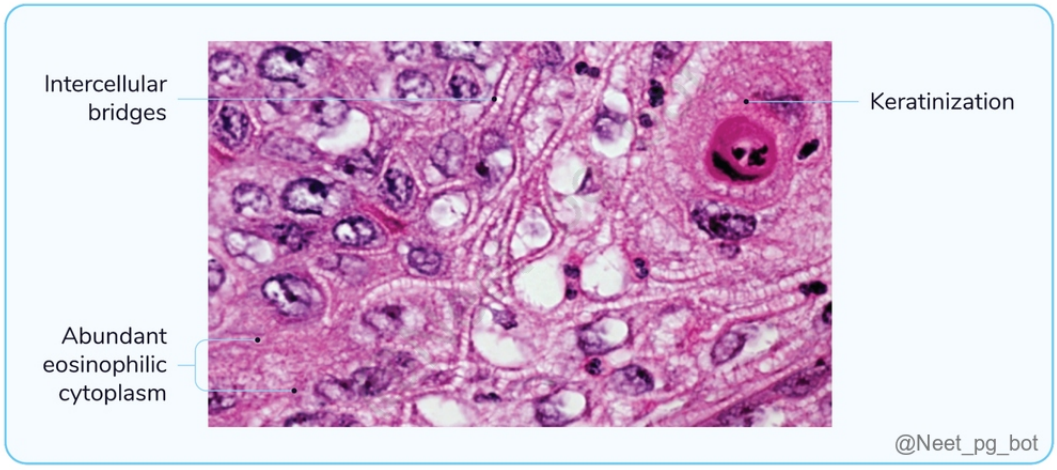
D. The squamous cell carcinoma described is likely a peripheral lung lesion.

Correct Answer: D. The squamous cell carcinoma described is likely a peripheral lung lesion.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Squamous Cell Carcinoma is typically found in the central regions of the lungs (Not peripheral), often originating in the major bronchi near the hilum. It can cause symptoms by obstructing airways. Histopathologically, it is characterised by keratin pearls, intercellular bridges, and nests of malignant squamous cells with abundant eosinophilic cytoplasm. Location of lung carcinomas: Central: Squamous cell carcinoma, Small cell carcinoma and Bronchial carcinoids. Peripheral: Adenocarcinoma and Large-cell carcinoma. Keratin pearls are not seen in poorly differentiated squamous cell carcinoma (Option A): Keratin pearls are a characteristic feature of well-differentiated squamous cell carcinoma p40 is the best marker for squamous cell carcinoma (Option B): p40 is the most specific and best marker for squamous cell carcinoma Squamous dysplasia is a recognised precursor lesion for squamous cell carcinoma (Option C): Squamous cell carcinomas often arise from pre-existing bronchial epithelial conditions such as squamous metaplasia or dysplasia.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 717

↑ *Back to this question in Part A*

@Neet_pg_bot

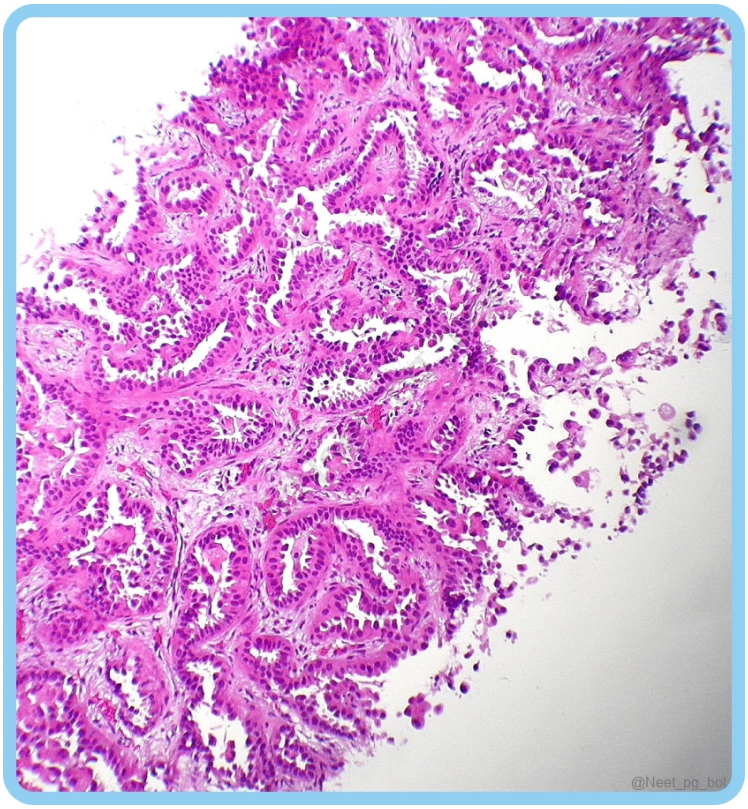
Q18: A 58-year-old male smoker presents with a persistent cough and mild shortness of breath. Chest imaging reveals a solitary pulmonary nodule. A biopsy is performed, and a histopathological examination of the lung tissue is shown in the image below. What is the most likely diagnosis? (Q845556)

A. Carcinoma in situ

B. Adenomatous hyperplasia

C. Adenocarcinoma in situ

D. Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia



Correct Answer: C. Adenocarcinoma in situ

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The histopathological image shows a localised proliferation of dysplastic cells along pre-existing alveolar septa, indicative of adenocarcinoma in situ (AIS) or bronchioloalveolar carcinoma which is a precancerous lesion of adenocarcinoma of the lung with severe cytologic atypia . AIS is an early stage of lung cancer where abnormal glandular cells are confined to the airway lining without invasion and exhibit a “lepidic growth pattern” (or butterfly on fence pattern), spreading along intact alveolar structures without invasion. Lesions are usually small, measuring ≤ 3 cm. Carcinoma in situ (Option A): Carcinoma in situ involves abnormal squamous cells confined to the epithelium without invading the surrounding structures. Adenomatous hyperplasia (Option B): Atypical adenomatous hyperplasia (AAH) is a precursor lesion of lung adenocarcinoma with mild cytologic atypia, characterised by dysplastic pneumocytes lining alveolar walls. These lesions are typically small, ≤5 mm , and can be single or multiple. AAH may be adjacent to invasive tumours or independently within the lung tissue and signifies an initial stage in adenocarcinoma development. Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (Option D): DIPNECH (Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia) is a preneoplastic condition characterised by the abnormal proliferation of neuroendocrine cells in the lungs, which can progress to develop into neuroendocrine tumours over time like small cell carcinoma and carcinoid tumours.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Pages 716-724

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 55-year-old male smoker presents to the clinic with chronic cough and hemoptysis. He has been smoking two packs of cigarettes per day for the past 30 years. Upon further evaluation, a biopsy reveals lung carcinoma. Which of the following statements regarding risk factors for lung carcinoma is false? (Q845473)

A. Smoking is a major risk factor for squamous cell carcinoma of the lung.

B. Smoking has no association with adenocarcinoma of the lung.

C. Smoking is a significant risk factor for small-cell lung carcinoma.

D. Asbestosis exposure, along with smoking, multiplies the risk of lung cancer.

Correct Answer: B. Smoking has no association with adenocarcinoma of the lung.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Smoking significantly increases the risk of adenocarcinoma of the lung, although to a lesser extent than other types. Adenocarcinoma, commonly found in non-smokers, can still occur due to tobacco smoking. It often involves mutations in growth factor receptor pathways and is the most prevalent subtype in non-smokers. Smoking is a major risk factor for squamous cell carcinoma of the lung (Option A): Smoking significantly increases the risk of squamous cell carcinoma of the lung as it has a strong association, resulting in chromosomal deletions involving tumour suppressor loci involving 3p,9p and 17p. Smoking is a significant risk factor for small-cell lung carcinoma (Option C): Small-cell carcinoma is almost always linked to smoking, exhibiting the highest mutation rate among lung cancers. SCLC is almost exclusively caused by smoking and usually involves the inactivation of both TP53 and RB genes. Asbestosis exposure, along with smoking, multiplies the risk of lung cancer (Option D): Asbestos exposure, especially when combined with smoking, significantly raises the risk of lung cancer . Non-smokers exposed to asbestos have a five-fold higher risk, while smokers have a 55-fold increased risk compared to non-smokers.

@Neet_pg_bot

Q20: A 55-year-old man presents with severe shortness of breath, cough, and fever after recent bacterial pneumonia. Physical examination shows tachypnea, hypoxia, and diffuse crackles on chest auscultation. Chest X-ray reveals bilateral opacities suggestive of pulmonary oedema. Histopathological examination of lung biopsy shows congested, edematous lungs with inflammation. Which histopathological finding is characteristic of the acute exudative stage in this patient's lung injury? (Q845471)

A. Proliferation of type II pneumocytes

B. Formation of fibrotic thickening in the alveolar septa

C. Presence of waxy hyaline membranes lining the alveolar walls

D. Resolution of granulation tissue in the alveolar spaces

Correct Answer: C. Presence of waxy hyaline membranes lining the alveolar walls

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: In the acute exudative stage of lung injury, such as acute respiratory distress syndrome (ARDS) triggered by bacterial pneumonia, lungs exhibit characteristic waxy hyaline membranes lining the alveolar walls.

These membranes comprise fibrin-rich oedema fluid mixed with remnants of necrotic epithelial cells, representing a hallmark feature of acute lung injury and ARDS. Pathological changes seen in acute respiratory distress syndrome (ARDS) Stage Features 1. Acute Exudative Stage Lungs appear heavy, firm, red, and boggy. Manifestations include congestion, interstitial and intra-alveolar oedema, inflammation, fibrin deposition, and diffuse alveolar damage. Alveolar walls are lined with “waxy hyaline membranes” composed of fibrin-rich oedema fluid mixed with remnants of necrotic epithelial cells. 2. Proliferative or Organizing Stage Proliferation of Type II pneumocytes. Granulation tissue forms in the alveolar walls and spaces. 3. Late Fibrotic Stage Fibrotic thickening of alveolar septa indicates persistent fibrosis and scarring that may develop in some cases of lung injury.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 677

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: Which of the following statements regarding the pathogenesis sequence of non-cardiogenic pulmonary oedema (NCPE) and acute respiratory distress syndrome (ARDS) is incorrect? Endothelial activation is the hallmark of pathogenesis. Release of cytokines by alveolar epithelial cells Macrophage activation resulting in the release of IL-8 and TNF Recruitment of lymphocytes by IL-8 (Q845470)

A. 1 and 3

B. 1, 2 and 3

C. 2 and 4

D. 1 and 4

Correct Answer: C. 2 and 4

- *Listen (English)*
- *Listen (Hindi)*

Explanation: In ARDS/NCPE, the primary source of pro-inflammatory cytokines is the alveolar macrophage, not the alveolar epithelial cell. Alveolar epithelial cells (type I and II pneumocytes) are secondarily injured and are mainly targets of inflammation rather than initiators. IL-8 is a potent neutrophil chemotactic factor, not a lymphocyte recruiter. The key inflammatory cells responsible for lung injury in ARDS are neutrophils, not lymphocytes. Pathogenesis of NCPE / ARDS: A precipitating insult (sepsis, trauma, aspiration, pancreatitis) triggers lung injury. Alveolar macrophages are activated and release cytokines such as TNF-α, IL-1, IL-6, and IL-8. (Statement 3) These mediators cause endothelial activation and injury, which is the hallmark of ARDS. (Statement 1) IL-8 recruits neutrophils to the pulmonary microcirculation and alveoli. Neutrophils release proteases, reactive oxygen species, and inflammatory mediators. This results in increased alveolar-capillary permeability, leading to protein-rich non-cardiogenic pulmonary oedema, hyaline membrane formation, and severe hypoxemia.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 676

↑ *Back to this question in Part A*

@Neet_pg_bot

Q22: A 45-year-old woman presents with progressive shortness of breath and fatigue. On examination, she has elevated jugular venous pressure and a loud pulmonary component of the second heart sound. Echocardiography reveals right ventricular hypertrophy and dilation. Which of the following statements is correct regarding the vascular changes of this condition? (Q845468)

A. BMPR2 mutations result in endothelial and vascular smooth muscle cell apoptosis.

B. Classic atherosclerotic changes are commonly observed in pulmonary arteries.

C. Plexiform lesions are early changes of pulmonary hypertension.

D. Pulmonary arterioles show medial hypertrophy and intimal fibrosis, narrowing the lumens.

Correct Answer: D. Pulmonary arterioles show medial hypertrophy and intimal fibrosis, narrowing the lumens.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's clinical presentation with symptoms of right heart failure, elevated jugular venous pressure, and findings of right ventricular hypertrophy and dilation on echocardiography suggest pulmonary hypertension. Histopathologically, pulmonary hypertension is characterised by the remodelling of pulmonary arterioles, which typically exhibit medial hypertrophy (thickening of the smooth muscle layer) and intimal fibrosis. These changes lead to the narrowing of the vessel lumens, increased pulmonary vascular resistance, and subsequent right heart strain. BMPR2 mutations result in endothelial and vascular smooth muscle cell apoptosis. (Option A): BMPR2 mutations are associated with familial pulmonary arterial hypertension, commonly associated with dysregulation of endothelial and vascular cellular processes involved in vascular homeostasis, including aberrant proliferation and resistance to apoptosis. Classic atherosclerotic changes are commonly observed in pulmonary arteries. (Option B): Classic atherosclerotic changes, such as plaque formation and lipid deposition, are not typical findings in pulmonary arteries affected by pulmonary hypertension. Plexiform lesions are early changes of pulmonary hypertension. (Option C): Plexiform lesions are characterised by tufts of capillary formations that are more specific to certain types of pulmonary hypertension, particularly in idiopathic and familial cases. Plexiform lesions of small arteries are characteristic of advanced pulmonary hypertension rather than early changes.

Q1: Ciliocytophthoria is seen in? (Q845391)

A. Kartagener syndrome

B. Cystic fibrosis

C. Situs inversus

D. Acute respiratory infection

Correct Answer: D. Acute respiratory infection

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Ciliocytophthoria is a degenerative process of the ciliated cells , occurring in viral infections such as acute respiratory infections and characterized by typical morphological changes. The images below show the ciliary changes: Kartagener's syndrome (Immotile cilia syndrome) (Option A) : It is a form of primary ciliary dyskinesia, characterized by a triad of: Sinusitis. Situs inversus (Option C) . Bronchiectasis. The ciliary ultrastructure is normal in cystic fibrosis (Option B)

www.ncbi.nlm.nih.gov/pmc/articles/PMC6502078/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Which of the following is false regarding extralobular sequestration? (Q845396)

A. It is external to the lung.

B. It most commonly presents as a mass lesion.

C. It most often occurs in older children.

D. It has a separate pleural covering.

Correct Answer: C. It most often occurs in older children.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The false statement regarding extra lobar sequestration is that it most often occurs in older children, most commonly in infants . Pulmonary sequestration is a discrete area of lung tissue not connected to the airways and has an abnormal blood supply from the aorta or its branches. It is of two types: Extralobar sequestration. Intralobar sequestration. Extralobar sequestration Intralobar sequestration Location External to the lung parenchyma (Option A) Within the lung parenchyma Pleural covering It has a separate pleural covering (Option D) Shares pleura with adjacent lung tissue Embryological origin Congenital anomaly of the primitive foregut Association It causes a mass effect (Option B) Localized infection or bronchiectasis Venous return The right side of the heart through IVC Pulmonary veins

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 674

↑ *Back to this question in Part A*

@Neet_pg_bot

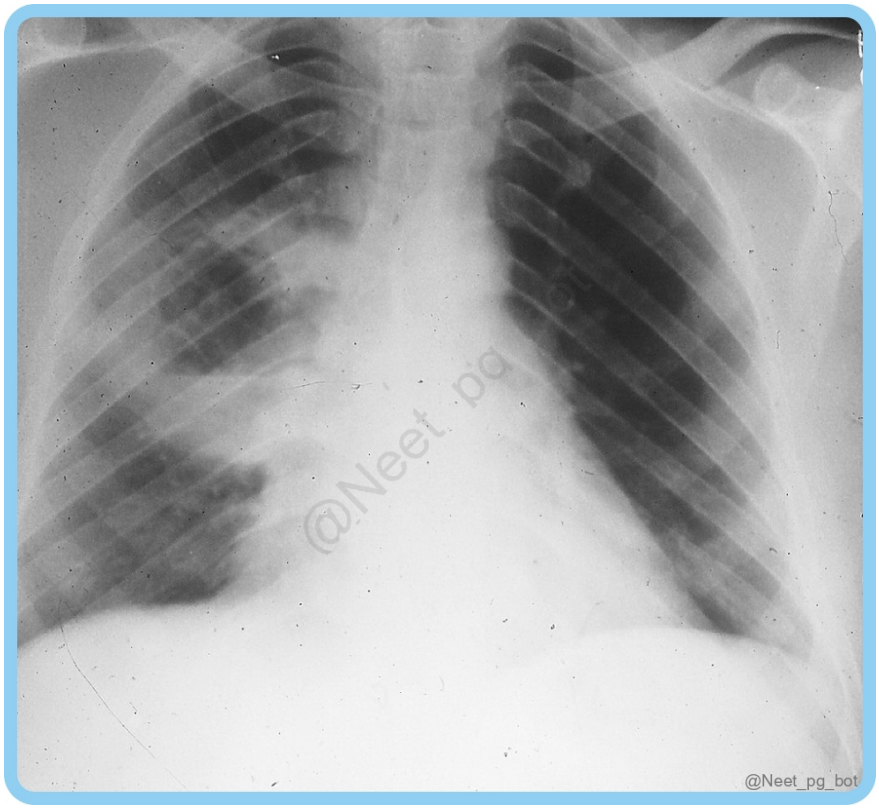
Q3: A 65-year-old female presents to the clinic with a productive cough, fever, and fatigue for the past two weeks. She has a history of poorly controlled diabetes mellitus and reports recent hospitalisation for a urinary tract infection. On physical examination, coarse crackles are auscultated over the right lower lung fields. The chest X-ray is shown below. Which of the following is the most common risk factor for developing this condition? (Q845399)

A. Antecedent primary lung infection

B. Aspiration of infective material

C. Septic embolism

D. Neoplasia



Correct Answer: B. Aspiration of infective material

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Given the clinical presentation of productive cough, fever, fatigue, and the presence of a thick-walled cavity with surrounding consolidation on chest X-ray, the most likely diagnosis is a lung abscess. Lung abscess: It describes a local suppurative process that produces necrosis of the lung tissue. Aetiology: Bacteroides , Fusobacterium , and Peptostreptococcus (the three most common bacteria). Aerobic and anaerobic Streptococci, S. aureus, and gram-negative organisms. Risk factors: Aspiration of infective material (the most frequent cause) (Option B) . Septic embolism. (Option C) Morphology: Pulmonary abscesses due to aspiration are more common on the right (because of the more vertical right main bronchus) and are most often single. The cardinal histologic change in all abscesses is the suppurative destruction of the lung parenchyma within the central area of cavitation. The image below shows a lung abscess

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 711,712

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 29-year-old previously healthy male presents with a one-week history of progressively worsening dry cough, fever, and shortness of breath. He denies any recent travel but mentions attending a crowded social gathering a week ago. He is febrile, tachypneic, and has crackles on auscultation. Laboratory investigations reveal leukocytosis. A chest X-ray demonstrates patchy infiltrates in the lower lobes bilaterally. Which of the following features is not associated with this condition? (Q845402)

A. Inflammatory changes are confined to the pulmonary interstitium.

B. Neutrophils are involved in this infection.

C. It is associated with viral infections

D. It is also known as walking pneumonia.

Correct Answer: B. Neutrophils are involved in this infection.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation of a patient with a history of attending a crowded social gathering, worsening dry cough, fever, shortness of breath, crackles on auscultation, and chest X-ray showing bilateral patchy infiltrates in the lower lobes is suggestive of Mycoplasma pneumoniae infection (Atypical pneumonia) . Neutrophils are not involved in this condition; rather, lymphocytes are involved. Neutrophils are involved in typical pneumonia. Atypical pneumonia: Definition An acute febrile respiratory disease characterised by patchy inflammatory changes in the lungs, largely confined to the alveolar septa and pulmonary interstitium. (Option A) Aetiology Atypical organisms: Mycoplasma pneumoniae (Most common). It is also known as walking pneumonia , as the patient is not bedridden. (Option D) Chlamydia pneumoniae. Coxiella burnetii (Q-fever). Viruses Morphology Interstitial inflammatory reaction , virtually localised within the walls of the alveoli. Alveolar septa are widened and edematous and usually have a mononuclear inflammatory infiltrate of lymphocytes , macrophages, and occasionally plasma cells. Herpes simplex , varicella , and adenovirus may be associated with bronchial and alveolar epithelium necrosis and acute inflammation. Typical pneumonia: Cause: Bacterial Streptococcus pneumoniae (most common). Haemophilus influenzae. Klebsiella pneumoniae. Neutrophils are involved in this condition. Features: Intra-alveolar exudate and productive cough.

@Neet_pg_bot

Q5: Red hepatisation of the lungs is seen on which day? (Q845405)

A. 1-2

B. 2-4

C. 5-7

D. Beyond 7 day

Correct Answer: B. 2-4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Stages of bacterial pneumonia: Stage Days Characteristics Congestion 1-2 (Option A) Gross: The lung is heavy, boggy, and red. Microscopic: Vascular engorgement , intra-alveolar fluid with neutrophils & bacteria. Red hepatization 2-4 (Option B) Gross: Red , firm, and airless , with a liver-like consistency , hence the term hepatization. Microscopic: Confluent exudation with neutrophils, RBCs , and fibrin filling the alveoli. Grey hepatization 5-8 (Option C) Gross: Greyish brown and dry surface. Microscopic: Disintegration of RBCs and persistence of a fibrinosuppurative exudate. Resolution 8-9 (Option D) Exudates within the alveoli are broken down by enzymatic digestion to produce granular debris. Debris may be reabsorbed/ingested by macrophages/expectorated/ organised by fibroblasts.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 708

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 55-year-old male with a long-standing history of chronic alcohol abuse presents with a one-week history of high-grade fever, productive cough with thick, mucoid, blood-tinged "currant jelly" sputum, and right-sided pleuritic chest pain. He reports frequent binge drinking episodes and he had several recent episodes of aspiration while intoxicated. On examination, he appears ill, with a temperature of 39.5°C, tachypnea, and signs of consolidation over the right upper lung fields. Laboratory investigations reveal leukocytosis with neutrophilia and elevated inflammatory markers. Chest X-ray shows bulging of right upper lobe fissure consistent with a dense lobar consolidation. What is the most likely organism implicated in this condition? (Q845409)

A. Mycoplasma pneumoniae

B. Legionella pneumophila

C. Moraxella catarrhalis

D. Klebsiella pneumoniae

Correct Answer: D. Klebsiella pneumoniae

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation of a patient who is a known alcoholic , presenting with high-grade fever, productive cough, blood-tinged " currant jelly" sputum, right-sided pleuritic chest pain, signs of consolidation over the right upper lung fields, and neutrophilia is suggestive of pneumonia caused by Klebsiella pneumoniae.

Klebsiella pneumoniae: It is the most common cause of gram-negative bacterial pneumonia. It causes typical pneumonia with neutrophil-rich exudate that fills the bronchi, bronchioles, and adjacent alveolar spaces. It commonly afflicts debilitated and malnourished people , particularly chronic alcoholics. Thick, mucoid (blood-tinged) sputum is characteristic because the organism produces an abundant viscid capsular polysaccharide , which the patient may have difficulty expectorating. Mycoplasma Pneumonia (Option A) Mycoplasma pneumonia causes atypical pneumonia with dry cough, fever, and fatigue. It often presents with mild symptoms but can lead to complications. It presents with a persistent dry cough, low-grade fever, sore throat, headache, and fatigue. Chest X-ray findings may appear worse than clinical symptoms. It spreads via respiratory droplets and is common in young adults and crowded settings. Treatment includes macrolides or tetracyclines. Legionella pneumophila (Option B): Legionella pneumophila is the agent of legionnaires' disease and Pontiac fever , a self-limited upper respiratory tract infection. It flourishes in artificial aquatic environments, such as water-cooling towers and the tubing systems of domestic (potable) water supplies. It is common in individuals with predisposing conditions such as cardiac, renal, immunologic, or hematologic disease and organ transplant recipients . Moraxella catarrhalis (Option C): Moraxella catarrhalis is recognised as a cause of bacterial pneumonia, especially in the elderly . It is the second most common bacterial cause of acute exacerbation of COPD. Along with S. pneumoniae and H. influenzae, M. catarrhalis is one of the three most common causes of otitis media in children.

@Neet_pg_bot

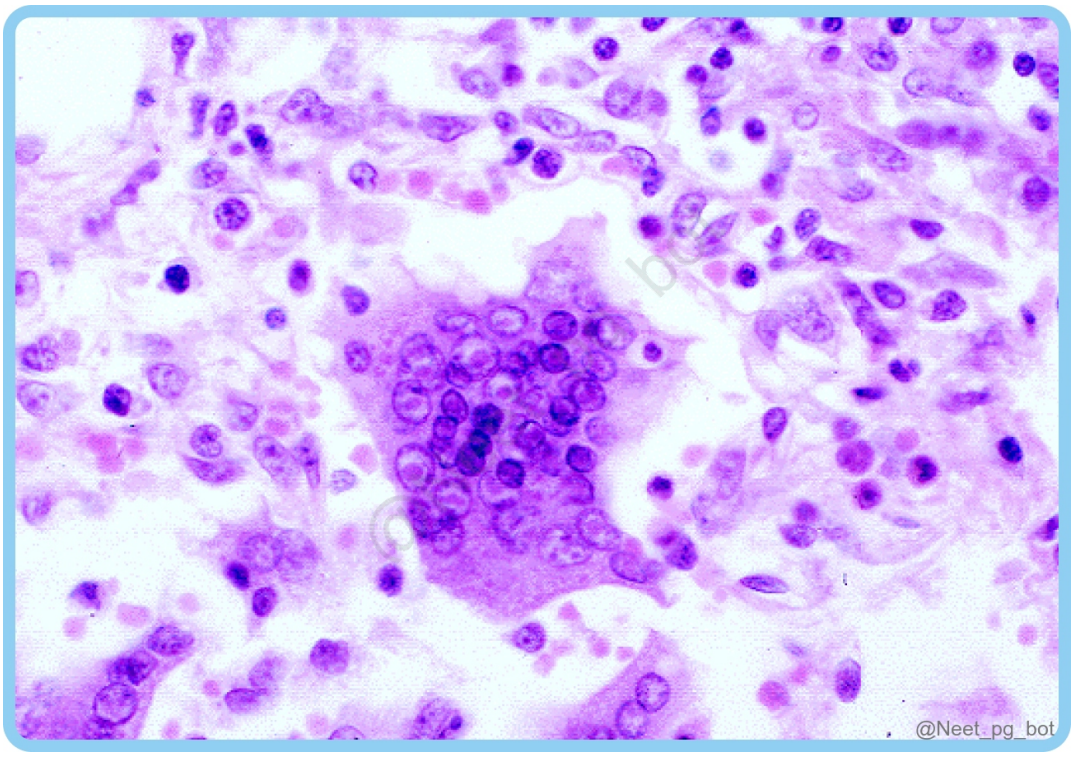
Q7: Match the following: 1) Pneumocystis pneumonia a) 2) Blastomycosis b) 3) Aspergillus c) 4) Measles d) (Q845414)

A. 1-b, 2-d, 3-c, 4-a

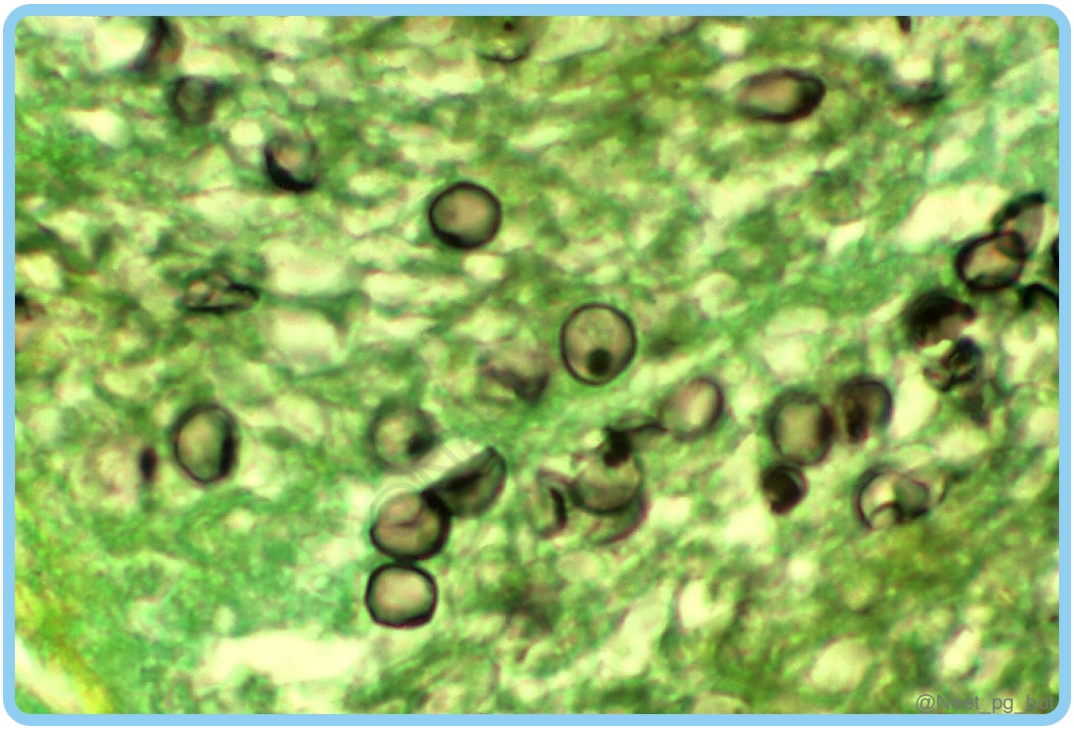
B. 1-a, 2-d, 3-c, 4-b

C. 1-c, 2-d, 3-b, 4-a

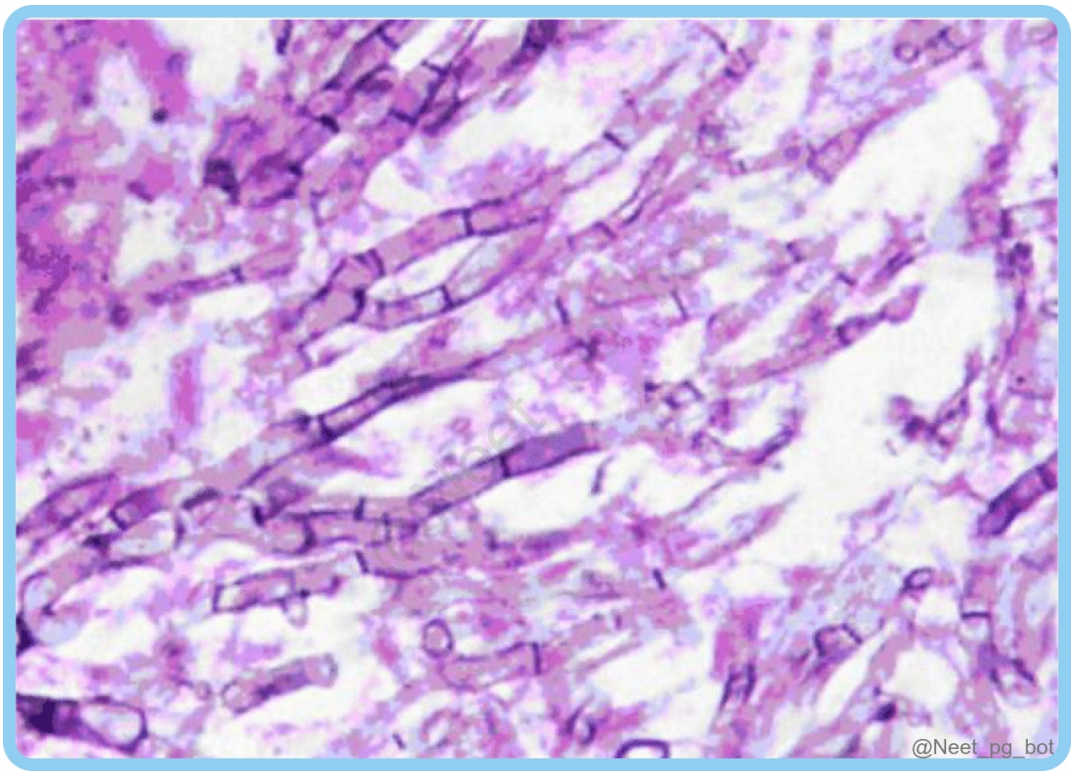
D. 1-b, 2-a, 3-c, 4-d

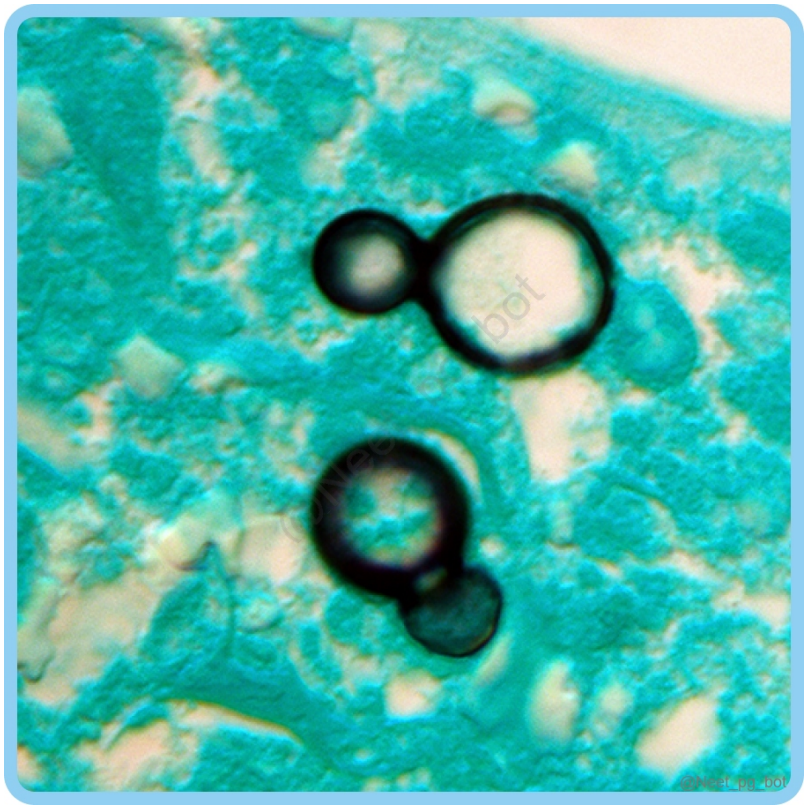


@Neet_pg_bot



@Neet_pg_bot



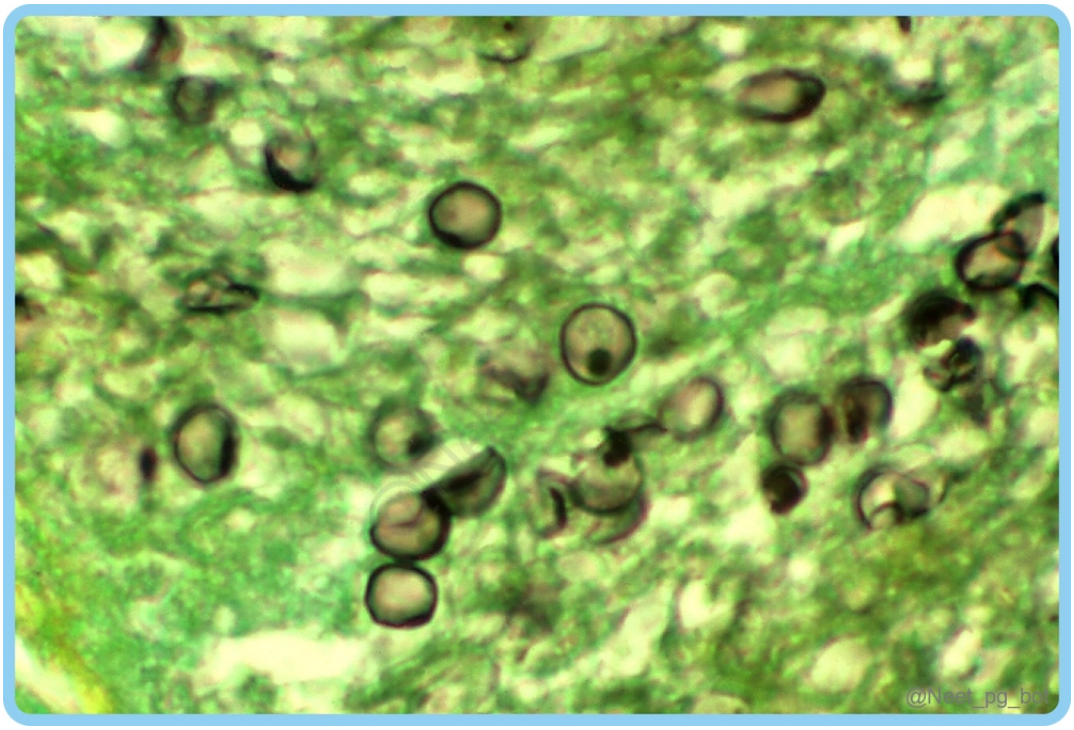


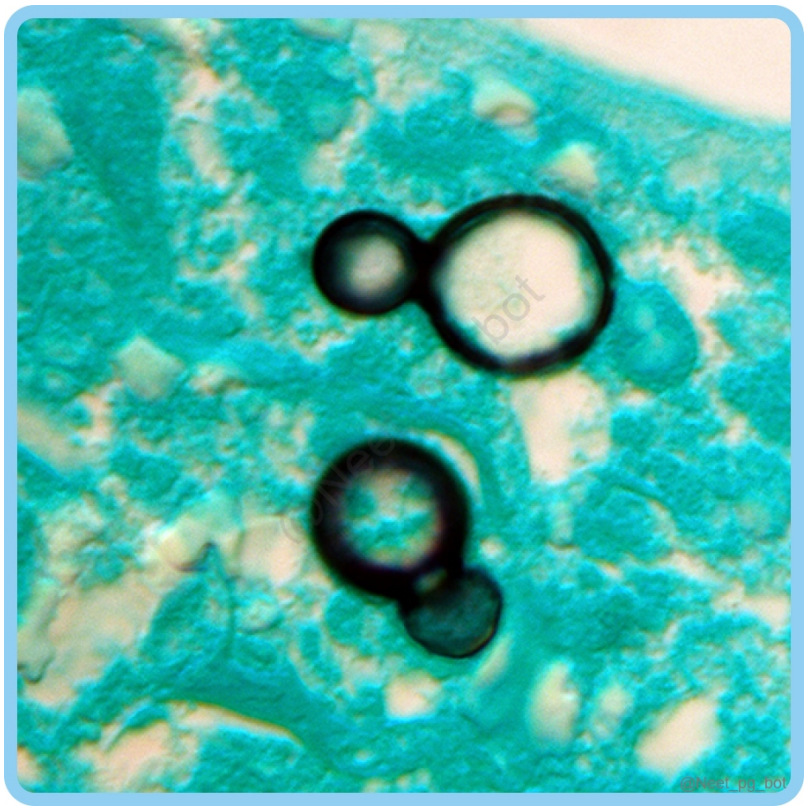
Correct Answer: A. 1-b, 2-d, 3-c, 4-a

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Pneumocystis jirovecii: Pneumocystis jirovecii is an opportunistic fungus that causes Pneumocystis pneumonia (PCP). PCP primarily affects immunocompromised individuals . Gomori's methenamine silver (GMS) staining is the method of choice to demonstrate the cysts of P. jirovecii. The cysts resemble black-coloured crushed ping-pong balls against the green background. Blastomycosis: Blastomycosis is a fungal infection caused by Blastomyces dermatitidis found in moist soil. Morphology: In the normal host, the lung lesions of blastomycosis are suppurative granulomas. Macrophages have a limited ability to ingest and kill B. dermatitidis, and the persistence of the yeast cells leads to the recruitment of neutrophils . In tissue, B. dermatitidis is a round, 5- to 15-µm yeast cell divided by broad-based budding. It has a thick, double-contoured cell wall and visible nuclei. Aspergillus: Aspergillosis is an invasive and allergic disease caused by a hyaline mould named Aspergillus. Glucocorticoid use is the most important risk factor for aspergillosis. Pulmonary aspergillosis is the most common form. KOH (10%) mount or histopathological staining of specimens reveals characteristic narrow septate hyaline hyphae with acute angle branching. Measles: The measles virus is a single-stranded RNA virus of the Paramyxoviridae family. It causes measles, an acute, highly contagious childhood disease characterised by fever and respiratory symptoms followed by a typical maculopapular rash. Virus isolation: Cytopathic effect may be observed after 7–10 days of inoculation into cell lines characterised by multinucleated giant cells (Warthin-Finkeldey cells) containing intranuclear and intracytoplasmic inclusion bodies. It can cause giant-cell pneumonitis (Hecht's pneumonia) in immunocompromised children and HIV-infected people.





@Neet_pg_bot

Q8: Which of the following conditions is not associated with aspiration? (Q845418)

A. Mendelson syndrome

B. Lipoid pneumonia

C. Meconium aspiration syndrome

D. Nelson syndrome

Correct Answer: D. Nelson syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Nelson syndrome is not associated with aspiration. It is a rare disorder that occurs in some individuals who have undergone surgical removal of both adrenal glands to treat Cushing's disease. It is characterised by the growth of a pituitary tumour, often resulting in elevated levels of ACTH and increased skin pigmentation. Aspiration pneumonia: It occurs in markedly debilitated patients or those who aspirate gastric contents either while unconscious (e.g., after a stroke) or during repeated vomiting. Predisposing factors: Abnormal gag and swallowing reflexes. The resultant pneumonia is partly chemical due to the irritating effects of gastric acid and partly bacterial (from the oral flora). More than one organism is recovered in culture (aerobes > anaerobes). It is often necrotising with a fulminant clinical course, and a frequent cause of death. In patients who survive, lung abscess is a common complication. Conditions associated with aspiration: Mendelson syndrome (Option A): It occurs due to aspiration of gastric contents during general anaesthesia. Risk factors: Pregnancy. Gastric volume >25 ml (0.4 mL/kg). Gastric pH <2.5 Meconium aspiration syndrome (Option C) : It usually occurs in term or post-term babies who are small for gestational age (IUGR). Lipoid pneumonia/Golden pneumonia (Option B): Associated with Oil aspiration- Mineral oil industry. Macrophages engulf the lipids. The image below shows the histology of lipoid pneumonia

@Neet_pg_bot

Q9: A 45-year-old man presents with a persistent cough, night sweats, and unintentional weight loss. Chest X-ray reveals an infiltrate in the upper lobe of the right lung. Which of the following pathological processes is not seen in this condition? (Q845422)

A. Th2-mediated macrophage activation and killing of bacteria.

B. The bacterium blocks phagolysosome formation.

C. M. tuberculosis is recognised by innate immunity receptors.

D. It causes granulomatous inflammation and damage.

Correct Answer: A. Th2-mediated macrophage activation and killing of bacteria.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation of a 45-year-old male with a persistent cough, night sweats, unintentional weight loss, and chest X-ray showing an infiltrate in the upper lobe of the right lung is suggestive of pulmonary tuberculosis. Th2-mediated macrophage activation and bacteria killing is not seen in tuberculosis. Rather, a Th-1-mediated response is seen. Pathogenesis of tuberculosis: Infection by M. tuberculosis proceeds in steps, from initial infection of macrophages to a subsequent Th1 response that both contains the bacteria and causes tissue damage. Early in infection, M. tuberculosis replicates essentially unchecked within macrophages, and later in infection, the cell response stimulates macrophages to contain the proliferation of the bacteria. The steps for infection are as follows: Entry into macrophages M. tuberculosis enters macrophages by phagocytosis . Replication in macrophages M. tuberculosis inhibits the maturation of the phagosome. It blocks the formation of the phagolysosome (Option B) , allowing the bacterium to replicate unchecked within the vesicle. Thus, during the earliest stage of primary tuberculosis (<3 weeks) in the nonsensitized individual, bacteria proliferate in the pulmonary alveolar macrophages and air spaces, resulting in bacteremia and seeding of multiple sites. Despite the bacteremia, most people at this stage are asymptomatic or have a mild flu-like illness. Innate immunity (Option C) Mycobacterial lipoarabinomannan binds TLR2 , and unmethylated CpG nucleotides bind TLR9. These interactions initiate and enhance the innate and adaptive immune responses to M. tuberculosis, as described below. Th1 response , Th1 mediated macrophage activation, and killing of the bacteria (mediated by IFN-γ). Granulomatous inflammation and damage (mediated by Th1 response) (Option D) . Caseous necrosis and giant cell formation (epithelioid histiocytes-giant cells, mediated by IFN-γ).

@Neet_pg_bot

Q10: Match the following lesions with their site of occurrence. Lesion Site 1 Puhl's focus i Lung + Lymph node 2 Simon focus ii Blood vessels 3 Ghon complex iii Supraclavicular region of the lung 4 Weighert focus iv The apex of the lung (Q845427)

A. 1-iii, 2-iv, 3-i, 4-ii

B. 1-iii, 2-iv, 3-ii, 4-i

C. 1-iv, 2-iii, 3-i, 4-ii

D. 1-iv, 2-i, 3-ii, 4-iii

Correct Answer: A. 1-iii, 2-iv, 3-i, 4-ii

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Puhl's focus Supraclavicular region of the lung Simon focus Apex of the lung Ghon complex Lung + Lymph node Weighert focus Blood vessel Tuberculosis is a bacterial infection caused by M. tuberculosis. It is of the following types. Primary tuberculosis It develops in a previously unexposed and therefore unsensitized person. The primary organ involved is mostly the lungs . Location: Sub-pleural region. Lower part of the upper lobe & upper part of the lower lobe. Ghon's focus: Grey-white area of inflammation with consolidation. Ghon's complex: Ghon's focus + inflamed regional lymph nodes (Statment iii) . Histology: Granulomatous inflammatory reaction with both caseating and non-caseating tubercles. Simon's focus: Occult hematogenous dissemination to the apex of the lung. (Statement ii) Fate: 95% of the cases are controlled by immunity, calcified, healed lesions and hilar lymph nodes (Ranke complex). 5% of the cases are progressive (Progressive primary TB). Resembles acute bacterial pneumonia. Lymphohematogenous dissemination may cause tuberculous meningitis and/or miliary TB. Secondary tuberculosis It arises in a previously sensitised host. It may follow shortly after primary tuberculosis, but more commonly, it appears months to years after the initial infection, usually when the host resistance is weakened. The apical and posterior lobe segments are involved due to high O 2 concentration (Puhl's focus) (Statement i) . The infraclavicular lesion is called Assman's focus. Regional lymph node involvement is late. Cavitation occurs readily with the erosion of the cavities into an airway. Histology: Active lesions show coalescent tubercles with central caseation (Caseous necrosis). Disseminated TB: Spread to other organs. The images below show the caseous necrosis seen in TB. Other foci: Simmond focus: Liver. Weighert focus: Blood vessels (Statement iv) Rich's focus: Brain.

[07_Respiratory System] 035 Sarcoidosis And Occupational Lung Diseases — Quick Jump

Q1 (p. 1808) *Q2 (p. 1808)* *Q3 (p. 1811)* *Q4 (p. 1811)* *Q5 (p. 1812)* *Q6 (p. 1815)*
Q7 (p. 1817) *Q8 (p. 1817)* *Q9 (p. 1820)* *Q10 (p. 1821)* *Q11 (p. 1822)*

Q1: Which immunologic abnormalities are observed in the local milieu of sarcoid granulomas? (Q845654)

A. Accumulation of CD8+ T cells and increased CD8/CD4 T-cell ratio

B. Oligoclonal expansion of B-cell subsets

C. Increased levels of Th1 cytokines such as IL-4 and IL-10

D. Accumulation of CD4+ T cells and increased CD4/CD8 T-cell ratios

Correct Answer: D. Accumulation of CD4+ T cells and increased CD4/CD8 T-cell ratios

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Sarcoidosis is a systemic granulomatous disease of unknown cause involving multiple organs. These abnormalities include: Intra-alveolar and interstitial accumulation of CD4+ T cells, resulting in increased CD4/CD8 T-cell ratios ranging from 5:1 to 15:1 (Normally it is 2:1), suggesting pathogenic involvement of CD4+ helper T cells. There is an oligoclonal expansion of T-cell subsets (Option B) Increased T cell-derived Th1 cytokines such as IL-2 and interferon (IFN)-γ may be responsible for T-cell expansion and macrophage activation, respectively. (Option C) Microscopically, sarcoid granulomas are typically non-caseating, and because the surrounding lymphocytic collar is usually absent, they are often referred to as “ naked granulomas .” Two bodies are seen in sarcoid granulomas: Asteroid bodies Schaumann bodies

@Neet_pg_bot

Q2: A 40-year-old male presents with fever, bilateral hilar lymphadenopathy, erythema nodosum, and acute polyarthritis affecting ankles and knees. He has a history of recurrent uveitis. Laboratory tests show elevated serum angiotensin-converting enzyme (ACE) levels and hypercalcemia. What is the most likely diagnosis? (Q845655)

A. Lupus pernio

B. Lofgren's syndrome

C. Mikulicz syndrome

D. Systemic Lupus Erythematosus

Correct Answer: B. Lofgren's syndrome

- *Listen (English)*
- *Listen (Hindi)*

Explanation: This patient's clinical presentation and lab findings are suggestive of Lofgren’s syndrome, which is associated with sarcoidosis. Multi-organ involvement in Lofgren's syndrome, which is associated with Sarcoidosis: (Mnemonic: Lofgren) L: Lymphadenopathy O: Ouch: Joint pain and arthralgia F: Fever GR: Granulomas (Sarcoidosis shows non-caseating granulomas) EN: Erythema nodosum (Skin finding) Recurrent uveitis is also a feature of Sarcoidosis Microscopic finding in sarcoidosis: It shows non-caseating granulomas and naked granulomas 2 bodies which are seen in sarcoidosis: Asteroid bodies Schaumann bodies Lupus pernio (Option A): Cutaneous manifestation of sarcoidosis characterised by violaceous or erythematous indurated plaques distributed on the central face, particularly the nose and cheeks. Mikulicz syndrome (Option C): Defined as diffuse and bilateral enlargement of the salivary and lacrimal glands. It can occur as an isolated phenomenon or as a part of systemic diseases like sarcoidosis, Sjögren syndrome, etc. Systemic Lupus Erythematosus (Option D): Autoimmune disease affecting multiple organs, including the skin, joints, kidneys, and heart. Common symptoms of SLE include joint pain, skin rash (such as the classic butterfly rash), fatigue, and organ involvement.

Q3: In a histopathological examination of a lung biopsy from a patient with suspected sarcoidosis, which of the following microscopic features would be most characteristic and supportive of the diagnosis? (Q845656)

A. Macrophages with abundant cytoplasm containing dusty brown pigment

B. Non-necrotizing granulomas with asteroid bodies and Schaumann bodies

C. Coalescent tubercles with central caseation

D. Curschmann spirals and Charcot-Leyden crystals

Correct Answer: B. Non-necrotizing granulomas with asteroid bodies and Schaumann bodies

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Sarcoidosis is characterised by non-necrotizing granulomas containing asteroid bodies (stellate-shaped structures) and Schaumann bodies (calcium and protein inclusions). Composition of Schaumann bodies: Calcium Non-caseating granulomas are common, but caseating granulomas can also be seen rarely. Caseating granulomas are mainly indicative of necrotising TB. (Option C ruled out) Macrophages with abundant cytoplasm containing dusty brown pigment is a normal finding seen after inhalation of dust particles. (Option A ruled out) Curschmann spirals and Charcot-Leyden crystals are associated with Asthma (Option D ruled out)

@Neet_pg_bot

Q4: A 55-year-old male presents with a chronic cough, dyspnea, and chest tightness. On examination, fine crackles are heard bilaterally. A lung biopsy reveals collections of carbon-laden macrophages within the respiratory bronchioles and alveolar ducts, along with focal fibrosis and occasional small granulomas. Which of the following is not a condition associated with this patient? (Q845657)

A. Anthracosis

B. Simple Coal Worker’s Pneumoconiosis

C. Complicated coal Worker’s pneumoconiosis

D. Psittacosis

Correct Answer: D. Psittacosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: As the histopathology shows carbon-laden macrophages, it is not associated with Psittacosis which is a zoonotic bacterial infection caused by Chlamydia psittaci, contracted from exposure to infected birds, such as parrots. Technical term for carbon pigment is Anthracotic pigment. Stages of Coal worker’s pneumoconiosis (CWP) . Anthracosis (Option A): Inhaled carbon pigment accumulates in lung & lymphatics leading to black lungs which is usully asymptomatic. Simple Coal Workers’ Pneumoconiosis (CWP) (Option B): When carbon is inhaled for some years, it can lead to centrilobular emphysema. Complicated CWP (Option C): Exposure to carbon for many years can lead to large fibrotic masses in lung (>2 cm), which can lead to respiratory insufficiency, pulmonary hypertension, cor pulmonale .

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 692

Psittacosis - StatPearls - NCBI Bookshelf (nih.gov)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 50-year-old sandblaster presents with chronic cough, dyspnea, and chest pain. Further investigation reveals a history of prolonged exposure to sandblasting. He has also worked for several years in mines, where he was exposed to chronic asbestos and beryllium. A chest X-ray was taken, which is shown below. What is the most likely diagnosis? (Q845658)

A. Byssinosis

B. Silicosis

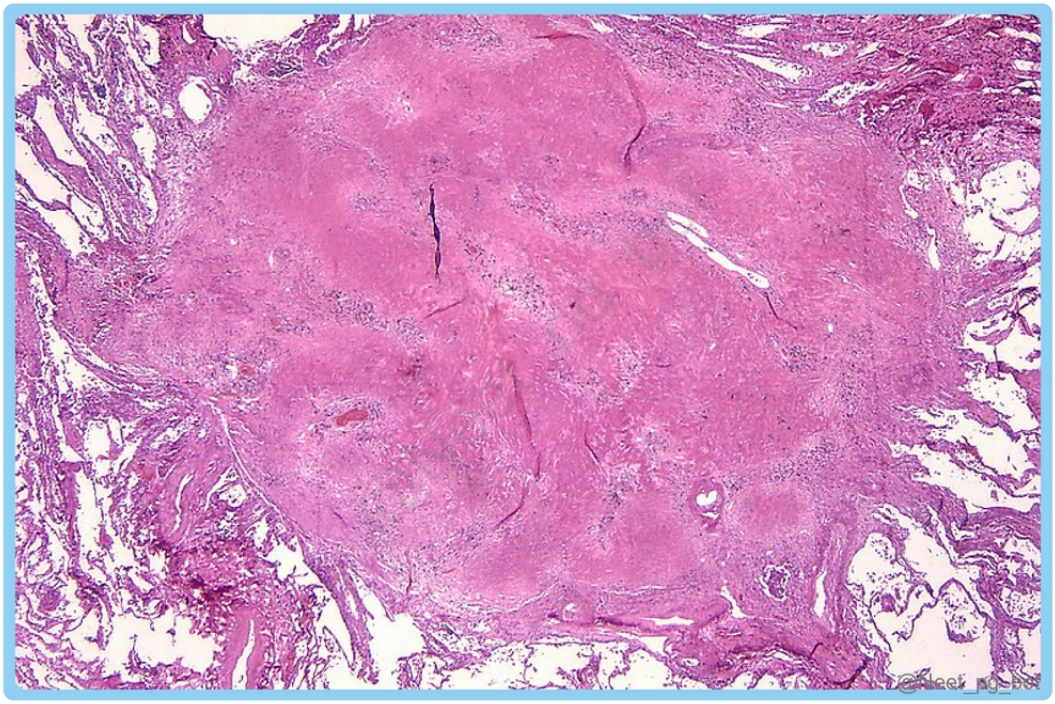
C. Asbestosis

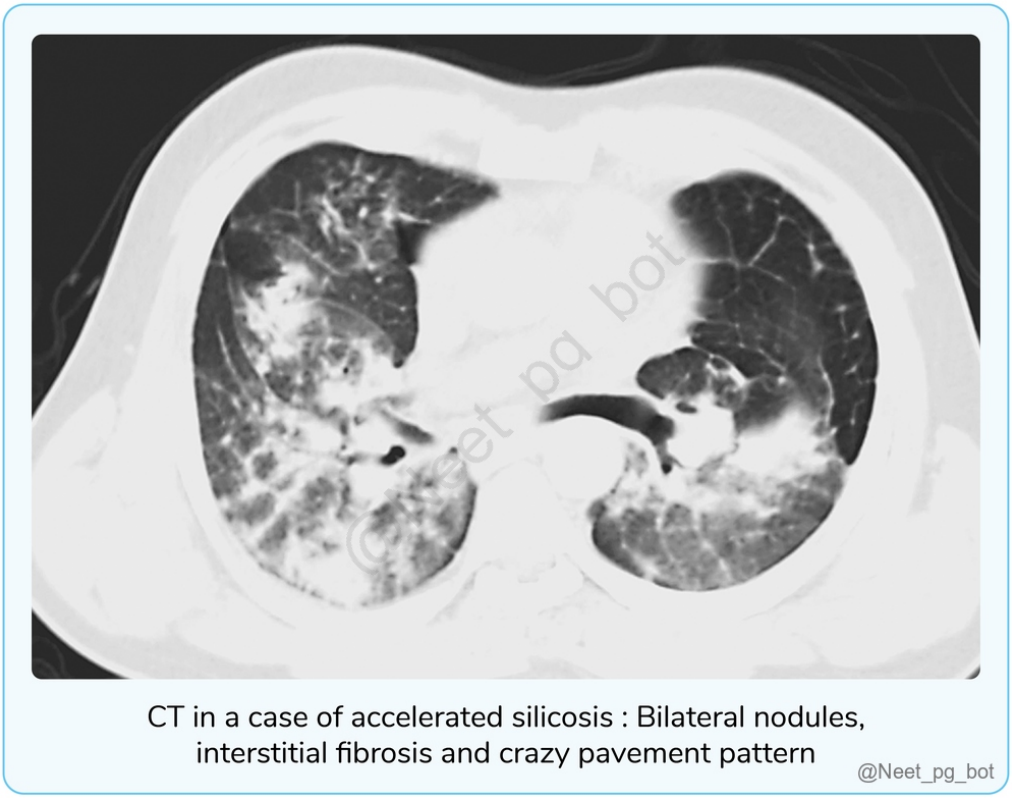
D. Berylliosis

Correct Answer: B. Silicosis

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The chest X-ray shows calcification of hilar lymph nodes, called eggshell calcification. The clinical picture, along with eggshell calcification, suggests silicosis. Silicosis: It is the most prevalent occupational lung disease in the world. Cause: Inhalation of proinflammatory crystalline silicon dioxide (silica). After many years of exposure, it typically manifests as a slowly progressive, nodular, fibrosing pneumoconiosis, which is later characterized by “egg-shell” calcifications of the hilar lymph nodes. Silicosis increases the risk of tuberculosis and cancers.





CT in a case of accelerated silicosis : Bilateral nodules, interstitial fibrosis and crazy pavement pattern

@Neet_pg_bot

@Neet_pg_bot

Q6: Which of the following is not a cause of eggshell calcification? (Q845659)

A. Silicosis

B. Sarcoidosis

C. Post-radiation therapy

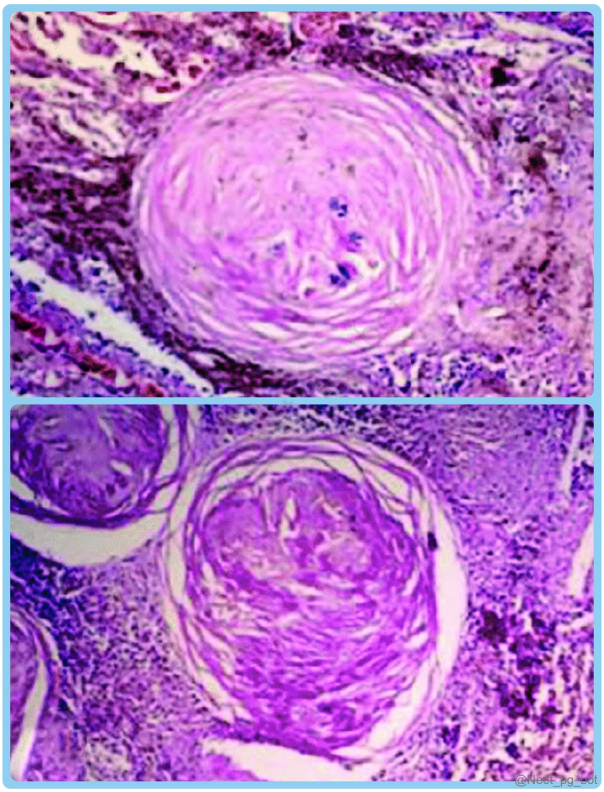
D. Metastatic lymph nodes

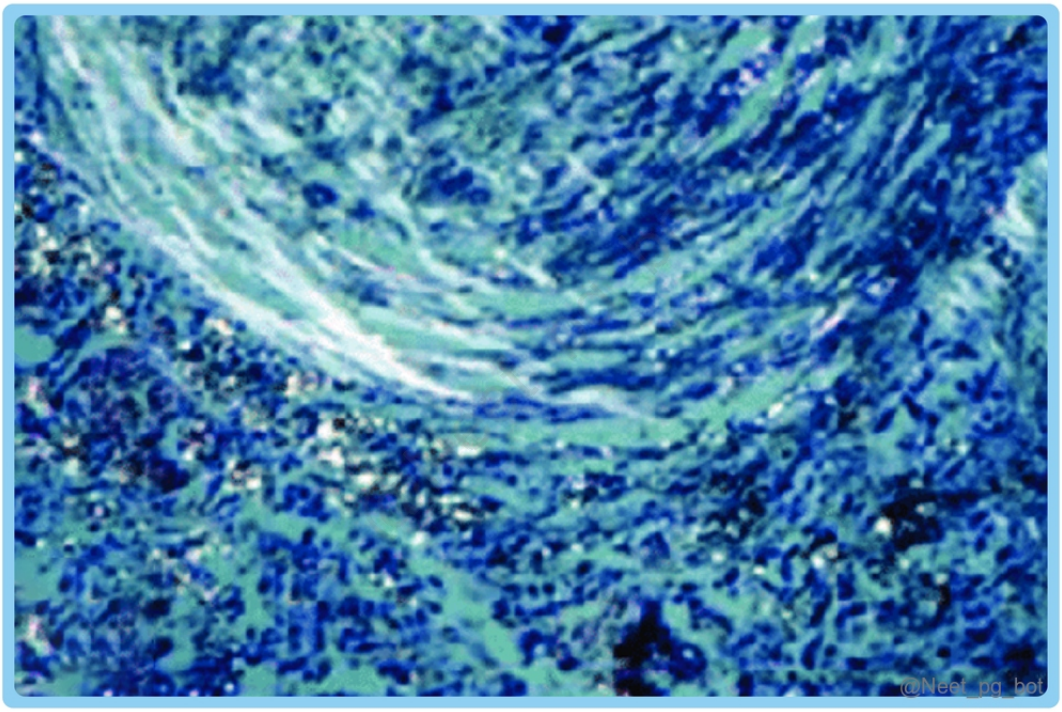
Correct Answer: D. Metastatic lymph nodes

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Eggshell calcification is not seen in metastatic lymph nodes. Eggshell calcification refers to a ring of calcification at the periphery of a lymph node and not in other parts of the lymph nodes Eggshell calcifications can also be seen in: Silicosis (Option A) Coal workers pneumoconiosis Sarcoidosis (Option B) Post-radiotherapy (Option C) Post-irradiation lymphoma Tuberculosis Amyloidosis Histoplasmosis Blastomycosis





References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 696

Silicosis (with egg shell calcification) | Radiology Case | Radiopaedia.org

@Neet_pg_bot

Q7: Which of the following forms of asbestos is more toxic? (Q845660)

A. Serpentine

B. Amphibole

C. Chrysolite

D. Erionite

Correct Answer: B. Amphibole

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Serpentine/ Chrysolite Amphibole/ Crocidolite/ Amosite Wavy (Snake like) Rigid and straight More common (90% of the asbestos) More pathogenic (amphiboles particularly associated with mesothelioma) Mnemonic: I am crying (Chrysotile) After looking at a snake (Serpentine) Snake is wavy Snakes can be seen more commonly (more common) Mnemonic: Saw a Crocodile (Crocidolite) Which is an Amphibian (Amosite) Crocodile is straight (rigid) Erionite is a type of asbestos. Exposure to it is associated with increased risks of lung cancer and mesothelioma. (Option D)

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 694

↑ *Back to this question in Part A*

@Neet_pg_bot

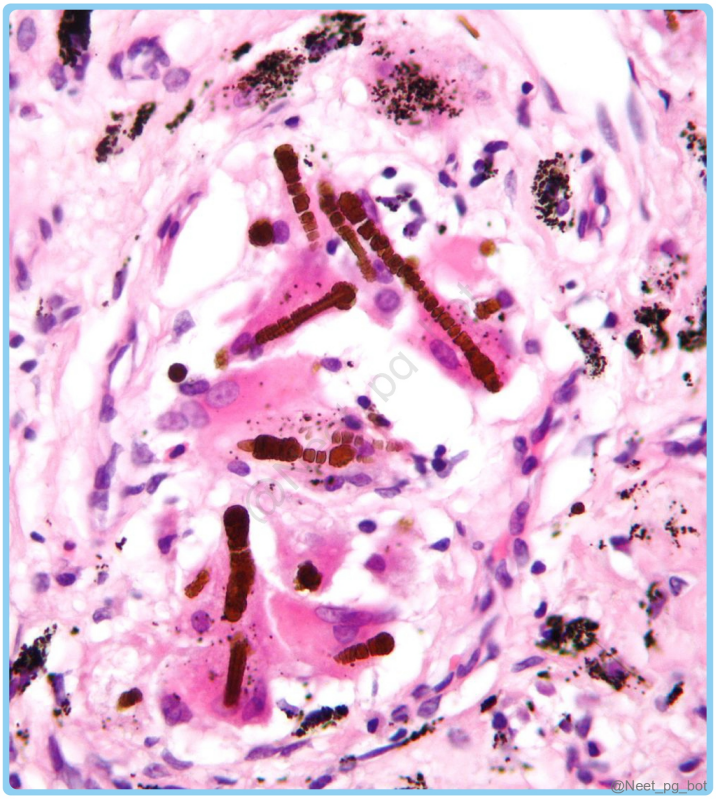
Q8: A patient has been experiencing dyspnea for the past few weeks. A biopsy of his lungs has revealed the finding given below. What is the characteristic finding shown below in this patient? (Q845661)

A. Creola body

B. Schaumann body

C. Ferruginous body

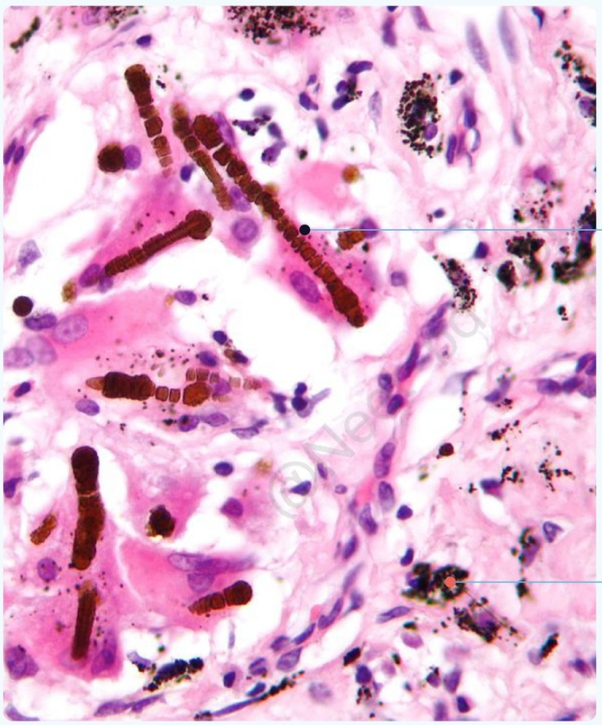
D. Asteroid body

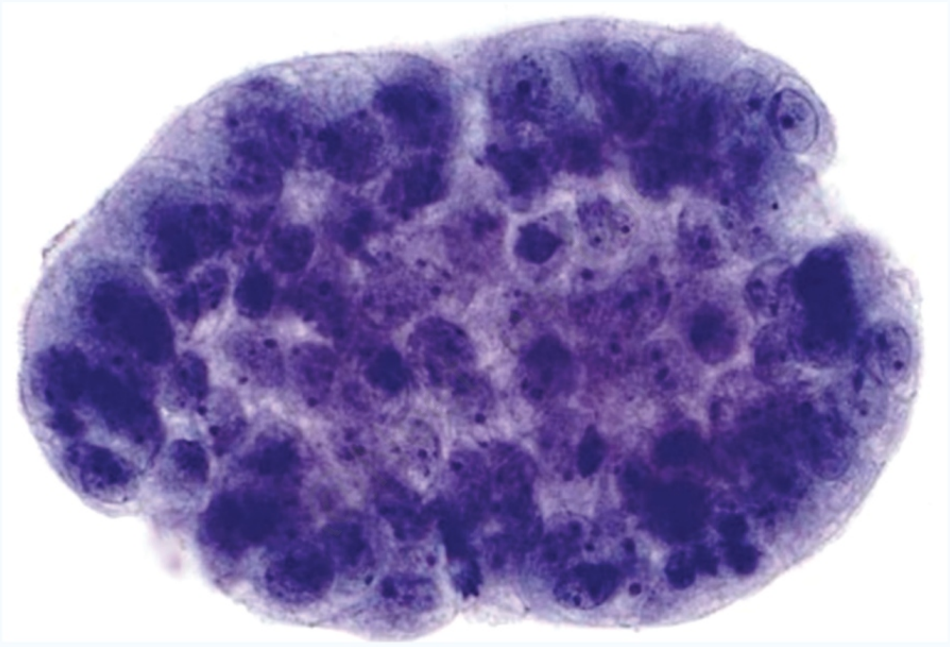


Correct Answer: C. Ferruginous body

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The histopathological slide shows golden brown, fusiform, or beaded rods with a translucent core containing asbestos fibres, when inhaled, our body deposits iron around it and thereafter it is known as ferruginous bodies . Asbestosis: It is due to occupational exposure associated in people working in shipyard or cement industry. It effects the pleura (outer covering of lung), so the first lesion formed is pleural plaque. After many years of exposure, pleural plaques may develop into pleural nodules, which, with prolonged exposure, can progress to cancers. Most common cancer seen in Asbestosis: Adenocarcinoma lung. Most specific cancer seen in Asbestosis: Mesothelioma lung Creola bodies (Option A): Seen in asthma. Schaumann bodies (Option B): These are calcium deposits that are seen in sarcoidosis. Asteroid bodies (Option D): Seen in sarcoidosis; Sporothrix schenckii (Rose gardner's disease), a fungal infection.





Creola bodies

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 697

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 55-year-old male presents to the clinic with complaints of persistent chest pain, shortness of breath, and unexplained weight loss. He was chronically exposed to minerals when he worked as a shipbuilder. Imaging studies revealed a growth that was subjected to needle biopsy. What is the most common lung malignancy associated with his occupational exposure? (Q845662)

A. Squamous cell carcinoma

B. Adenocarcinoma

C. Mesothelioma

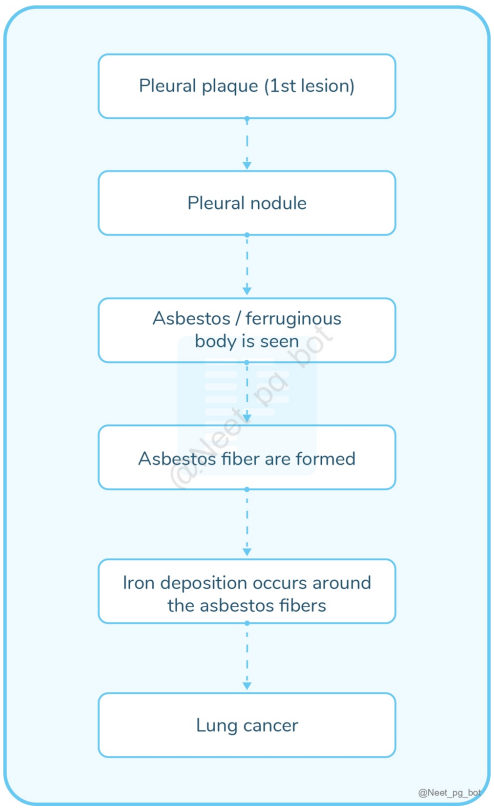
D. Small cell cancer

Correct Answer: B. Adenocarcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's occupational history where he worked as a Shipbuilder (Shipyard industry) suggests that he was chronically exposed to Asbestos and the most common lung malignancy seen with occupational asbestos exposure is adenocarcinoma . Most specific lung cancer seen with occupational asbestos exposure is mesothelioma .



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 694

www.ncbi.nlm.nih.gov/books/NBK555985/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Match the following occupational lung diseases with their characteristics. A) Byssinosis 1. Iron exposure B) Bagassosis 2. Monday disease C) Siderosis 3. Non-caseating granuloma. D) Berylliosis 4. Sugarcane dust exposure (Q845663)

A. A-4, B-2, C-1, D-3

B. A-2, B-4, C-1, D-3

C. A-3, B-1, C-4, D-2

D. A-2, B-1, C-4, D-3

Correct Answer: B. A-2, B-4, C-1, D-3

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Byssinosis: Cotton dust/ organic dust exposure. The patient usually complains that the symptoms worsen when they come to work on Monday, hence the name Monday chest syndrome. They get better when off work, and symptoms reduce as the week progresses. This cycle is repeated. This occurs because, after a gap of 1–2 days, re-exposure takes place and the symptoms return. Bagassosis: sugarcane dust exposure. Siderosis: iron exposure. Berylliosis is caused by beryllium exposure. It leads to non-caseating granulomas in the lungs, as in sarcoidosis and can be differentiated based on industry exposure.

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 692 Byssinosis - StatPearls - NCBI Bookshelf (nih.gov) Bagassosis - StatPearls - NCBI Bookshelf (nih.gov)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following is incorrect about mesothelioma? (Q846631)

A. Most specific cancer associated with asbestos exposure

B. Can lead to frozen hemithorax

C. Leads to a mediastinal shift

D. Not associated with smoking

Correct Answer: C. Leads to a mediastinal shift

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Malignant mesothelioma is a pleural malignancy that arises from mesothelial cells of the pleura and is classically associated with asbestos exposure, commonly seen in occupations such as shipyard work, cement, and insulation industries. Malignant mesothelioma causes diffuse pleural thickening that encases the lung, leading to restrictive lung disease and pleural effusion. A characteristic description is the “ frozen hemithorax ,” where the lung appears encased in a rind-like thick pleura. Clinically, it presents with dyspnea, chest pain, and recurrent pleural effusions. (Option B) Asbestos exposure is the strongest and most specific association. (Option A) Unlike bronchogenic carcinoma, smoking has no role in the causation of mesothelioma. In bronchogenic carcinoma, smoking and asbestos act synergistically. (Option C) A common genetic alteration is deletion on chromosome 9p21, resulting in loss of CDKN2A. In mesothelioma, pleural thickening/fibrosis causes lung entrapment, does not cause mediastinal shift unlike large pleural effusions or pneumothorax. (Option B) Mesothelioma- Gross Mesothelioma- H & E stain Mesothelioma- Calretinin stain Lobulated pleural soft tissue mass encasing the right lung. Associated erosion of the right 3rd rib anteriorly. Calcified pleural plaques were noted bilaterally, indicating previous asbestos exposure. Coarse, partially calcified right pleural plaques, accompanied by massive right pleural

effusion, causing total right lung collapse and mass effect.

Q1: A chronic smoker who worked in a cement factory for 20 years developed mesothelioma. It is due to? (Q855446)

A. Silicosis

B. Asbestosis

C. Coal worker pneumoconiosis

D. Bagassosis

Correct Answer: B. Asbestosis

Explanation: Mesothelioma is primarily caused by exposure to asbestos fibres, which is a known risk factor for this type of cancer. Long-term exposure to asbestos, especially in industries such as cement factories, is the most common occupational cause of mesothelioma. Asbestos exposure is a well-established risk factor for developing laryngeal, ovarian, colon, lung, and pleural cancers. Lung mesothelioma is a more specific tumour associated with asbestos exposure. It is common but is less prevalent than Adenocarcinoma. Mesothelioma A rare cancer arising from mesothelial cells that most commonly affects the pleura, and it can also affect the peritoneum, pericardium, and tunica vaginalis Etiology Mesothelioma is the most specific asbestos-associated cancer Pathology Advanced pleural mesothelioma can cause extensive pleural fibrosis and thickening, making the affected side rigid and immobile Later stages fix the mediastinum in place due to pleural thickening and fibrosis. A mediastinal shift is not a characteristic feature of mesothelioma. Clinical features Progressive dyspnea, chest pain, weight loss, chronic cough, hemoptysis Decreased breath sounds and dullness to percussion (due to pleural effusion or thickening). Diagnosis CT scan shows Pleural thickening, effusion, or frozen hemithorax (not causing a mediastinal shift in the presence of effusion) {{caption_text}} {{caption_text}} Biopsy (Diagnosis can be confirmed) Epithelioid mesothelioma shows tubules, nests, or papillary structures with uniform round to oval nuclei and eosinophilic cytoplasm. Sarcomatoid mesothelioma consists of spindle-shaped cells resembling fibrosarcoma. Biphasic mesothelioma displays a mixture of both patterns. Specific markers for mesothelioma Calretinin Epithelial membrane antigen Cytokeratin Mesothelin Prognosis Poor - median survival of 9-21 months Incorrect Options: Silicosis (Option A) is caused by the inhalation of silica dust , commonly seen in industries such as mining and construction. While silica exposure can lead to lung fibrosis, it is not a direct cause of

mesothelioma. Coal worker pneumoconiosis (Option C), also known as black lung disease , results from the inhalation of coal dust. This condition affects the lungs but is not linked to mesothelioma. Bagassosis (Option D) is caused by the inhalation of mouldy sugarcane dust and can lead to lung disease, but it is not associated with mesothelioma.

@Neet_pg_bot

Q2: Which of the following is a post-mortem finding seen in the lung after the death of a patient from COVID-19 after a week? (Q855970)

A. Fresh and old intra-alveolar hemorrhage

B. Thick layer of fibrin

C. Perivascular cuffing

D. Pulmonary artery hypertrophy with increased resistance

Correct Answer: B. Thick layer of fibrin

Explanation: : These can occur in COVID-19, especially in the acute phase; it is typically seen in earlier stages of the disease, not necessarily after a week. After a week, haemorrhage may be less prominent, and fibrin deposition would be a more characteristic finding. Perivascular cuffing (Option C) refers to the accumulation of lymphocytes around blood vessels, commonly seen in viral infections, usually in the early stages . By the later week , this feature may still be present but is not as defining as fibrin deposition after a week of death in COVID-19. Pulmonary artery hypertrophy with increased resistance (Option D) can develop with long-standing lung disease or after multiple episodes of severe illness. However, this is a chronic finding rather than an acute post-mortem feature . Pulmonary artery hypertrophy is a very rare complication after COVID-19 and would not commonly be a primary finding after one week of death from COVID-19.

@Neet_pg_bot

Q3: A 30-year-old woman with a long history of dyspnea, chronic cough with sputum, and wheezing died of respiratory failure following a bout of lobar pneumonia. She was

not a smoker or an alcoholic. The lung at autopsy is shown in the image below. Which of the following is most likely to cause the pathological changes shown? (Q854883)

A. Alpha-1 antitrypsin deficiency

B. Cystic fibrosis

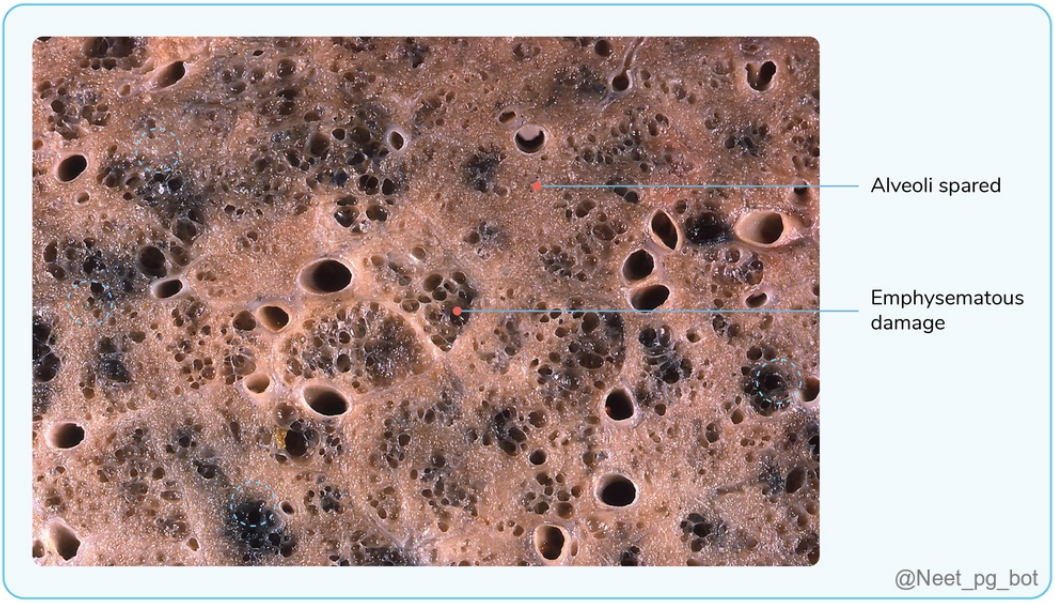
C. Mutation in dynein arms

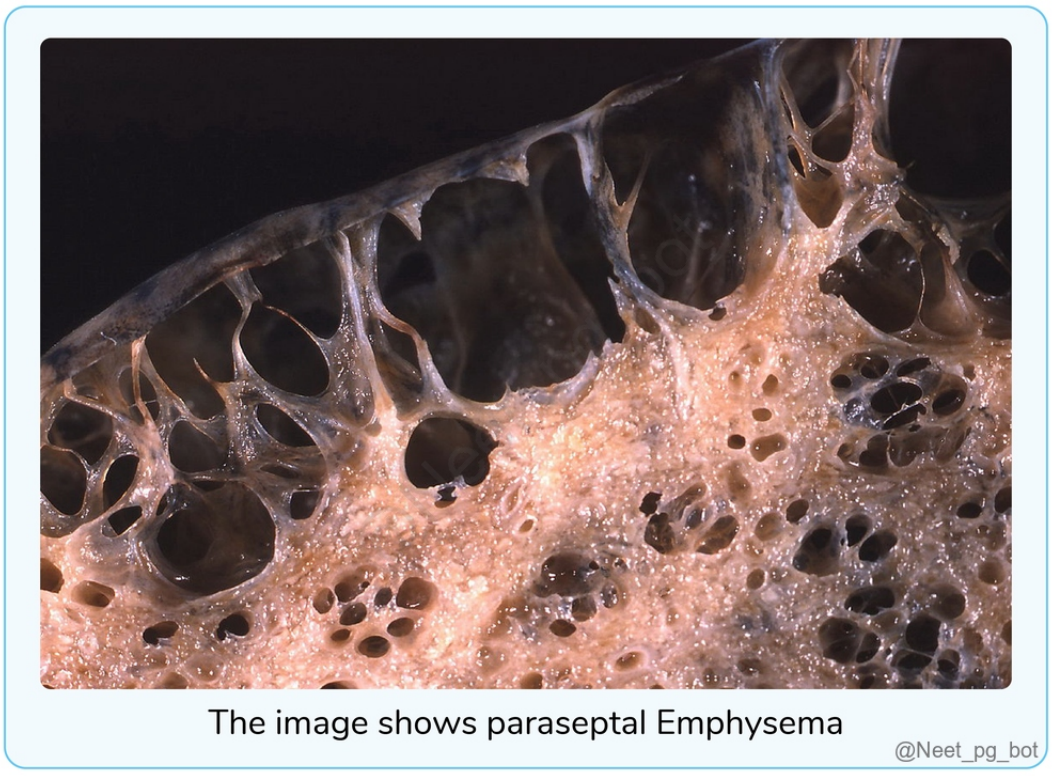
D. Antibodies against type-IV collagen

Correct Answer: A. Alpha-1 antitrypsin deficiency

Explanation: The clinical presentation and the gross specimen showing emphysematous damage involving the enlargement of the entire acinus are consistent with panacinar emphysema . This pattern of emphysema is most commonly associated with alpha-1 antitrypsin deficiency . Alpha-1 antitrypsin deficiency: It is an autosomal recessive disorder caused by mutations in the alpha-1 antitrypsin gene located on Chromosome 14 . Normal individuals have the PiMM genotype , while those with the disease have the PiZZ genotype. This results in significantly reduced levels of functional alpha-1 antitrypsin protein. Carriers possess the PiMZ genotype. The condition primarily affects the lungs, leading to panacinar emphysema and the liver, causing cirrhosis due to abnormal protein accumulation. Emphysema is classified according to its anatomic distribution within the lobule. Based on the segments of the respiratory units that are involved, emphysema is subdivided into four major types: Features Centriacinar (M/C) Panacinar Paraseptal Irregular Involves Proximal acinus Proximal & distal acini Distal acinus Irregular involvement Site Upper lobes, especially apical segments Lower zones & anterior margins of the lung. More severe at the base of the lung. The upper half of the lungs (more severe). Airspaces can form

cyst-like structures. Any part of the lung can be involved. Aetiology Smokers Chronic bronchitis α1-antitrypsin deficiency Spontaneous pneumothorax Depends on involvement, most found in autopsy The image below shows centriacinar emphysema. {{caption_text}} {{caption_text}} {{caption_text}}





The image below shows panacinar emphysema

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 679,680

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 55-year-old male presents with a chronic cough, shortness of breath, and chest pain. He has a history of working in construction for several decades, where he was exposed to asbestos. Physical examination reveals decreased breath sounds over the lower lung fields. A chest X-ray shows bilateral, diffuse interstitial opacities. Pulmonary function tests reveal a restrictive pattern. High-resolution computed tomography (HRCT) of the chest demonstrates "honeycombing" in the lung parenchyma. What is the diagnosis? (Q856495)

A. Tuberculosis

B. Chronic Obstructive Pulmonary Disease (COPD)

C. Asbestosis

D. Pneumonia

Correct Answer: C. Asbestosis

Explanation: The patient’s prolonged asbestos exposure, chronic cough, shortness of breath, and chest pain suggest asbestosis, a form of interstitial lung disease (ILD). Imaging findings, including bilateral interstitial opacities and honeycombing on HRCT, along with a restrictive pattern on pulmonary function tests, support the diagnosis of asbestos-induced pulmonary fibrosis. Asbestos exposure is a well-established risk factor for developing laryngeal, ovarian, colon, lung, and pleural cancers. {{caption_text}} Asbestos-related lung carcinoma is markedly magnified by smoking. Thus, asbestos workers (particularly those who smoke) are at much higher risk of dying of lung carcinoma than mesothelioma. Compared to other occupational lung diseases, which affect the upper lobes of the lungs, it commonly affects the lower lobes. Adenocarcinoma (primary bronchogenic carcinoma) is the most common type of cancer, accounting for about 45%, followed by squamous cell carcinoma. Lung mesothelioma is a more specific tumour associated with asbestos exposure but is less prevalent than Adenocarcinoma.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 694

https://www.ncbi.nlm.nih.gov/books/NBK555985/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: The most common lung finding in a COVID-19 infection is: (Q856477)

A. Pulmonary infarction

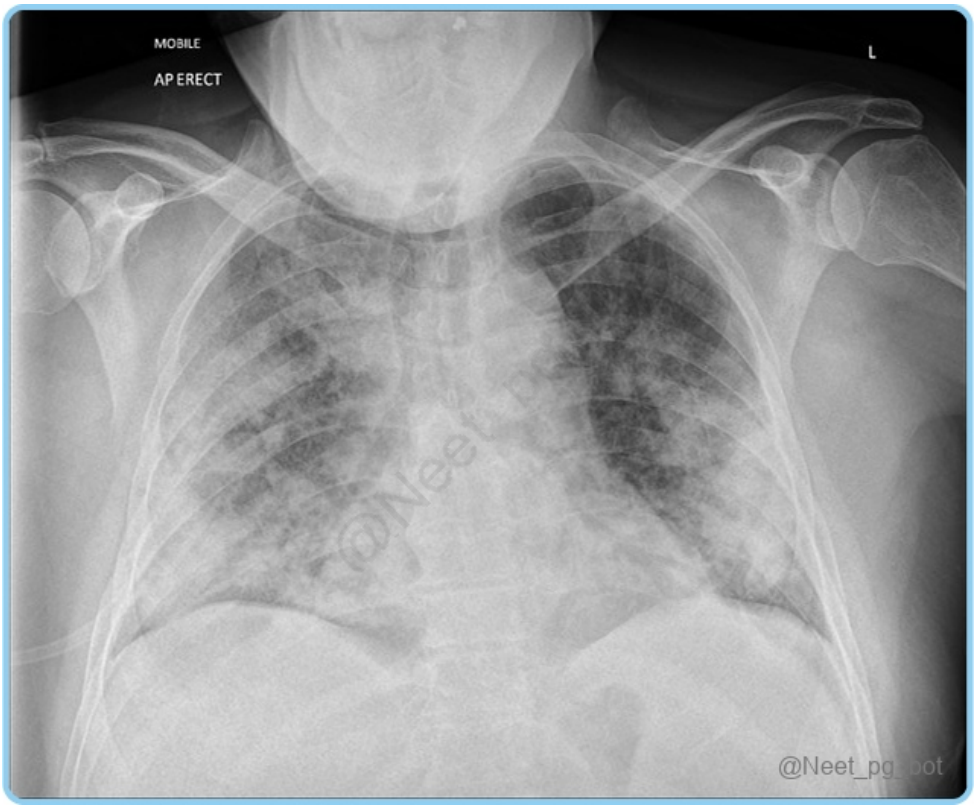
B. Diffuse alveolar damage

C. Endothelial injury

D. Fibrin clots

Correct Answer: B. Diffuse alveolar damage

Explanation: The most common lung finding in COVID-19 is diffuse alveolar damage (DAD). It represents the histopathological correlate of ARDS, frequently seen in moderate to severe cases. DAD shows hyaline membrane formation, alveolar edema, and type II pneumocyte hyperplasia. It results from widespread injury to alveolar epithelial cells. DAD explains the severe hypoxemia seen clinically. It is the hallmark lesion in the lungs during both early (exudative) and later (organizing) phases of COVID-19. Hence, DAD is the characteristic and most common pathological finding. {{caption_text}} Incorrect Options: Option A) Pulmonary infarction: Not a common feature; seen only when significant thromboembolic events occur, which are less frequent. Option C) Endothelial injury: Present in COVID-19 but not the main lung pathology; it contributes to severity, not the primary finding. Option D) Fibrin clots: Microthrombi can occur, but they are secondary features and not the dominant or most common lung lesion.



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 353

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 42-year-old female patient presents with a cough, a low-grade fever, and hemoptysis. Investigations reveal a cavitary lesion on her right lung apex, which, on biopsy, reveals caseous necrosis. The underlying pathophysiology is: (Q856728)

A. Enzyme degradation

B. Type-4 hypersensitivity reaction

C. Fibrinoid deposition

D. Sudden cut off of blood supply

Correct Answer: B. Type-4 hypersensitivity reaction

Explanation: The given scenario of cough, fever, hemoptysis, and a cavitary lesion with caseous necrosis at the right lung apex strongly suggests Pulmonary Tuberculosis , which involves a type-4 hypersensitivity reaction. CD4+ T cells activate macrophages, but Mycobacterium tuberculosis survives within them, causing granuloma formation with caseous necrosis, driven by a type 4 hypersensitivity reaction and resulting in tissue damage. It is a bacterial infection caused by Mycobacterium tuberculosis and can be classified into the following types: 1. Primary tuberculosis It develops in a previously unexposed and, therefore, unsensitized person. The primary organ involved is mostly the lungs. Location: Sub-pleural region. Lower part of the upper lobe & upper part of the lower lobe. Ghon’s focus: Grey-white area of inflammation with consolidation. Ghon’s complex: Ghon’s focus + inflamed regional lymph nodes. Histology : Granulomatous inflammatory reaction with both caseating and non-caseating tubercles. {{caption_text}} Simon’s focus: Occult hematogenous dissemination to the apex of the lung. Fate: 95% of the cases are controlled by immunity, calcified, healed lesions and hilar lymph nodes (Ranke complex) . 5% of the cases are progressive (Progressive primary TB) . Resembles acute bacterial pneumonia. Lymphohematogenous dissemination may cause tuberculous meningitis and/or miliary TB. 2. Secondary tuberculosis It arises in a previously sensitised host. It may follow shortly after primary tuberculosis, but more commonly, it appears months to years after the initial infection, usually when the host resistance is weakened. The apical and posterior lobe segments are involved due to high O 2 concentration (Puhl’s focus) . The infraclavicular lesion is called Assman’s focus. Regional lymph node involvement is late. Cavitation occurs readily with the erosion of the cavities into an airway. Histology: Active lesions show coalescent tubercles with central caseation (Caseous necrosis). 3. Disseminated TB : Spread to other organs. The images below show the caseous necrosis seen in TB. {{caption_text}} {{caption_text}} Enzyme degradation (Option A) may be involved in the breakdown of tissue during infection. The primary mechanism of tissue damage in tuberculosis is the type-4 hypersensitivity reaction. Fibrinoid deposition (Option C) refers to the accumulation of fibrin-like material in the walls of blood vessels. It is typically associated with conditions such as vasculitis. Sudden cutoff of blood supply (Option D) occurs when the blood supply to a tissue is abruptly interrupted, leading to ischemia and subsequent tissue death. In the case of tuberculosis, the tissue damage is primarily caused by the immune response and the

formation of granulomas.

Robbins & Cotran Pathologic Basis of Disease,10th Edition, Page 371-373.

↑ *Back to this question in Part A*

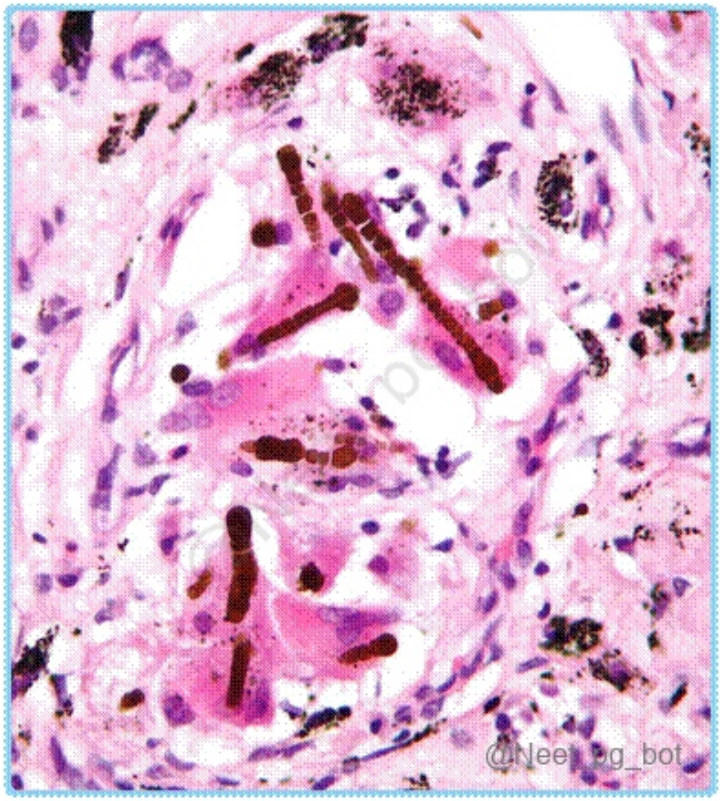
Q7: A person working in an industry for a long time develops progressive breathlessness. The histopathological image of his lung biopsy is given below. What industry was the person most likely working in? (Q856697)

A. Silica

B. Asbestos

C. Coal dust

D. Cotton



Correct Answer: B. Asbestos

Explanation: The histopathological image shows ferruginous bodies, suggestive of Asbestosis , indicating the person likely worked in the asbestos industry. It is a chronic lung condition caused by the inhalation of asbestos fibres over a prolonged period. These fibres accumulate in the lung tissue, leading to inflammation, fibrosis, and scarring. Symptoms: Includes shortness of breath, coughing, and chest tightness The histopathological features seen in asbestosis include: Interstitial fibrosis: Asbestos fibres cause injury to the lung parenchyma, resulting in the deposition of collagen and fibrous tissue in the interstitium. This fibrosis leads to thickening of the alveolar walls

and restrictive lung function. Ferruginous bodies: Asbestos fibres can be recognized in the lung tissue as long, golden-brown, rod-shaped structures called ferruginous bodies. These bodies are composed of asbestos fibre coated with iron and protein. {{caption_text}} Silica (Option A) exposure is associated with a lung disease called silicosis. Histopathological features of silicosis include nodular lesions with silica particles, collagenous fibrosis, and concentric silicotic nodules featuring central collagen and a peripheral zone of dust-laden macrophages. {{caption_text}} Coal dust (Option C) exposure is associated with coal worker's pneumoconiosis (CWP). Histopathological features of CWP include the presence of coal macules (collections of carbon-laden macrophages) and coal nodules (fibrotic lesions with central cores of coal dust). {{caption_text}} Cotton (Option D) exposure can lead to a lung disease known as byssinosis, also called brown lung disease. Histopathological findings in byssinosis include bronchiolitis and chronic bronchitis with peribronchiolar fibrosis. {{caption_text}}

@Neet_pg_bot

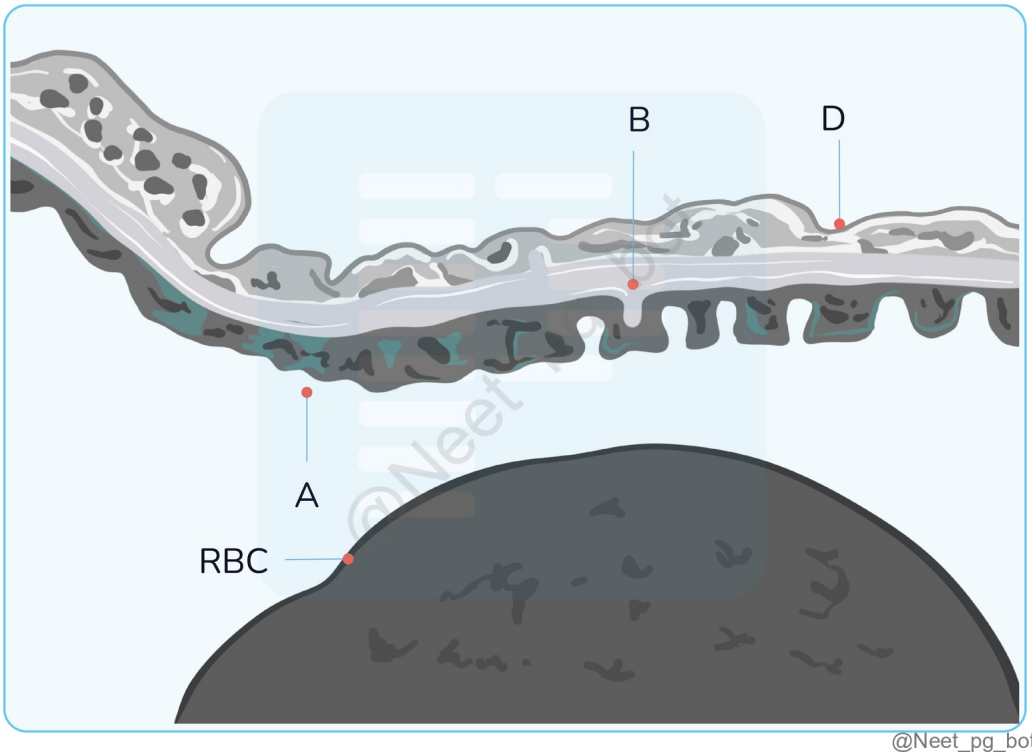
Q8: Below is an electron microscopic image of lung tissue. A patient infected with SARS-CoV2 presents with ARDS. The infection would affect and expand in which of the following labelled layers? (Q855415)

A. B

B. A

C. D

D. None of the above



Correct Answer: B. A

Explanation: In the electron microscopic image of the lung tissue, the structure labelled "A" represents the endothelium, where SARS-CoV-2 infection would impact and cause expansion. It is the virus causing COVID-19. It leads to acute respiratory distress syndrome (ARDS). Mechanism: The virus can directly infect the endothelial cells that line the blood vessels in the lungs, disrupting the normal function and integrity of the endothelial cells, resulting in increased vascular permeability, inflammation, and the onset of pulmonary edema. (Option B) Layer B (Option A) represents the basal lamina, which offers structural support to the epithelial cells and separates them from the underlying connective tissue. However, it is not the primary site of infection in SARS-CoV-2-related ARDS. Layer D (Option C) represents epithelium that lines the airways and plays a key role in the respiratory system's defence mechanisms. However, it is not the primary target in SARS-CoV-2-related ARDS, where the main pathological changes occur in the endothelium.

@Neet_pg_bot

Q9: A 45-year-old patient who has been working in a factory for the past 20 years presents with breathlessness. HRCT of the chest shows pleural thickening and fibrosis.

What is the person suffering from? (Q857611)

A. Asbestosis

B. Coal worker pneumoconiosis

C. Silicosis

D. Berylliosis

Correct Answer: A. Asbestosis

Explanation: The patient's history of working in a factory for a prolonged period, along with the HRCT chest findings of pleural thickening and fibrosis, points towards the diagnosis of Asbestosis , a lung disease caused by the inhalation of asbestos fibres commonly encountered in occupational settings. Prolonged exposure to asbestos can lead to the deposition of fibres in the lungs, triggering an inflammatory response that results in fibrosis and scarring of lung tissue, including the pleura. Occupational Lung Disease Associated Agents Features Diagnostic Tools Preventive Measures Asbestosis (Option A) Asbestos fibers Characterised by progressive pulmonary fibrosis. Symptoms include dyspnea, non-productive cough, and chest pain. Often associated with pleural plaques and increased risk of mesothelioma and lung cancer. HRCT, pulmonary function tests, occupational history Use of protective gear, proper ventilation, asbestos abatement programs Silicosis (Option C ruled out) Crystalline silica (quartz dust) Presents with nodular pulmonary fibrosis, primarily in the upper lobes. Increased risk of TB and other respiratory infections. Chronic exposure can lead to progressive massive fibrosis. Chest X-ray, HRCT, occupational history Dust control measures, respirators, regular health check-ups Coal Worker's Pneumoconiosis (CWP) (Option B ruled out) Coal dust Also known as "black lung disease." Features similar to silicosis but usually affect the upper lungs with coal dust deposition and fibrosis, without the silicotic nodules. Chest X-ray, HRCT, pulmonary function tests Dust control, respiratory protective equipment, regular monitoring Byssinosis Cotton, flax, hemp dust "Monday fever" describes worsening symptoms at the beginning of the workweek. Symptoms include chest tightness and wheezing, predominantly in textile workers. Clinical evaluation, occupational history Improved ventilation, dust suppression, health education Berylliosis (Option D ruled out) Beryllium and its compounds Acute or chronic lung disease caused by beryllium. Chronic form mimics sarcoidosis with systemic symptoms and granulomatous inflammation. Lung biopsy, beryllium lymphocyte proliferation test (BeLPT), imaging Limiting exposure, personal protective equipment, medical surveillance Farmer's Lung Moldy hay, crops, and compost dust A type of hypersensitivity pneumonitis caused by inhaling organic dust, presenting with malaise, cough, and breathlessness that may become chronic. HRCT, pulmonary function tests, specific IgG testing for antigens Respiratory protective equipment, proper storage of agricultural products

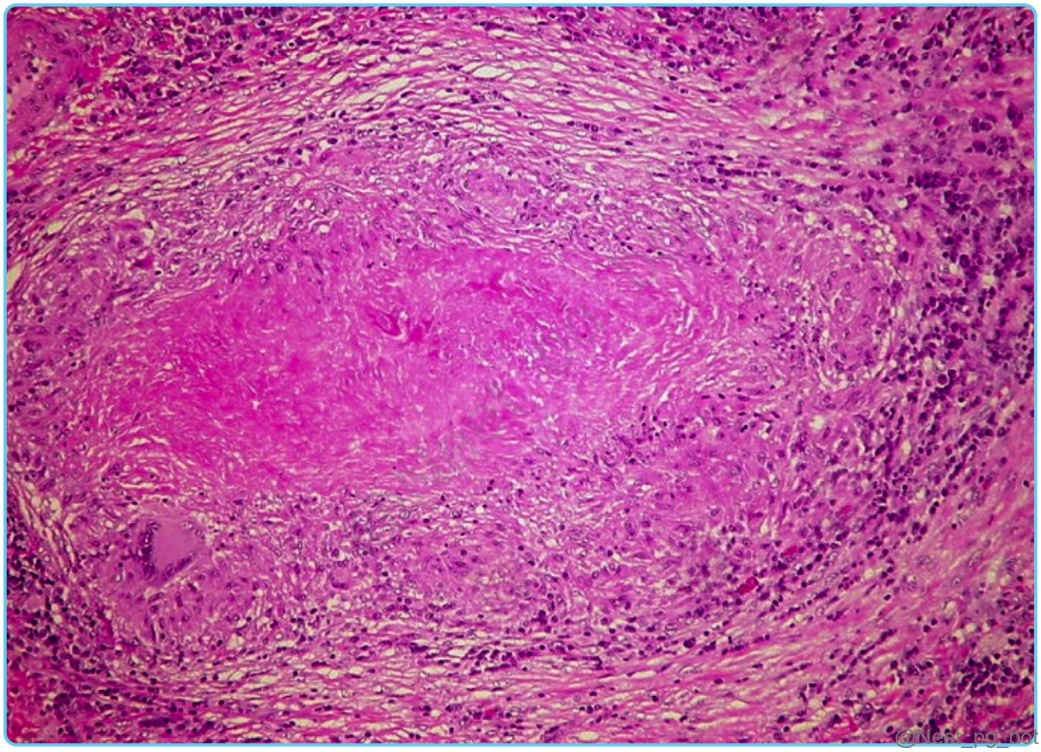
Q10: A 12-year-old child presents with a persistent cough for 15 days. Upon examination, cervical lymphadenopathy is observed. A lymph node biopsy image is given below. What is the most likely diagnosis? (Q857586)

A. Tuberculosis

B. Leprosy

C. Sarcoidosis

D. Syphilis



Correct Answer: A. Tuberculosis

Explanation: The clinical presentation and caseating granulomas (central necrosis surrounded by epithelioid macrophages and lymphocytes) in the biopsy strongly suggest Tuberculosis. {{caption_text}} Type of Granuloma Examples Caseating Granuloma Tuberculosis, Histoplasmosis, Coccidioidomycosis, Syphilis Non-caseating Granuloma Sarcoidosis , Crohn’s disease, Leprosy Foreign Body Granuloma Silicosis, Asbestos-related diseases, Foreign body reactions Immune Granuloma Wegener’s granulomatosis, Giant cell arteritis Durck’s Granuloma Cerebral malaria Stellate Granuloma Cat scratch disease Causes of granuloma formation Infectious causes Non-infectious causes TB (Caseating and non-caseating granuloma) Leprosy Syphilis Malaria (Durck granuloma) Cat-scratch disease and Lymphogranuloma venerum (Stellate granuloma) Q fever (Doughnut granuloma/ Fibrin ring granuloma) Sarcoidosis (Naked granuloma) Giant cell arteritis Crohn’s disease Churg-Strauss syndrome (Eosinophilic granuloma) Berylliosis (Foreign body granuloma)

@Neet_pg_bot

Q11: A middle-aged man working in the sandblasting industry developed hemoptysis and a productive cough. A chest x-ray is suggestive of tuberculosis. Which of the following is associated with the same? (Q857109)

A. Asbestosis

B. Silicosis

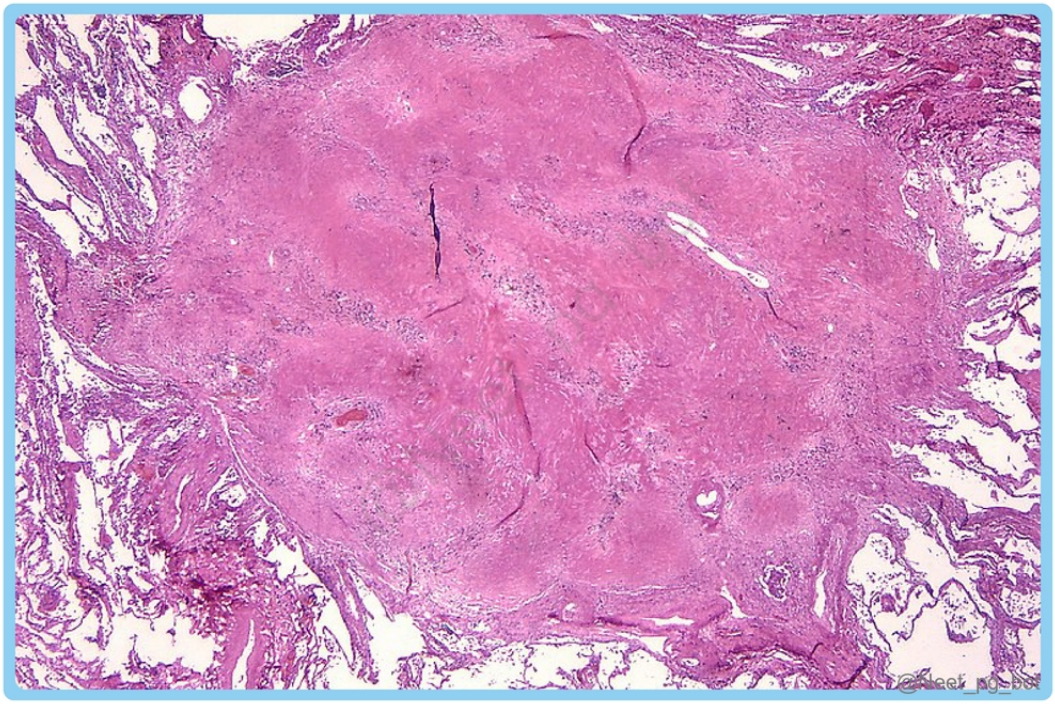
C. Anthracosis

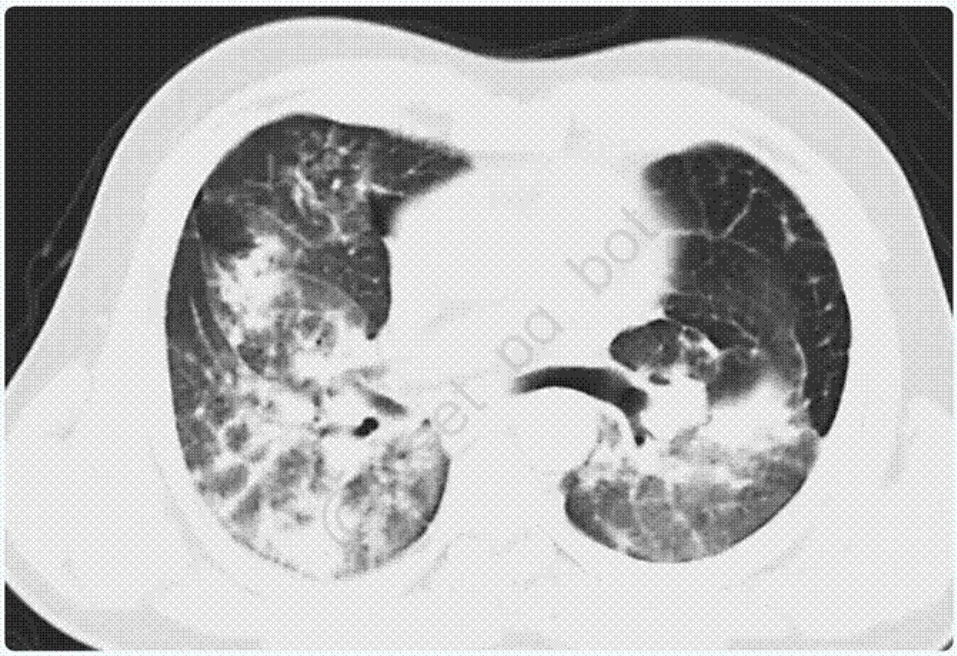
D. Siderosis

Correct Answer: B. Silicosis

Explanation: Silicosis is a type of pneumoconiosis caused by inhalation of crystalline silica dust, which is commonly found in industries like sandblasting. It is associated with a higher risk of developing tuberculosis due to the impairment of the immune response in the lung Silicosis: It is the most prevalent occupational lung disease in the world. Cause: Inhalation of proinflammatory crystalline silicon dioxide (silica). After decades of exposure, it usually presents as slowly progressing, nodular, fibrosing pneumoconiosis. Occupations at risk: Foundry work.

Sandblasting. Hard rock mining. Stone cutting. Jewellers using chalk moulds. Pathogenesis: Phagocytosis of inhaled silica crystals by macrophages activates the inflammasome and stimulates the release of inflammatory mediators, particularly IL-1 and IL-18. This, in turn, recruits additional inflammatory cells and activates interstitial fibroblasts, leading to collagen deposition. Forms of silica: Amorphous. Crystalline (quartz, cristobalite, and tridymite)- more fibrogenic. Forms of silicosis: Acute Heavy exposure in closed spaces Associated with Silico-tuberculosis and Secondary pulmonary alveolar proteinosis (SPAP) Can present within 2 years. Chronic (simple): Long-term (10-30 years) less intense exposure. Chronic Complicated: Chronic cough and progressive dyspnea on exertion. Morphology: Discrete nodules in hilar nodes and upper zones of lungs. Hard collagenous scars. Fibrotic lesions in nodes and pleura (pleural thickening). Eggshell calcification (thin sheets of calcification in lymph nodes; calcium surrounding a zone lacking calcification). Progressive massive fibrosis (1-10 cm). Lung cancer (2-fold risk). Increased susceptibility to tuberculosis infection. Histological hallmark: Central collagen with a peripheral zone of dust-laden macrophages. Polarized microscopy: Weakly birefringent silicate particles. CT scan: Crazy pavement pattern and interstitial fibrosis. {{caption_text}} {{caption_text}} Asbestosis (Option A) is caused by inhaling asbestos fibres, primarily leading to lung fibrosis and increasing the risk of lung cancer and mesothelioma. However, it is not directly linked to an increased risk of tuberculosis. {{caption_text}} Anthracosis (Option C) , or "coal miner’s lung," results from inhaling coal dust. It can cause chronic bronchitis or emphysema but does not have a direct association with tuberculosis. {{caption_text}} Siderosis (Option D) is caused by inhaling iron oxide dust, typically seen in occupations like welding. It can lead to pulmonary fibrosis but does not significantly increase the risk of tuberculosis. {{caption_text}}





CT in a case of accelerated silicosis : Bilateral nodules, interstitial fibrosis and crazy pavement pattern

@Neet_pg_bot

Q12: What is the diagnosis for a patient with a history of smoking 24 packs, currently experiencing breathlessness and chest pain, and found to have a lung tumour with positive chromogranin staining? (Q855092)

A. Adenocarcinoma

B. Squamous cell carcinoma

C. Mesothelioma

D. Small cell carcinoma

Correct Answer: D. Small cell carcinoma

Explanation: The patient's clinical presentation and positive staining for neuroendocrine markers such as Chromogranin and synaptophysin are highly suggestive of Small-cell lung cancer (SCLC) originating from neuroendocrine cells. It is a highly malignant form of lung cancer associated with smoking and is known for its aggressive behaviour and early metastasis. The genetic landscape of SCLC typically involves the inactivation of TP53 and RB genes. L-MYC amplification is a common feature in some SCLC cases, contributing to the tumour's rapid growth and aggressive nature. Characteristic Small Cell Carcinoma Squamous Cell Carcinoma (Option B) Carcinoid Tumor Adenocarcinoma (Option A) Origin Neuroendocrine cells of the lung. Squamous cells of the lung. Neuroendocrine cells of bronchial epithelium. Glandular cells of the lung. Cells in histopathology Small, round to oval, blue cells with scant cytoplasm and finely granular chromatin with a “salt and pepper” appearance. Sheets of polygonal cells with keratinization and intercellular bridges Nesting (organoid) growth pattern with uniform round nuclei, moderate eosinophilic cytoplasm , and a “ salt-and-pepper” chromatin pattern. Glandular or epithelial cells forming acinar, papillary, or solid patterns Mitotic rate High Variable Low to moderate Variable Electron microscopy findings Dense core neurosecretory granules. Desmosomes, tonofilaments, keratinisation Dense core neurosecretory granules. Variable organelles, sometimes containing mucin vacuoles IHC markers Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin). P63, p40 , CK5/6 Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin) Variable (e.g., TTF-1, Napsin A for primary lung adenocarcinoma) {{caption_text}} {{caption_text}} {{caption_text}} {{caption_text}} Mesothelioma (Option C) is a cancer associated with asbestos exposure, not typically associated with smoking. Additionally, it does not usually show chromogranin positivity. It usually arises from the pleura and presents with different symptoms, such as pleuritic chest pain and shortness of breath.

Q13: A chronic smoker who worked in a cement factory for the past 20 years developed mesothelioma. This association is most likely due to? (Q866738)

A. Bagassosis

B. Silicosis

C. Asbestosis

D. Adenocarcinoma

Correct Answer: C. Asbestosis

Explanation: Mesothelioma is a malignant tumour of the pleura (and sometimes peritoneum or pericardium) that is strongly associated with asbestos exposure. Asbestos fibres are commonly encountered in: Shipbuilding Construction Cement manufacturing Insulation materials Chronic inhalation of asbestos fibres → fibres lodge in pleura → chronic inflammation & fibrosis → mutations → mesothelioma (and also increased risk of bronchogenic carcinoma, especially in smokers). Asbestos exposure is a well-established risk factor for developing laryngeal, ovarian, colon, lung, and pleural cancers. Asbestos-related lung carcinoma is markedly magnified by smoking. Thus, asbestos workers (particularly those who smoke) are at much higher risk of dying of lung carcinoma than mesothelioma. Compared to other occupational lung diseases, which affect the upper lobes of the lungs, it commonly affects the lower lobes. Adenocarcinoma (primary bronchogenic carcinoma) is the most common type of cancer, accounting for about 45%, followed by squamous cell carcinoma. Lung mesothelioma is a more specific tumour associated with asbestos exposure but is less prevalent than Adenocarcinoma.

@Neet_pg_bot

Q14: An elderly male smoker presents with a chronic cough, significant weight loss, and fatigue. The serum calcium level is raised. A lung biopsy reveals large atypical cells with hyperchromasia. What is the probable diagnosis? (Q855423)

A. Large cell neuroendocrine tumour

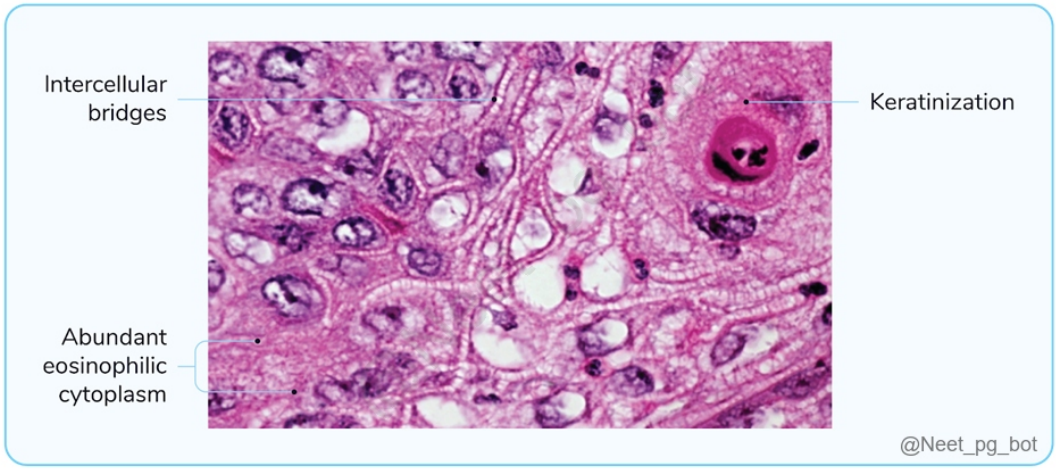
B. Small cell carcinoma

C. Adenocarcinoma

D. Squamous cell carcinoma

Correct Answer: D. Squamous cell carcinoma

Explanation: An elderly male smoker with chronic cough, weight loss, fatigue, and elevated serum calcium likely has squamous cell carcinoma of the lung. This cancer is associated with paraneoplastic hypercalcemia due to PTHrP secretion . The biopsy showing large atypical cells with hyperchromasia supports this diagnosis. Smoking significantly increases the risk of squamous cell carcinoma of the lung as it has a strong association, resulting in chromosomal deletions involving tumour suppressor loci involving 3p,9p and 17p. Squamous cell carcinoma: Squamous Cell Carcinoma is typically found in the central regions of the lungs (Not peripheral) , often originating in the major bronchi near the hilum. It can cause symptoms by obstructing airways. Histopathologically, it is characterised by keratin pearls, intercellular bridges , and nests of malignant squamous cells with abundant eosinophilic cytoplasm. {{caption_text}} Location of lung carcinomas: Central: Squamous cell carcinoma, Small cell carcinoma, and Bronchial carcinoids. Peripheral: Adenocarcinoma and Large-cell carcinoma. Type of Lung Carcinoma Paraneoplastic Syndrome Squamous cell carcinoma Hypercalcemia Adenocarcinoma Migratory thrombophlebitis (Trousseau syndrome) Small cell or oat cell Carcinoma SIADH (syndrome of inappropriate anti-diuretic hormone secretion) Cushing's syndrome Lambert Eaton syndrome Large cell carcinoma Gynaecomastia Characteristic Small Cell Carcinoma (Option B) Squamous Cell Carcinoma (Option D) Carcinoid Tumor (Option A) Adenocarcinoma (Option C) Origin Neuroendocrine cells of the lung. Squamous cells of the lung. Neuroendocrine cells of bronchial epithelium. Glandular cells of the lung. Cells in histopathology Small, round to oval, blue cells with scant cytoplasm and finely granular chromatin with a “salt and pepper” appearance. {{caption_text}} Sheets of polygonal cells with keratinisation and intercellular bridges {{caption_text}} Nesting (organoid) growth pattern with uniform round nuclei, moderate eosinophilic cytoplasm , and a “ salt-and-pepper” chromatin pattern. {{caption_text}} Glandular or epithelial cells forming acinar, papillary, or solid patterns {{caption_text}} Mitotic rate High Variable Low to moderate Variable Electron microscopy findings Dense core neurosecretory granules. Desmosomes, tonofilaments, keratinisation Dense core neurosecretory granules. Variable organelles, sometimes containing mucin vacuoles IHC markers Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin). P63, p40 , CK5/6 Positive for neuroendocrine markers (e.g., chromogranin, synaptophysin) Variable (e.g., TTF-1, Napsin A for primary lung adenocarcinoma)



Intercellular bridges
Keratinization
Abundant eosinophilic cytoplasm

@Neet_pg_bot

Q15: A 30-year-old patient arrives at the emergency room with complaints of respiratory discomfort. The patient has been experiencing shortness of breath, coughing, and chest pain for the past few weeks. The patient's medical history is unremarkable, and there is no significant smoking history. Upon further investigation, a lung biopsy is performed, and microscopic examination reveals the presence of asteroid bodies. What is the most likely diagnosis for this patient? (Q820569)

A. Sarcoidosis

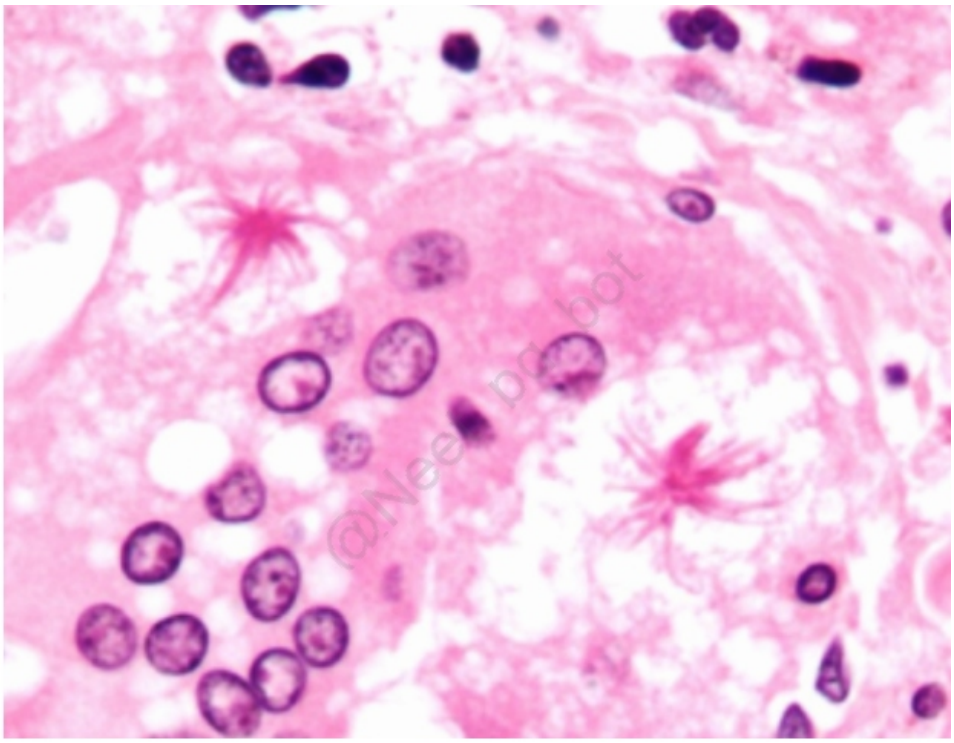
B. RA

C. Sjogren syndrome

D. SLE

Correct Answer: A. Sarcoidosis

Explanation: Correct Option A - Sarcoidosis: The patient's presentation with shortness of breath, coughing, and chest pain for the past few weeks with lung biopsy performed and microscopic examination revealing the presence of asteroid bodies is suggestive of sarcoidosis. Asteroid bodies are star-shaped inclusions seen within giant cells in granulomas and are a hallmark of sarcoidosis. Incorrect Options: Options B, C, and D are incorrect.



Asteroid bodies in Multinucleated giant cell

@Neet_pg_bot

Q16: Match the following: A. Caplan's syndrome 1. Found first in coal worker B. Asbestosis 2. Crazy pavement C. Mesothelioma 3. Involves lower lobe D. Silicosis 4. Pleural effusion (Q857428)

A. A-1, B-3, C-4, D-2

B. A-2, B-4, C-1, D-3

C. A-3, B-2, C-1, D-4

D. A-4, B-1, C-2, D-3

Correct Answer: A. A-1, B-3, C-4, D-2

Explanation: A. Caplan’s syndrome It is characterised by the formation of multiple well-defined pulmonary nodules, typically located in the lung periphery, in individuals with rheumatoid arthritis who have been exposed to inorganic dust. It is primarily associated with coal worker's pneumoconiosis but can also occur in other forms of pneumoconiosis. B. Asbestosis It primarily affects the lower lobes of the lungs and increases the risk of laryngeal, ovarian, colon, lung, and pleural cancers, with lung cancer risk significantly heightened in smokers. Asbestos-related lung carcinoma typically targets the lower lobes, unlike other occupational lung diseases that affect the upper lobes. C. Mesothelioma It is a rare cancer originating from mesothelial cells, most commonly affecting the pleura. CT scan typically shows pleural thickening, effusion, or frozen hemithorax. It can also involve the peritoneum, pericardium, and tunica vaginalis. D. Silicosis It is the most prevalent occupational lung disease and is caused by inhaling proinflammatory crystalline silica. After decades of exposure, it typically presents as slowly progressing, nodular, fibrosing pneumoconiosis. The CT scan shows a "crazy pavement" pattern and interstitial fibrosis.

@Neet_pg_bot

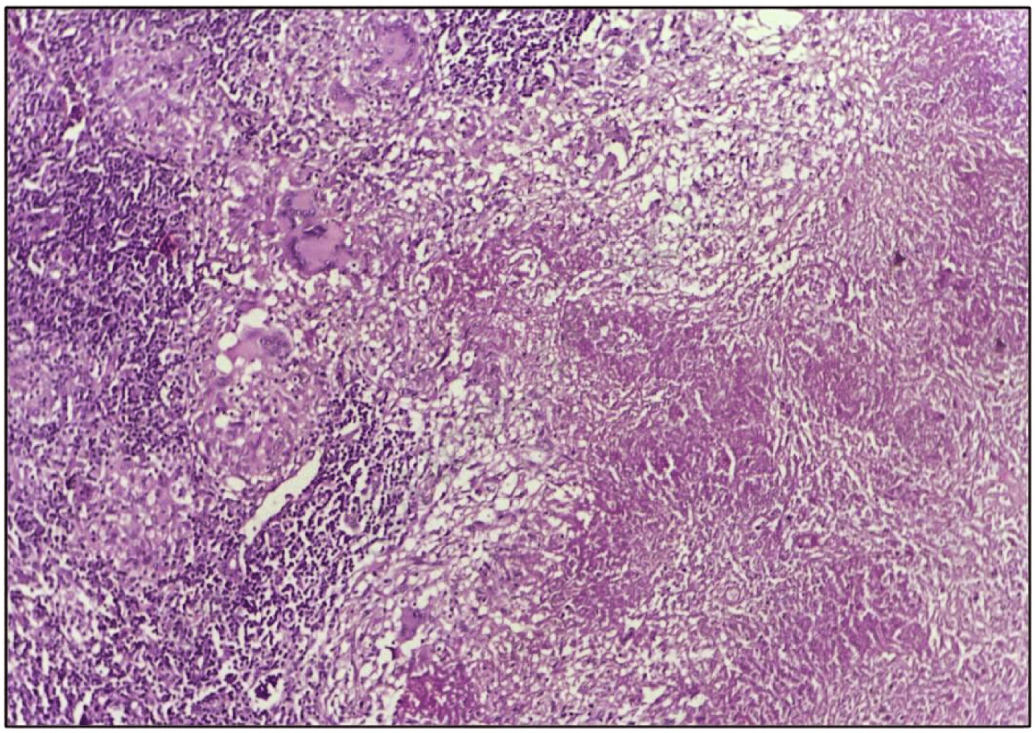
Q17: What is the most probable diagnosis based on the provided histopathology of the enlarged cervical lymph node? (Q840059)

A. Sarcoidosis

B. Tuberculosis

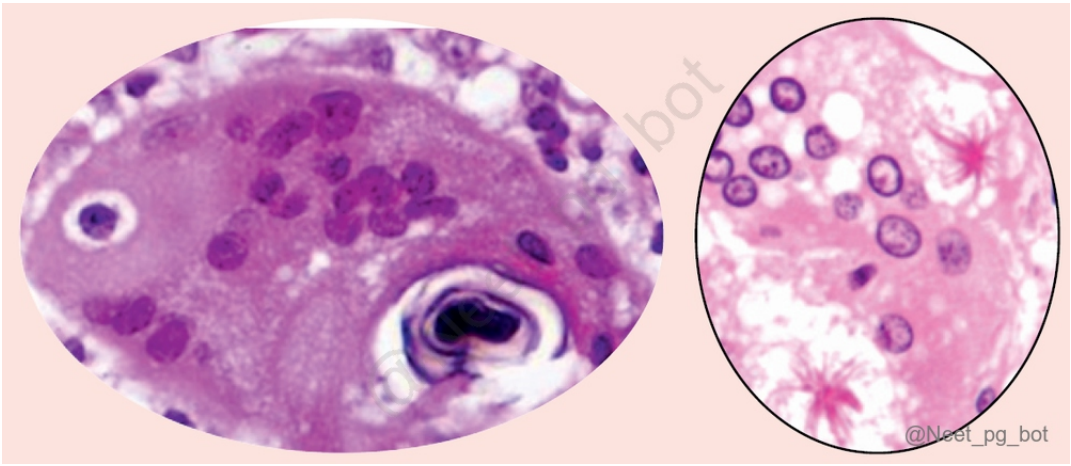
C. Histoplasmosis

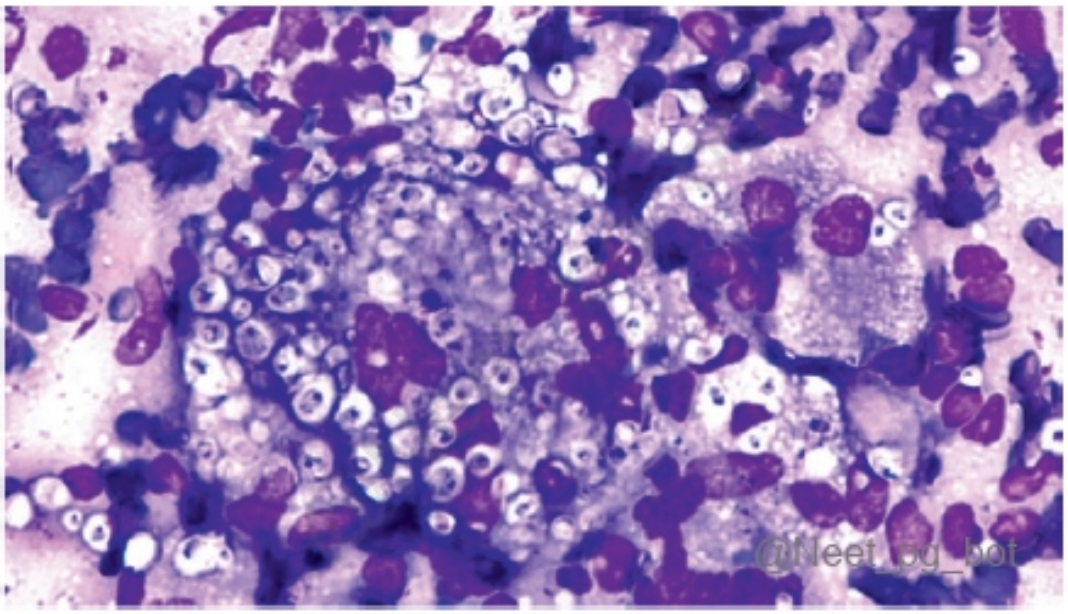
D. Brucellosis



Correct Answer: B. Tuberculosis

Explanation: The given histopathological image shows signs of chronic granulomatous inflammation, along with areas of caseous necrosis (seen as pink-colored areas) and Langerhans giant cells. All these findings are suggestive of Tuberculosis. Incorrect Options: Sarcoidosis (Option A): Sarcoidosis typically presents with non-caseating granuloma or naked granuloma (lymphocytic collar absent). Histoplasmosis (Option C): Histoplasmosis shows the presence of small Histoplasma capsulatum yeasts. Brucellosis (Option D): Brucellosis does not show caseous necrosis and Langerhans giant cells.





References:

.

@Neet_pg_bot

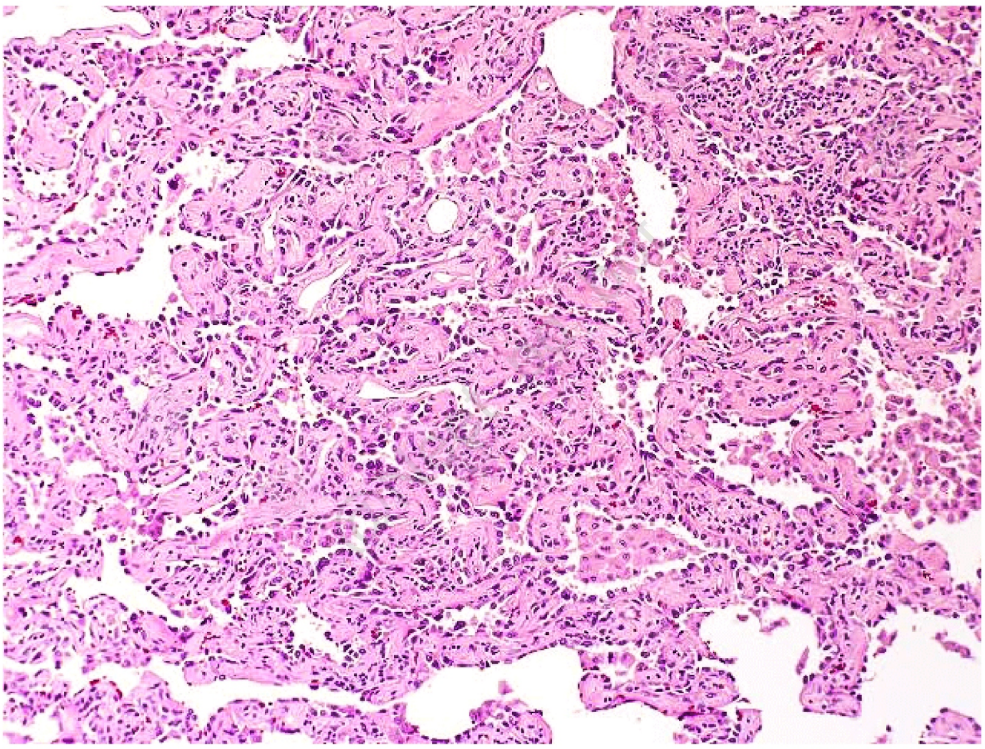
Q18: Based on the biopsy image given below, what is the most probable diagnosis? (Q840057)

A. Adenocarcinoma

B. Squamous cell carcinoma

C. Small cell carcinoma

D. Large cell carcinoma



@Neet_pg_bot

Correct Answer: A. Adenocarcinoma

Explanation: Correct Option A – Adenocarcinoma : The presence of glands in the given histopatholgy image indicates adenocarcinoma of the lung. In adenocarcinoma of the lung, neoplastic epithelial cells proliferate in a glandular pattern, forming well-differentiated tumors characterized by distinct glandular structures. Incorrect Options: Option B - Squamous cell carcinoma: The absence of keratin pearls and desmosomes in the image indicates that it does not correspond to squamous cell carcinoma. Option C - Small cell carcinoma: The image does not exhibit the salt and pepper appearance of chromatin or the Azzopardi Effect, features of small cell carcinoma. Option D - Large cell carcinoma: Large cell carcinoma is an undifferentiated tumor characterized by the presence of large nuclei.

@Neet_pg_bot

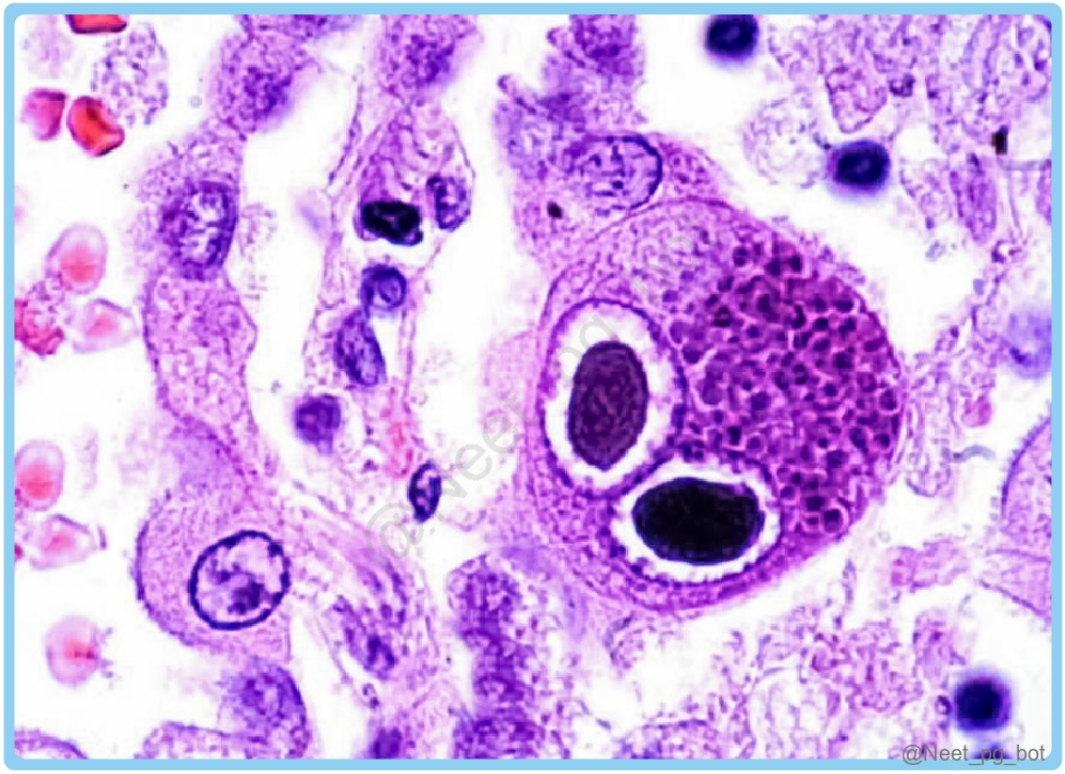
Q19: A 65-year-old patient on immunosuppressive therapy presents with a cough, fever, and pneumonia. A biopsy reveals the given findings. Which organism is responsible for the infection? (Q860561)

A. EBV

B. CMV

C. Pox virus

D. Chickenpox



Correct Answer: B. CMV

Explanation: The patient's presentation with fever and breathlessness for 2 weeks and history of HIV with owl eye appearance in the image is suggestive of CMV (cytomegalovirus) pneumonia. CMV (cytomegalovirus) Class Betaherpesvirinae subfamily of the Herpesviridae family. Modes of transmission Oral route, respiratory & body secretions (most common) Vertical transmission Sexual transmission Organ transplantation Blood transfusion Host cells Salivary gland Kidney Clinical features Congenital infection Most common intrauterine infection with congenital defects. Common presentation: Petechiae Hepatosplenomegaly Jaundice Less common presentation: Microcephaly Cerebral calcifications Intrauterine growth retardation Prematurity Other defects: Sensorineural hearing loss. Perinatal infection Commonly asymptomatic. Occasionally, premature infants present with interstitial pneumonitis. Immunocompromised This is seen in AIDS, HIV, organ transplant patients and cancer patients undergoing chemotherapy. Presentations in AIDS and HIV CMV chorioretinitis Progressive dementia, Cranial nerve defects, Presentations in Organ transplant Bilateral interstitial pneumonia Febrile leukopenia Obliterative bronchiolitis Graft atherosclerosis Rejection of renal allografts. Immunocompetent Usually, it occurs following a blood transfusion. It presents similar to infectious mononucleosis, but heterophile antibody tests would be negative. Investigations Peripheral smear: Owl’s eye appearance of inclusion bodies. {{caption_text}} Virus isolation It is done by Human fibroblast cell line culture Shell vial culture Antigen detected: PP65 Antibody detection It is done by ELISA, and the antibodies detected are CMV IgM antibodies CMV IgG antibodies Against

PP150 and PP65, Against the PP52 PCR Used in detecting CMV DNA Quantitative nucleic acid testing (QNAT) by PCR is the most sensitive and specific testing. Treatment Ganciclovir (Drug of choice) Foscarnet (in Ganciclovir resistance) CMV immunoglobulins and Ganciclovir are given to bone marrow transplant patients. EBV (Epstein Barr virus) (Option A) primarily causes infectious mononucleosis, marked by fever, sore throat, swollen lymph nodes, and fatigue, and usually does not lead to pneumonia. Downey cells, or atypical lymphocytes, are large, vacuolated, and often display a ballerina skirt appearance. {{caption_text}} Pox virus (Option C) , like smallpox (eradicated) and molluscum contagiosum , causes skin lesions such as pustules or bumps. While they don't typically cause pneumonia, they can lead to systemic infections, especially in immunocompromised individuals. Chickenpox (Option D) , caused by varicella-zoster virus (VZV), leads to a rash of red spots and blisters. In immunocompromised patients, it can cause severe complications like varicella pneumonia, though less commonly than CMV or bacterial pneumonia, and may require antiviral treatment.

@Neet_pg_bot

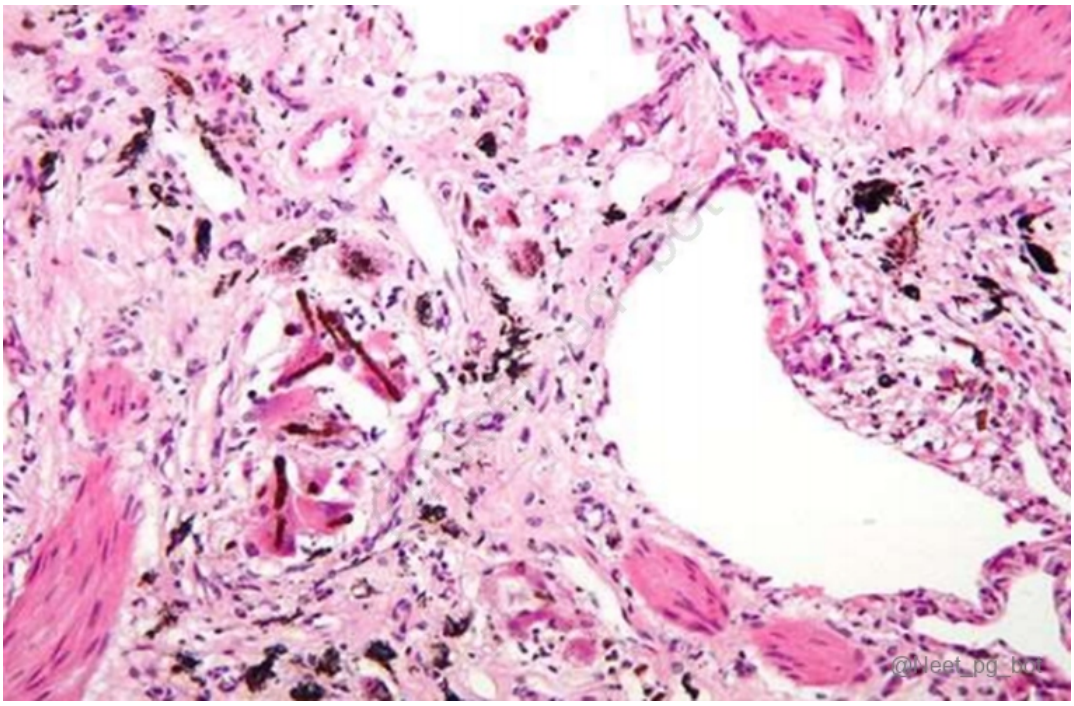
Q20: A patient presented with interstitial lung disease with an occupational history of working in a factory for 20 years and underwent a biopsy. Based on the findings, what is the most likely diagnosis? (Q844241)

A. Stanosis

B. Silicosis

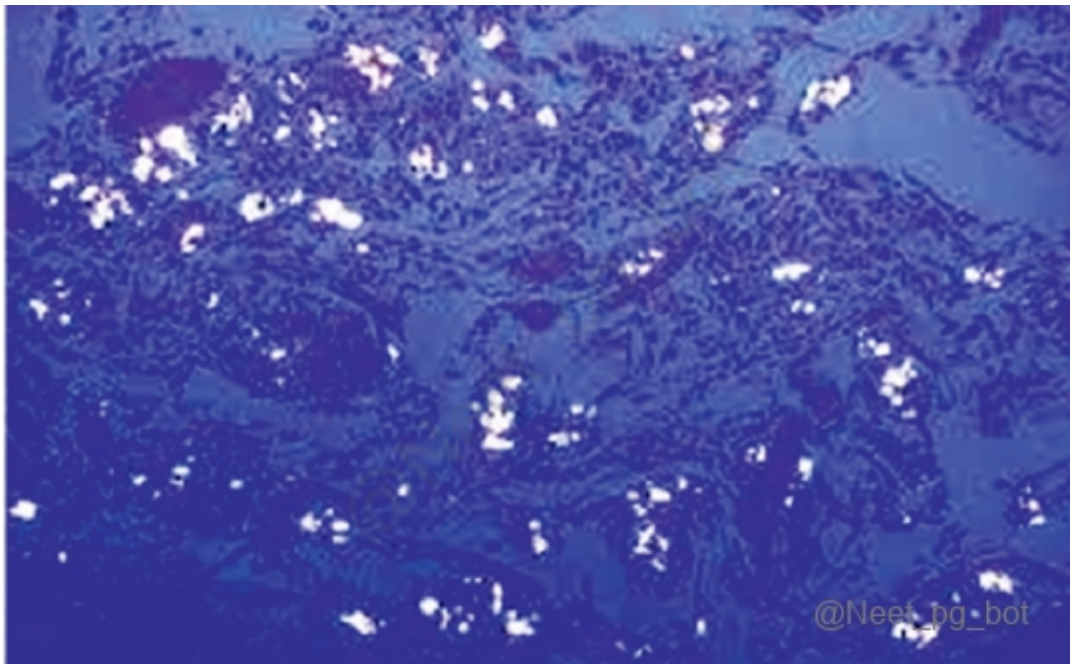
C. Byssinosis

D. Asbestosis



Correct Answer: D. Asbestosis

Explanation: Correct Option D – Asbestosis: The given image shows dumbbell-shaped asbestos bodies, which, along with the history, suggests asbestosis. Incorrect Options: Option A – Stanosis: Stanosis occurs due to tin/lead exposure. Option B – Silicosis: Silicosis will show silicon particles on polarizing microscopy. Option C – Byssinosis: Byssinosis occurs due to cotton dust/organic dust exposure, which is not mentioned in the patient's history.



↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A patient presents with respiratory distress and is diagnosed with pan-acinar emphysema. Which deficiency is responsible for his condition? (Q844156)

A. Type 1 surfactant

B. Type 2 surfactant

C. Alpha-1 antitrypsin deficiency

D. Albumin

Correct Answer: C. Alpha-1 antitrypsin deficiency

Explanation: Alpha-1 antitrypsin (A1AT) is a protease inhibitor that protects alveoli from neutrophil elastase. Deficiency of A1AT leads to unopposed elastase activity, causing destruction of alveolar walls. This manifests as pan-acinar emphysema, classically involving lower lobes of the lungs. It can present in younger patients (40s–50s), often with family history, and may be associated with liver disease. Other types of emphysema (centrilobular) are usually related to smoking, not A1AT deficiency. Incorrect Options: Option A) Type 1 surfactant – Deficiency causes neonatal respiratory distress syndrome, not emphysema. Option B) Type 2 surfactant – Also associated with alveolar collapse in neonates, causes neonatal respiratory distress syndrome, not emphysema. Option D) Albumin – Low albumin causes edema, not emphysematous changes.

@Neet_pg_bot

Q22: A male patient is diagnosed with ARDS and is not responding to oxygen therapy. What is the role of IL-8 in ARDS? (Q844145)

A. Endothelial cell activation

B. Neutrophil recruitment

C. Macrophage activation

D. Promotion of surfactant production

Correct Answer: B. Neutrophil recruitment

Explanation: Correct Option B - Neutrophil recruitment: Interleukin-8 (IL-8) is a potent chemokine that plays a significant role in the inflammatory response in Acute Respiratory Distress Syndrome (ARDS). Its primary function is to recruit neutrophils to the site of inflammation in the lungs. Once recruited, neutrophils release enzymes and reactive oxygen species that contribute to lung tissue damage, a hallmark of ARDS. Incorrect Options: Options A, C, and D are not influenced by IL-8.

↑ *Back to this question in Part A*

@Neet_pg_bot

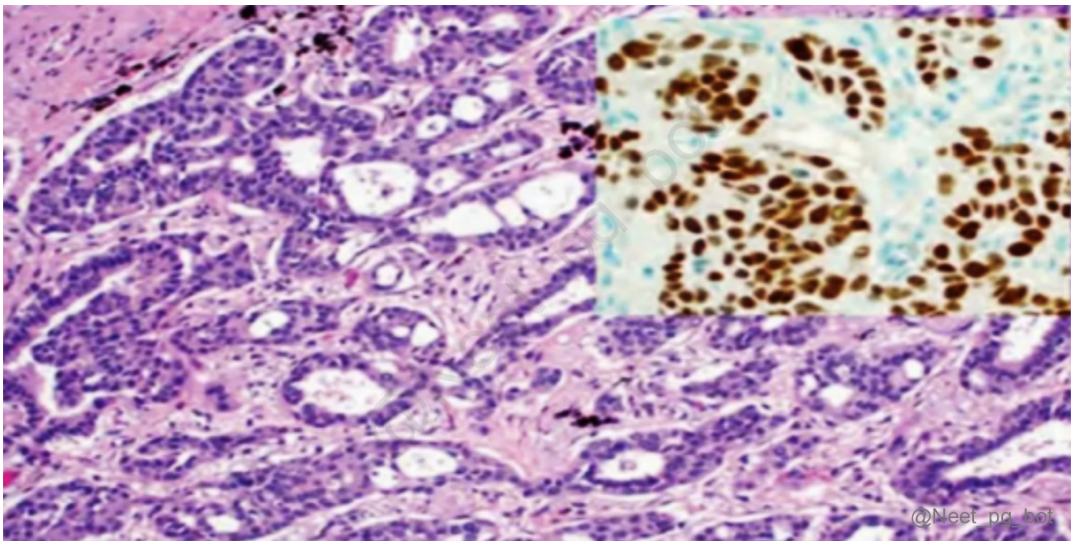
Q23: TTF-1 immunohistochemical marker is associated with which of the following cancers? (Q844039)

A. Squamous cell carcinoma

B. Lung adenocarcinoma

C. Small cell carcinoma

D. Large cell carcinoma



Correct Answer: B. Lung adenocarcinoma

Explanation: Correct Option B - Lung adenocarcinoma: TTF-1 is an immunohistochemical marker for lung adenocarcinoma. Incorrect Options: Options A, C, and D: TTF -1 is not an immunohistochemical marker for these tumors.

References:

.

@Neet_pg_bot

Q24: A 40-year-old female patient presents with skin lesions, respiratory symptoms, and enlarged lymph nodes. Skin lesions appear as raised, erythematous nodules, and a chest X-ray shows bilateral hilar lymphadenopathy. A biopsy of the affected tissues is performed. Microscopic examination reveals the presence of granulomas without central necrosis. What is the most likely histological finding in this scenario? (Q820587)

A. Caseating granuloma

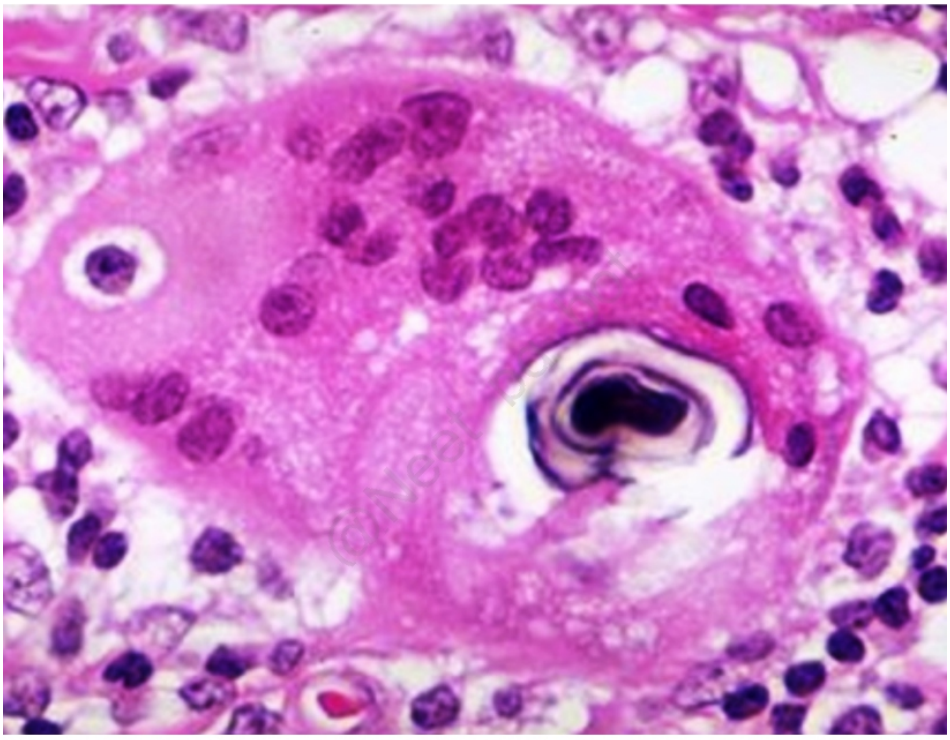
B. Stellate granuloma

C. Non-caseating granuloma

D. Eosinophilic granuloma

Correct Answer: C. Non-caseating granuloma

Explanation: Correct Option C - Non-caseating granuloma: . The patient's presentation with raised erythematous nodules and a chest X-ray shows bilateral hilar lymphadenopathy is suggestive of sarcoidosis. Sarcoidosis is associated with non-caseating granulomas with Schaumann bodies. Incorrect Options: Options A, B, and D are incorrect.



Schaumann bodies in Multinucleated giant cell

@Neet_pg_bot

Q25: Which malignancy is most commonly associated with asbestosis? (Q857561)

A. Mesothelioma

B. Anthracosis

C. Hepatocellular carcinoma

D. Renal cell carcinoma

Correct Answer: A. Mesothelioma

Explanation: Asbestosis, a pneumoconiosis caused by asbestos inhalation, is strongly associated with mesothelioma, a malignancy of the pleura or peritoneum. Asbestos exposure also increases the risk of lung, laryngeal, ovarian, colon, and pleural cancers. Smoking significantly amplifies the risk of asbestos-related lung carcinoma, making asbestos workers, especially smokers, more likely to die from lung cancer than mesothelioma.

{{caption_text}} {{caption_text}} Compared to other occupational lung diseases, which affect the upper lobes of the lungs, it commonly affects the lower lobes. Adenocarcinoma (primary bronchogenic carcinoma) is the most common type of cancer, accounting for about 45%, followed by squamous cell carcinoma. Lung mesothelioma is a more specific tumour associated with asbestos exposure. It is common but is less prevalent than Adenocarcinoma. {{caption_text}} Anthracosis (Option B) , associated with bronchial arthrofibrosis (BAF), is a condition characterised by the black staining of the bronchial mucosa, which can obstruct the bronchial lumen. It typically manifests in elderly non-smokers, either male or female, with a chronic course of symptoms like dyspnea and/or cough. It occurs due to the accumulation of carbon, silica, and quartz particles in macrophages, mucosa, and submucosa, leading to anthracosis. {{caption_text}} Hepatocellular carcinoma (HCC) (Option C) is the most common form of primary liver cancer. It typically develops in individuals with chronic liver diseases such as cirrhosis, which can be caused by chronic Hepatitis B or C infection. Other causes of cirrhosis include alcohol abuse, autoimmune diseases, chronic liver inflammation, and iron overload (hemochromatosis). HCC arises from long-term liver damage and scarring. Renal cell carcinoma (RCC) (Option D) is the most common type, accounting for approximately 90–95% of adult kidney cancers. It originates in the lining of the proximal convoluted tubules (PCTs). Symptoms of RCC include blood in the urine, flank pain, abdominal mass, weight loss, fever, high blood pressure, night sweats, and malaise. When RCC metastasises, it commonly spreads to the lymph nodes, lungs, liver, adrenal glands, brain, or bones.

« Back to Folder Directory

[08_Salivary Glands] 037 Salivary Gland Pathology — Quick Jump

Q1 (p. 1874) *Q2 (p. 1875)* *Q3 (p. 1878)* *Q4 (p. 1879)* *Q5 (p. 1880)* *Q6 (p. 1881)*
Q7 (p. 1882) *Q8 (p. 1884)*

Q1: A 28-year-old female presents with a painless, bluish, fluctuant and translucent swelling on the lower lip that enlarges with eating or pressure, as shown in the image below. She reports a history of accidentally biting her lip frequently. What histopathological feature would be expected on biopsy of the lesion? (Q845534)

A. Mucin-filled cavity surroundedby granulation tissue and chronic inflammatory cells.

B. Proliferation of ductal cells within fibrous connective tissue

C. Epithelial dysplasia and atypical cells.

D. Eosinophilic granuloma with multinucleated giant cells

Correct Answer: A. Mucin-filled cavity surroundedby granulation tissue and chronic inflammatory cells.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and the image suggest Mucocele, a benign cystic lesion caused by the accumulation of saliva due to trauma or obstruction of the salivary gland duct. Histologically, it is characterized by a mucin-filled cavity without an epithelial lining (in the extravasation type), surrounded by granulation tissue and chronic inflammatory cells , especially macrophages (mucinophages). Mucin-filled cavity incites an inflammatory response, and for the repair of this, the body will start making granulation tissue. A mucocele is an extravasation cyst : Due to excessive lip biting or any trauma, accumulation of lots of saliva and mucus occurs, resulting in a cystic lesion. It does not have any ductal epithelium or ductal lining. A t rue cyst lined by ductal epithelium. Treatment: Cryotherapy Laser Treatment Surgical Excision: Removal of the cyst Ranula: A ranula is a mucous extravasation cyst occurring in the floor of the mouth due to leakage of saliva from the Sublingual gland. It is the most common cystic swelling of the floor of the mouth and is not a true cyst because it lacks an epithelial lining. Usually arises from: Sublingual gland (most common) Rarely from minor salivary glands Clinical Features: ■■■ Soft, fluctuant swelling in the floor of the mouth Located lateral to the midline Bluish and translucent in appearance Usually painless As it enlarges, it may cause: Difficulty in speech Interference with chewing Elevation of the tongue It typically lies above the Mylohyoid muscle , confined to the oral cavity. Diagnosis: Ultrasound or MRI is used if deeper extension is suspected. Aspiration reveals thick, mucinous fluid with high amylase content. Management: Simple drainage has a high recurrence rate. Marsupialization may be attempted but often recurs. Definitive treatment is excision of the sublingual gland , because the gland is the source of mucus leakage. Plunging Ranula: A plunging ranula is a deeper extension of a ranula into the neck. Instead of remaining confined above the mylohyoid muscle, the mucus dissects through a defect or passes around the posterior border of the Mylohyoid muscle and enters the submandibular space. Pathophysiology: The mylohyoid muscle normally forms a diaphragm separating the oral cavity from the neck. If there is: A congenital defect A dehiscence Or posterior free border passage Mucus from the sublingual gland tracks downward into the neck, producing a swelling in the submandibular region. Clinical Presentation: Plunging ranula typically presents as: A painless, soft swelling in the upper neck Located in the submandibular region Usually without skin discoloration MRI may show the “tail sign” , which indicates communication with the sublingual space.

@Neet_pg_bot

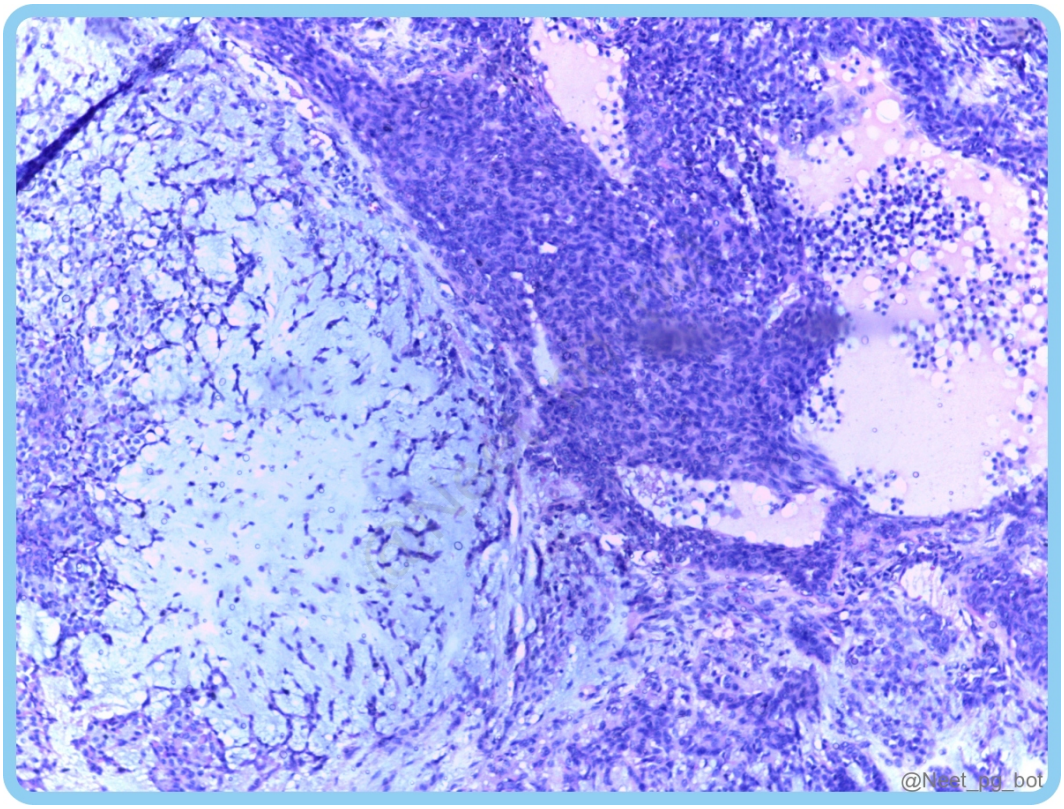
Q3: A 45-year-old female presents with a painless, slowly growing mass in her left parotid gland. Examination reveals a firm, mobile mass. Biopsy confirms pleomorphic adenoma with characteristic islands of cartilage and foci of bone in a myxoid stroma. Which of the following is incorrect regarding this condition? (Q845536)

A. Mostly found in the parotid gland

B. Mixed tumours with ductal, myoepithelial and mesenchymal cells

C. Radiation exposure is a risk factor

D. Down-regulation of PLAG1 results in abnormal cell proliferation



Correct Answer: D. Down-regulation of PLAG1 results in abnormal cell proliferation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Pleomorphic adenoma is a benign mixed tumor predominantly of the parotid gland and is commonly seen in females. It contains both epithelial (ductal and myoepithelial) and mesenchymal components (myxoid, chondroid, and osseous tissue). Radiation exposure is a known risk factor for salivary gland tumors, including pleomorphic adenoma. The PLAG1 (PLAG= Pleomorphic Adenoma Gene) gene is an oncogene, and up-regulation or overexpression (not down-regulation) of PLAG1 leads to abnormal cell proliferation and tumorigenesis in pleomorphic adenoma.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 748

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 55-year-old male has a painless, slowly enlarging mass in the left parotid gland over several years. Examination reveals a firm, mobile, non-tender mass. Histological findings confirm pleomorphic adenoma. Which factor is associated with an increased risk of malignant transformation in pleomorphic adenomas? (Q845537)

A. Younger age of the patient

B. Larger size of the tumour

C. Increased age of the lesion

D. Presence of hyalinized stroma within the tumour

Correct Answer: C. Increased age of the lesion

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Rates of malignant transformation in pleomorphic adenoma correlate with the age of the lesion When the age of pleomorphic adenoma's lesion exceeds 15-20 years, the chances of malignant transformations increase: Carcinoma ex pleomorphic adenoma (Carcinoma has originated inside a pre-existing pleomorphic adenoma). Pleomorphic adenoma It is a benign mixed tumor Most common salivary gland tumor and most commonly occurs in the parotid. Mostly seen in females. On FNAC or biopsy: It shows epithelial and mesenchymal cells (mixed tumor) Epithelial components: Epithelia, myoepithelial and ductal cells Mesenchymal tissue comprise of chondromyxoid stroma

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 748

↑ *Back to this question in Part A*

@Neet_pg_bot

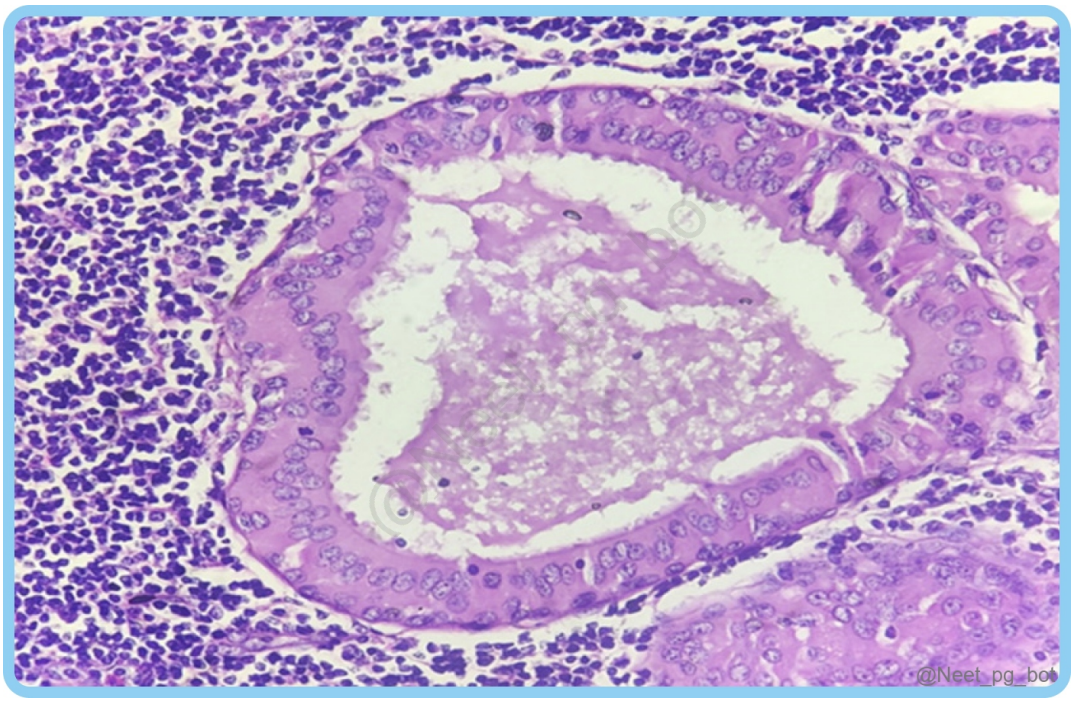
Q5: A 50-year-old male smoker presents with a painless swelling in the parotid region. Fine needle aspiration cytology (FNAC) reveals murky fluid. Which of the following histopathological features is true regarding this condition? (Q845538)

A. Proliferation of squamous epithelial cells with keratinisation

B. Oncocytic cells with double-layered lining

C. Neuroendocrine differentiation

D. Papillary architecture with psammoma bodies



Correct Answer: B. Oncocytic cells with double-layered lining

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation (history of chronic smoking) and histopathological image (Murky fluid on FNAC) suggest a Warthin tumour or Papillary cystadenoma lymphomatosum , a benign salivary gland tumour that typically occurs in the parotid gland. On histopathology i t is characterised by : Pink coloured oncocytic cells, which are double-layered. Deep blue coloured lymphocytes. Papillary cystadenoma lymphomatosum: Papillary: Shows papillary projections Cyst: Cyst which is filled with murky fluid which is aspirated on FNAC. Adenoma: Because it is a benign tumor Lymphomatosum: It contains significant lymphoid components. It is seen in chronic smokers and commonly involves bilateral parotid glands. This characteristic appearance is often referred to as "Cystic oncocytic hyperplasia." ■■■■■■■Proliferation of squamous epithelial cells with keratinisation (Option A): Seen in pleomorphic adenoma

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 749 - 750

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which of the following statements about Warthin's tumour is true? (Q845539)

A. It is the most common malignant tumour of the salivary glands.

B. They are typically located in the parotid gland.

C. It is more common in females.

D. Associated with human papillomavirus (HPV) infection.

Correct Answer: B. They are typically located in the parotid gland.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Warthin tumour or Papillary cystadenoma lymphomatosum is a benign salivary gland tumour primarily affecting the parotid gland. It is more common in males and is strongly associated with a history of smoking. Parotid involvement can be bilateral. On FNAC, Murky fluid is aspirated. Histopathological features: Shows papillary projections It is a benign tumour with cyst formation. Cells: Double-layered pink-coloured oncocytic cells and a lot of lymphocytic infiltrates. It is the most common malignant tumour of the salivary glands (Option A): Warthin tumour is a benign tumour It is more common in females (Option C): It is more common in males, especially with a history of smoking. Associated with human papillomavirus (HPV) infection (Option D): It is associated with heavy chronic smoking.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 751

↑ *Back to this question in Part A*

@Neet_pg_bot

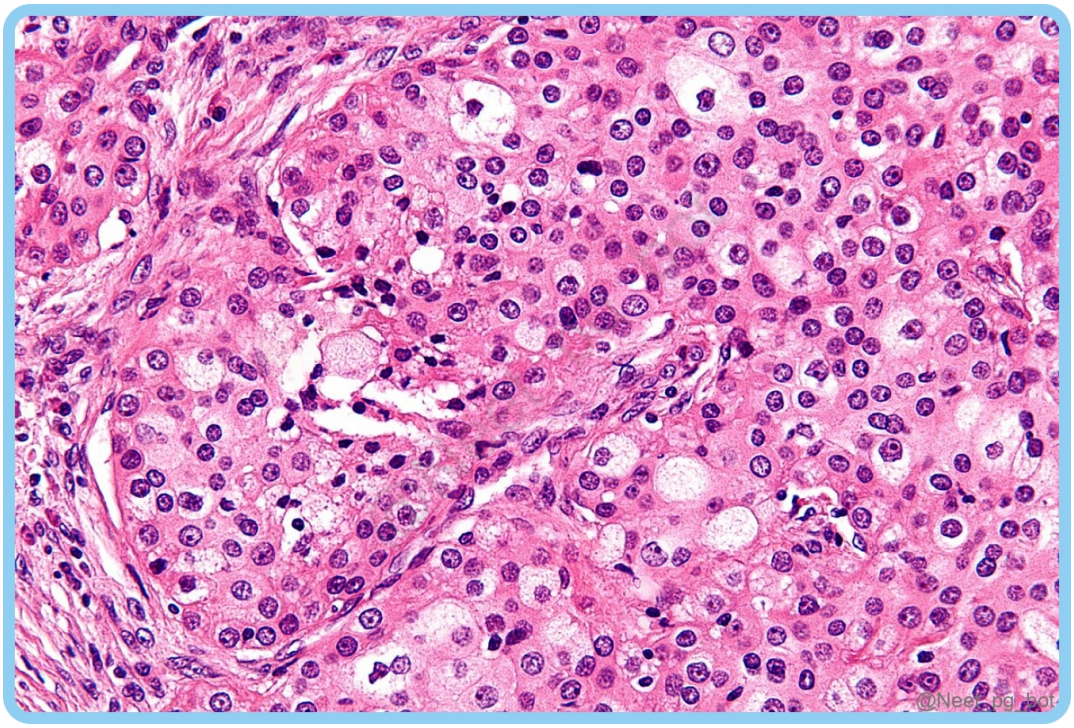
Q7: A 45-year-old female presents with a slow-growing painless mass in the left submandibular gland region. Imaging studies reveal a solid lesion with cystic components. Fine needle aspiration cytology (FNAC) shows a mixture of mucin-producing, epidermoid, and intermediate cells. A histopathology image is given below. Which of the following features is true regarding this condition? (Q845540)

A. Most commonly found in the sublingual salivary glands.

B. Most are associated with a (11;19) translocation.

C. Encapsulated tumours.

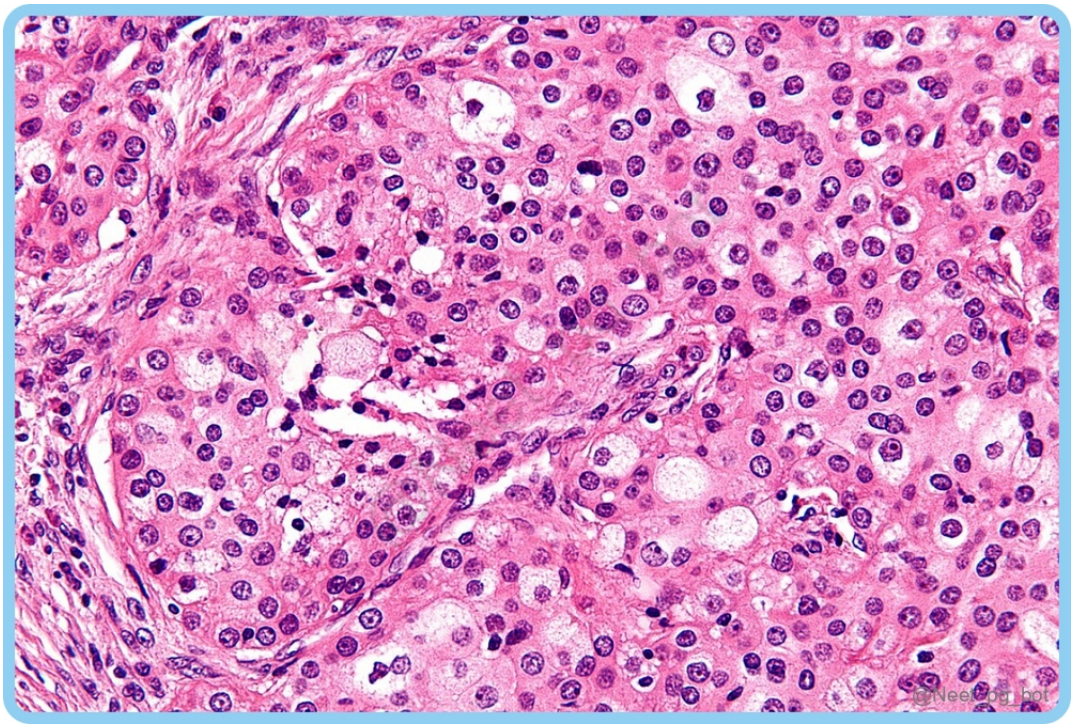
D. Histologically characterized by the presence of spindle cells



Correct Answer: B. Most are associated with a (11;19) translocation.

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Mucoepidermoid carcinoma (MEC): It is the most common malignant tumour of salivary glands, often found in parotid and submandibular glands. (Option A) It does not have a capsule (Option C) It is associated with the (11;19) chromosomal translocation, creating CRTC1-MAML2 fusion protein. Histologically, it exhibits squamous and mucous cell features. (Option D) There are 3 types of cells in Mucoepidermoid carcinoma: Mucus-producing cells Epidermoid or Squamoid cells Intermediate cells. Grading: Low grade MEC: If mucus component is predominant. High grade MEC: If epidermoid or squamoid component is predominant. Image: Low-power view showing sheets and micro cysts containing cells of varying morphologies in Mucoepidermoid Carcinoma.



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 751.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 55-year-old male presents with a slowly enlarging painless mass in the right parotid gland region. Imaging studies reveal a solid tumour with a characteristic "Swiss cheese" appearance on MRI. Fine needle aspiration cytology (FNAC) shows basaloid cells with cribriform and tubular patterns. Which of the following statements is true regarding this condition? (Q845541)

A. Most commonly occur in the parotid and submandibular glands.

B. MYB-NFIB gene rearrangements are present in all cases

C. Encapsulated lesions with a smooth surface.

D. Tend to grow rapidly and have a high mitotic rate.

Correct Answer: A. Most commonly occur in the parotid and submandibular glands.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and characteristic ‘Swiss cheese’ appearance on MRI with basaloid cells and cribriform pattern on FNAC suggest Adenoid cystic carcinoma, which most commonly affects parotid and submandibular glands. Cribriform pattern in a salivary gland tumor always tells us about Adenoid Cystic Carcinoma. MYB-NFIB gene rearrangements are present in all cases (Option B): MYB-NFIB gene rearrangements are present in a subset of adenoid cystic carcinomas and not in all cases. Encapsulated lesions with a smooth surface (Option C): It is poorly capsulated Tend to grow rapidly and have a high mitotic rate (Option D): Adenoid cystic carcinomas are slow-growing tumours that tend to invade perineural spaces (therefore painful lesions), indicating a low mitotic rate. Image: Three typical growth patterns, including cribriform (left), tubular (center), and solid (right).

« Back to Folder Directory

[08_Salivary Glands] 038 Previous Year Questions — Quick Jump

Q1 (p. 1886) *Q2 (p. 1887)* *Q3 (p. 1887)*

Q1: A middle-aged woman presents with dry eyes and dry mouth. Laboratory tests reveal positive anti-Ro (SSA) and anti-La (SSB) antibodies. What is the most likely underlying pathological mechanism? (Q866381)

A. Destruction of exocrine glands by neutrophils

B. IgE-mediated hypersensitivity reaction

C. Lymphocytic infiltration and destruction of salivary and lacrimal glands

D. Deposition of amyloid in salivary glands

Correct Answer: C. Lymphocytic infiltration and destruction of salivary and lacrimal glands

Explanation: This presentation is classic for Sjögren’s syndrome , an autoimmune disorder characterised by chronic lymphocytic infiltration of the salivary and lacrimal glands, leading to xerostomia (dry mouth) and keratoconjunctivitis sicca (dry eyes). The condition is most common in middle-aged women and is associated with anti-Ro (SSA) and anti-La (SSB) autoantibodies. Pathophysiology Epithelial cells aS active players. Salivary/lacrimal epithelial cells (the target tissue) can act like antigen-presenting cells under stress or after viral/other triggers. They upregulate type I interferons, express costimulatory molecules and release chemokines that recruit lymphocytes. Autoantigen exposure. Apoptosis or other epithelial injury exposes intracellular ribonucleoproteins (Ro/SSA, La/SSB) to the immune system, promoting an autoimmune response. T-cell-driven inflammation. Early lesions are dominated by CD4■ T cells that home to the glands and cause inflammation and cytokine release (TH1/TH17 pathways are implicated). B-cell activation & ectopic germinal centres. Chronic inflammation induces local B-cell activation, formation of ectopic germinal–centre–like structures within glands, and production of autoantibodies (anti-Ro/SSA, anti-La/SSB, rheumatoid factor). Elevated BAFF (B-cell activating factor) supports B-cell survival. Structural loss of secretory tissue. Progressive acinar atrophy, ductal dilation and replacement by lymphoid infiltrates/fibrosis → functional loss of saliva and tears. Incorrect Options: Destruction of exocrine glands by neutrophils (Option A): is more typical of suppurative infections, not autoimmune Sjögren’s. IgE-mediated hypersensitivity reaction (Option B): occurs in allergies and anaphylaxis, not in this chronic autoimmune process. Deposition of amyloid in salivary glands (Option D): can occur in systemic amyloidosis, but is not the main mechanism in Sjögren’s syndrome.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Warthin's tumor is also called? (Q820513)

A. Adenolymphoma

B. Pleomorphic adenoma

C. Mucoepidermoid carcinoma

D. Acinic cell carcinoma

Correct Answer: A. Adenolymphoma

Explanation: Correct Option A - Adenolymphoma: Warthin's tumor is also known as adenolymphoma. It's a benign tumor that most commonly occurs in the parotid gland, which is a salivary gland located in the cheek. It's characterized by its unique histological appearance, with cystic spaces and papillary projections lined by double-layered oncocytic epithelial cells and lymphoid stroma. Incorrect Options: Option B - Pleomorphic Adenoma: Pleomorphic adenoma is another type of salivary gland tumor. It is the most common type of salivary gland tumor, but it is distinct from Warthin's tumor. Pleomorphic adenoma is characterized by a mixture of epithelial and myoepithelial cells in a chondromyxoid stroma. Option C - Mucoepidermoid Carcinoma: Mucoepidermoid carcinoma is a malignant salivary gland tumor. It is not synonymous with Warthin's tumor. Mucoepidermoid carcinoma is characterized by a combination of mucous-secreting, epidermoid (squamous), and intermediate cells. It is one of the most common malignant salivary gland tumors. Option D - Acinic Cell Carcinoma: Acinic cell carcinoma is another type of malignant salivary gland tumor. It is characterized by the presence of acinar cells, which produce serous (watery) secretions. It is not the same as Warthin's tumor.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following features is not observed in pleomorphic adenoma? (Q855079)

A. Myoepithelial cells

B. Keratin pearls

C. Chondroid differentiation

D. Perineural invasion

Correct Answer: D. Perineural invasion

Explanation: Perineural invasion is not observed in pleomorphic adenoma, as it is a benign tumour. Perineural invasion occurs in carcinoma ex pleomorphic adenoma , a malignant transformation of pleomorphic adenoma. Pleomorphic Adenoma: Most common salivary gland neoplasm : Represents ~60% of parotid tumours, less common in submandibular and minor salivary glands. Benign tumour : Composed of ductal (epithelial) , myoepithelial , and mesenchymal cells (also called mixed tumour). Risk factors : Radiation exposure increases risk. Chromosomal rearrangements, including overexpression of PLAG1 and mutations in HMGA2 , are commonly associated. Clinical presentation : Painless, slow-growing, mobile, discrete masses, usually in the parotid, submandibular, or buccal cavity. Recurrence : 4% recurrence rate after parotidectomy; 25% after simple enucleation due to tumour extension beyond the capsule. Malignant transformation : Occurs more often with the age of the lesion. 2% of tumours present <5 years develop malignancy; 10% present >15 years develop malignancy, usually adenocarcinomas or undifferentiated carcinomas. Aggressive cancers : If malignant transformation occurs, cancers are highly infiltrative, with a 30-50% mortality rate at 5 years. Morphology: Size : Typically rounded, well-demarcated masses <6 cm. Histological features : Heterogeneous morphology with ductal, acinar, tubule-like structures, and myoepithelial cells (Option A) . Background of myxoid, hyaline, and chondroid stroma (Option C) (cartilage-like areas). Rare bone foci. No significant epithelial dysplasia or mitotic activity. Tumour behaviour : Similar clinical course regardless of whether epithelial or mesenchymal elements dominate. Keratin pearls (Option B) : While rare, keratin pearls can occasionally be observed in pleomorphic adenoma, especially when there is squamous metaplasia within the tumour.

@Neet_pg_bot

Q2: A 58-year-old male presents with chronic heartburn and regurgitation. Upper endoscopy reveals the presence of Barrett's esophagus. What is the primary cellular change seen in this condition? (Q845637)

A. Metaplasia of squamous epithelium

B. Dysplasia of squamous epithelium

C. Hyperplasia of columnar epithelium

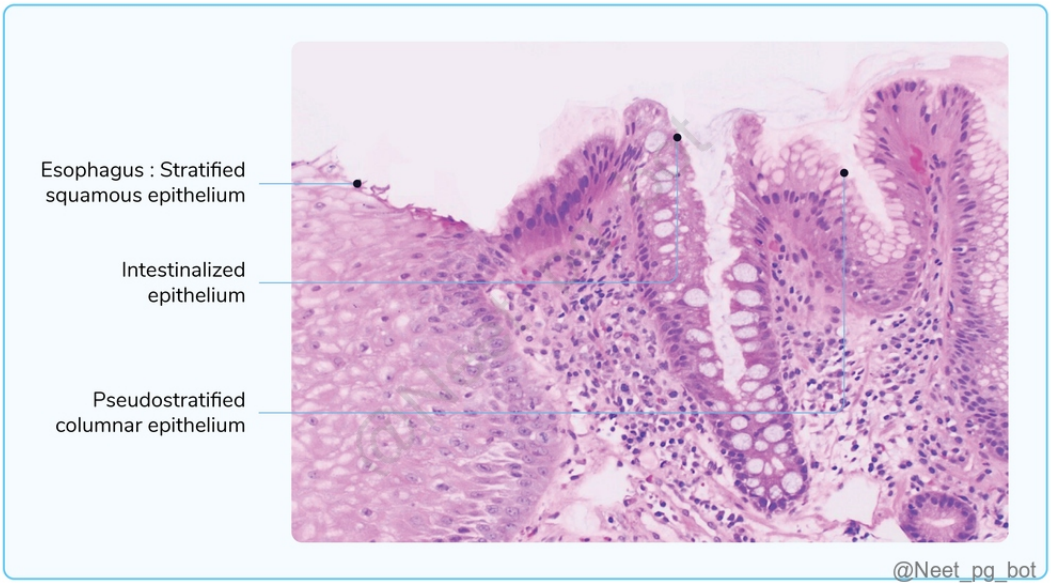
D. Hypertrophy of columnar epithelium

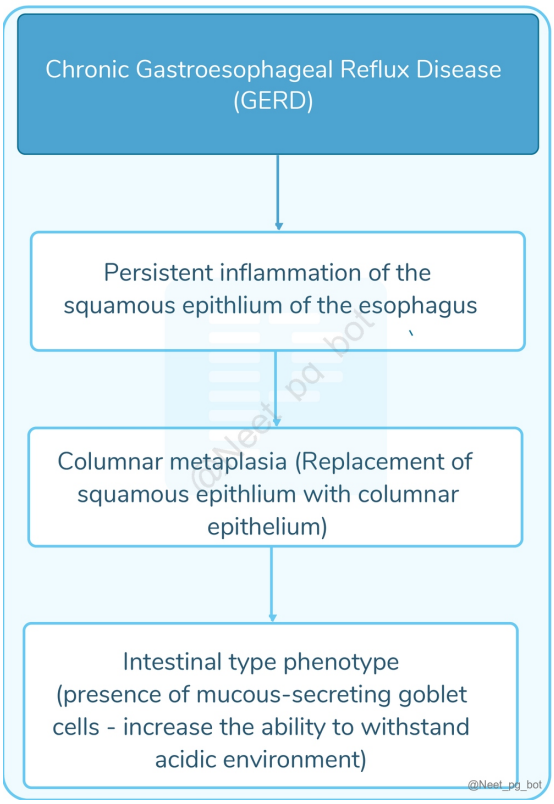
Correct Answer: A. Metaplasia of squamous epithelium

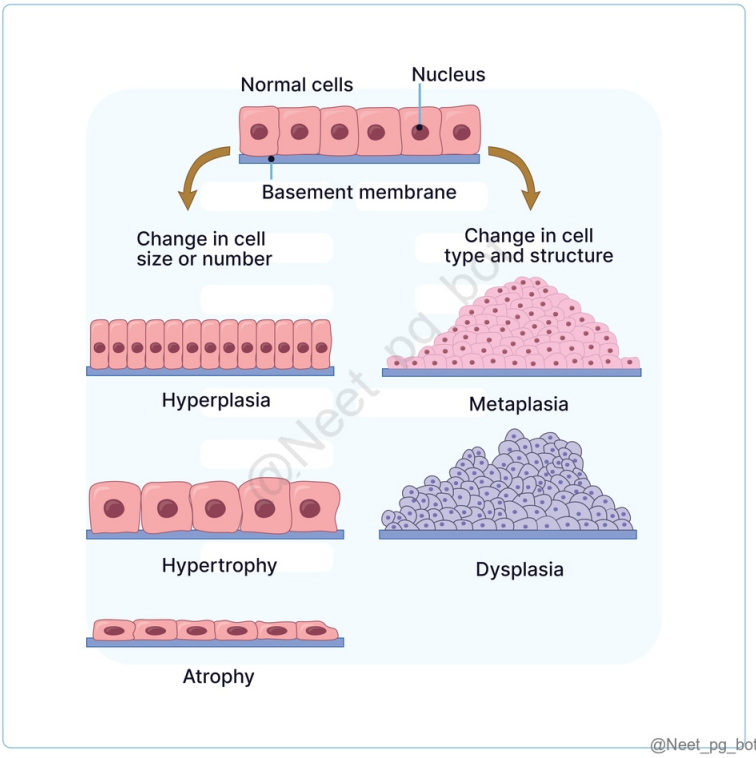
Listen (English)

Listen (Hindi)

Explanation: The primary cellular change seen in Barrett's oesophagus is metaplasia of squamous epithelium into intestinal columnar epithelium because of acid reflux/GERD. Intestinal columnar epithelium has goblet cells , which are filled with acidic mucin. Acidic mucin is stained by the Alcian blue stain . Metaplasia is 100% reversible. So this metaplasia can be reversed if GERD is controlled with the help of drugs. If GERD is not controlled, then it can lead to adenocarcinoma of esophagus.







References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page no: 762, 272

↑ *Back to this question in Part A*

@Neet_pg_bot

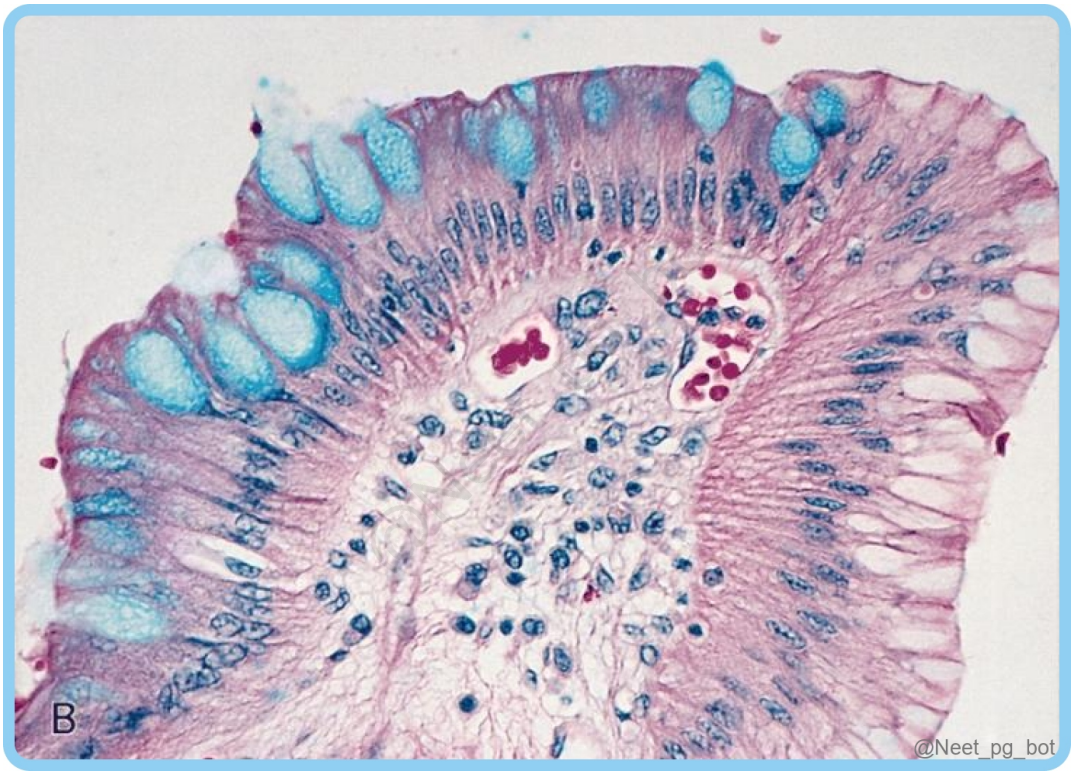
Q3: A 50-year-old male presents with chronic heartburn for two years. An endoscopy is performed, and the biopsy of the esophageal specimen stained with special stain is shown below. Which of the following conditions is the patient at an increased risk of? (Q845640)

A. Squamous cell carcinoma

B. Adenocarcinoma

C. Plummer Vinson syndrome

D. MALToma



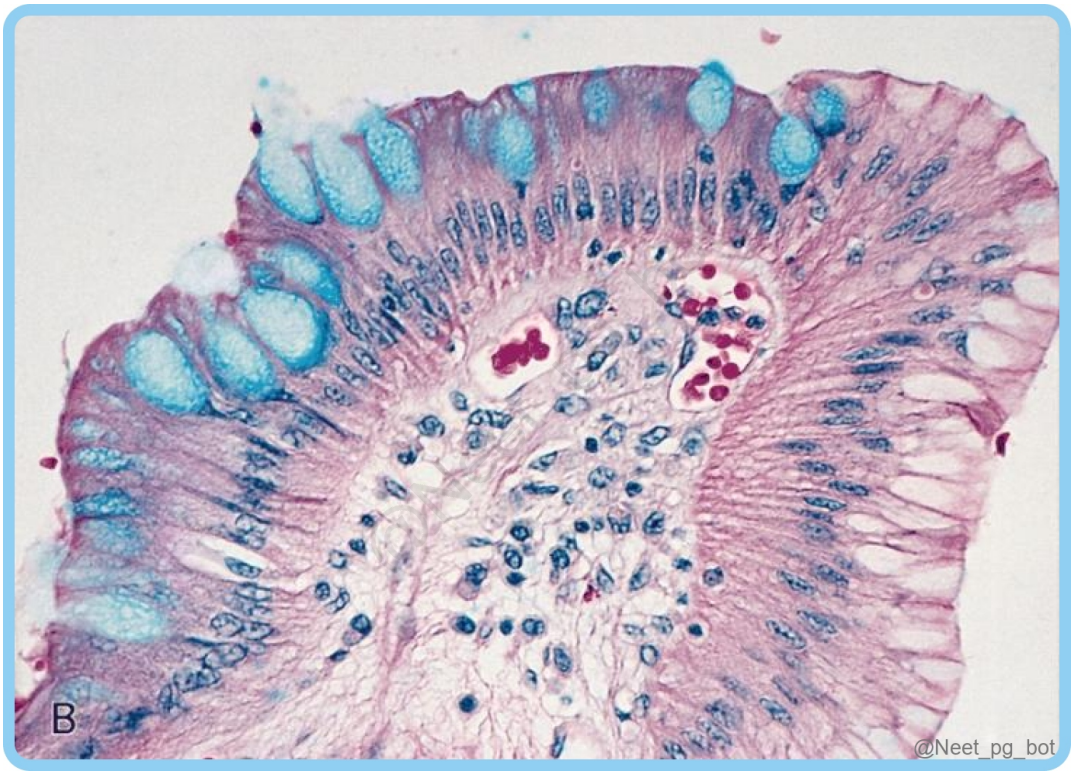
Correct Answer: B. Adenocarcinoma

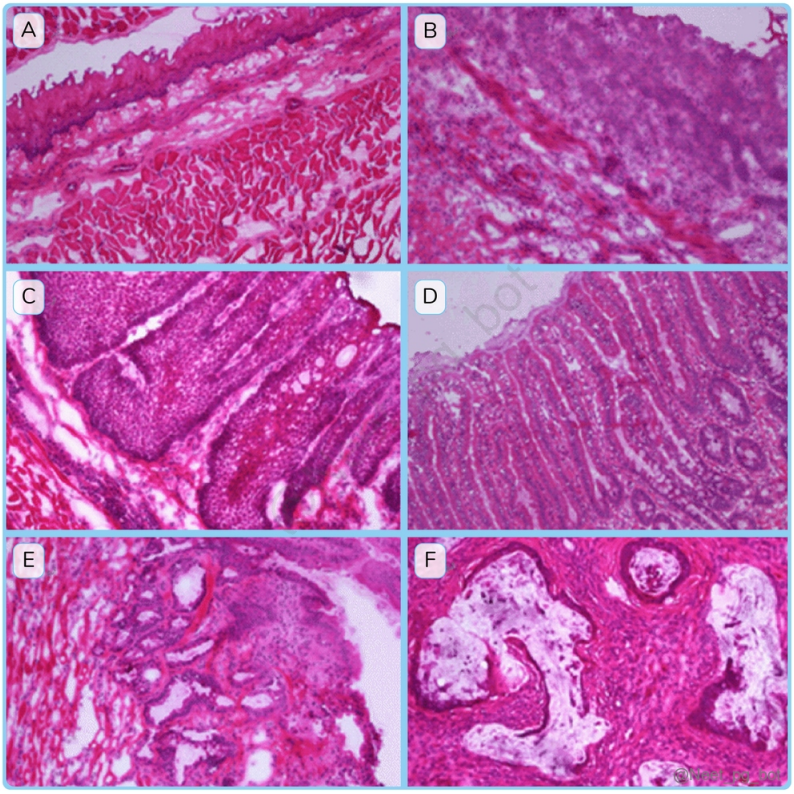
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above scenario and an image showing goblet cells within the columnar epithelium suggest Barret's esophagus, which puts the patient at an increased risk of adenocarcinoma of the esophagus .

Microscopically, the squamous layer is replaced with intestinal-type metaplasia containing goblet cells. Goblet cells are diagnostic of Barrett esophagus and have distinct mucous vacuoles that stain blue with Alcian blue . Esophageal disease progression: A: Normal esophagus; B: Esophagitis; C: BE with goblet cells; D: Dysplasia; E: EAC. EAC: Esophageal adenocarcinoma; BE: Barrett's esophagus. Squamous Cell Carcinoma and Adenocarcinoma: Feature Squamous Cell Carcinoma (SqCC) Adenocarcinoma (Adeno) Cell of Origin Stratified squamous epithelium Glandular cells (metaplastic columnar) Primary Location Mid to Upper 1/3 of the esophagus Distal (Lower) 1/3 and GE junction Major Risk Factors Alcohol, Tobacco, Hot liquids, Poor nutrition GERD, Obesity, Tobacco, Barrett's Esophagus Global Prevalence Most common worldwide (90% of cases) Rising in Western/Developed countries Demographics Associated with lower SES; more common in Black populations (US) More common in White males; associated with higher SES Precursor Lesion Squamous dysplasia Barrett’s Esophagus Molecular Profile Similar to Head & Neck SCC Similar to Gastric/Chromosomal Instability (CIN) Chemosensitivity Generally more sensitive to radiation Often less responsive to chemoradiation alone Surgical Approach Frequently requires cervical anastomosis Usually Ivor-Lewis (intrathoracic anastomosis)





References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 761-763, 767.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A woman presented with dysphagia to solids for a month. On examination, there are multiple lesions on the lips. An endoscopy reveals obstructive lesions in the upper oesophagus. Which of the following additional findings can be seen in this patient? (Q845641)

A. Development of GI polyps

B. Degeneration of nitric oxide–producing neurons

C. Iron deficiency anemia

D. Apple core appearance on imaging

Correct Answer: C. Iron deficiency anemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This patient's condition is most likely suggestive of Plummer-Vinson syndrome, which is associated with iron deficiency anemia. Plummer-Vinson Syndrome (Sideropenic Dysphagia) Other names: Paterson-Brown-Kelly syndrome Characterized by a triad of: Iron-deficiency anemia (Sideropenia) Atrophic glossitis Post- Cricoid Dysphagia (Upper esophageal webs) Common in middle-aged women Increased risk of squamous cell carcinoma (pharynx and proximal esophagus) Post cricoid Dysphagia is caused by esophageal webs/rings in the upper esophagus which leads to swallowing difficulties.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 45-year-old male presents with complaints of severe odynophagia, retrosternal chest pain, and difficulty in swallowing solids and liquids for the past week. He has a

history of untreated HIV infection with a CD4 count of 80 cells/mm^3. An upper gastrointestinal endoscopy image is shown below. What is the most likely diagnosis? (Q845642)

A. CMV esophagitis

B. HSV esophagitis

C. Eosinophilic esophagitis

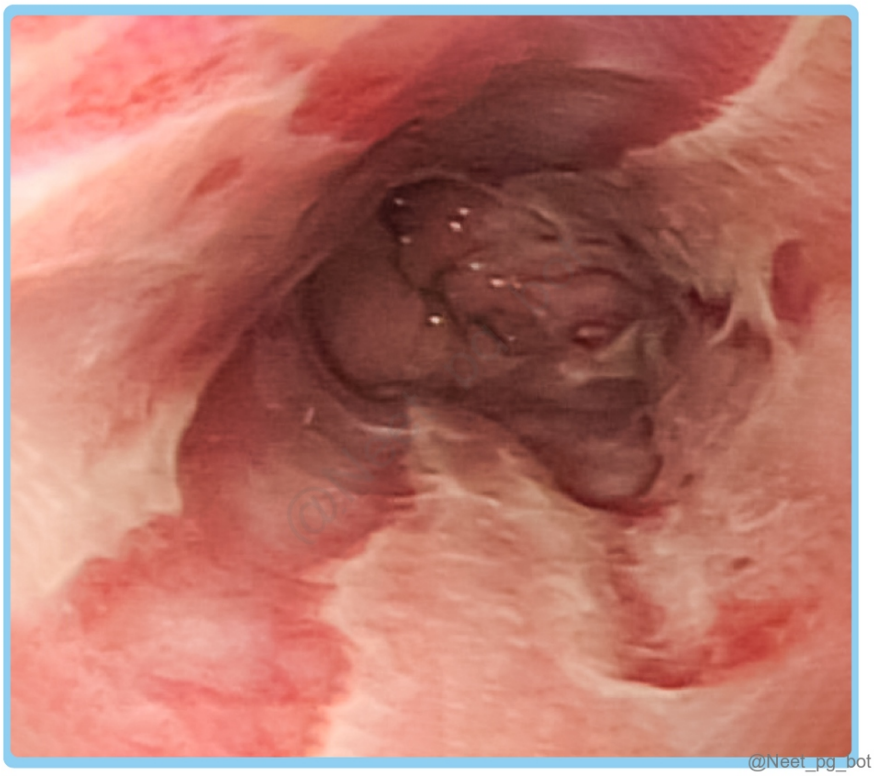
D. Candida esophagitis

Correct Answer: D. Candida esophagitis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario and endoscopy showing curd-like plaques suggest Candida esophagitis. Candida esophagitis is an opportunistic infection seen in immunocompromised individuals (e.g., HIV/AIDS, cancer patients, long-term corticosteroid therapy or long-term immunosuppressive therapy) CMV esophagitis (Option A): Shallow, linear, or serpiginous ulcers on endoscopy. HSV esophagitis (Option B): Punched-out ulcers on endoscopy Eosinophilic esophagitis (Option C): Seen in patients with allergy and atopy but not associated with immunodeficiency.



@Neet_pg_bot

@Neet_pg_bot

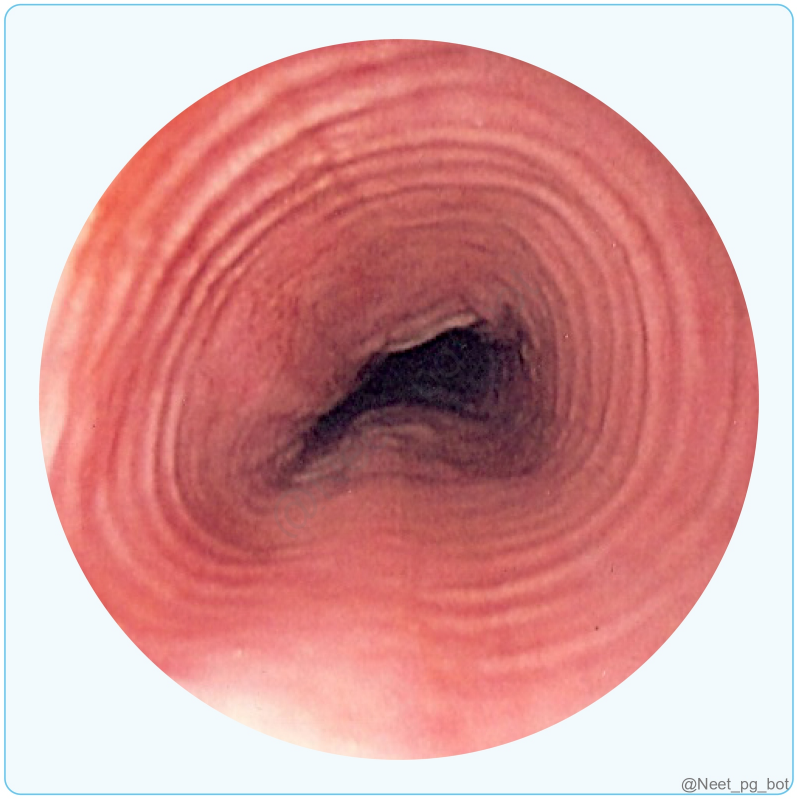
Q6: Which of the following is true regarding the condition shown in the endoscopic image below? (Q845643)

A. Its cause is primarily infectious.

B. Characteristic rat tail appearance.

C. Interleukin 5 has a major role in pathogenesis.

D. Diagnosed by observing at least ten lymphocytes/HPF.



Correct Answer: C. Interleukin 5 has a major role in pathogenesis.

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The given image suggests eosinophilic esophagitis, where Interleukin 5 has a major role in pathogenesis. Eosinophilic Esophagitis: Triggered by allergic reactions to food or environmental allergens (Option A) Associated with atopic dermatitis, allergic rhinitis, asthma, and peripheral eosinophilia Pathophysiology Interleukin 5 (IL-5) key cytokine for eosinophil maturation and activation Clinical Manifestations Dysphagia Epigastric pain Dyspepsia Chest pain Food impaction Diagnostic Criteria Eosinophils ≥ 15 per high power field (HPF) on HPE (Option D) Endoscopic Findings: Stacked circular rings ("feline esophagus") (Option C) Strictures Linear furrows Characteristic rat tail appearance (Option B)- Rat tail appearance is seen in achalasia cardia. The characteristic appearance seen in eosinophilic esophagitis on endoscopy is "feline esophagus" which refers to the presence of stacked circular rings.

@Neet_pg_bot

Q8: Which of the following is the most common site of fistulization in congenital GI anomalies? (Q890287)

A. Ileum

B. Colon

C. Esophagus

D. Stomach

Correct Answer: C. Esophagus

Explanation: The most common congenital fistula involving the gastrointestinal tract is a tracheoesophageal fistula (TEF) , which involves an abnormal communication between the esophagus and the trachea. TEF is most often associated with esophageal atresia and represents the most frequent site of fistulization among congenital GI anomalies. The most common pattern is proximal esophageal atresia with a distal tracheoesophageal fistula . Atresia: A complete obstruction of the lumen due to failure of normal recanalisation during development (e.g., esophageal or intestinal atresia). Fistula: An abnormal communication between two epithelial-lined structures , such as the trachea and esophagus in tracheoesophageal fistula. Ileum (Option A): Congenital anomalies of the ileum most commonly include Meckel diverticulum or intestinal atresia , rather than fistula formation. Colon (Option B): Congenital fistulas involving the colon may occur in anorectal malformations , but they are less common than tracheoesophageal fistula. Stomach (Option D): Congenital fistulas involving the stomach are rare and are not the most common form of fistulization in GI developmental anomalies.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 688

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Heterotopic (ectopic) gastric mucosa most commonly occurs in which of the following locations? (Q890289)

A. Cervical oesophagus

B. Rectum

C. Ileum (outside Meckel diverticulum)

D. Colon

Correct Answer: A. Cervical oesophagus

Explanation: Ectopic gastric mucosa most commonly occurs in the proximal (cervical) oesophagus as an “inlet patch”. It is usually a congenital lesion located just below the upper oesophageal sphincter and is often asymptomatic, discovered incidentally during endoscopy. Endoscopic appearance: Well-defined salmon-coloured patch Contrasts with the normal grey-white squamous oesophageal mucosa Most inlet patches are asymptomatic Possible complications: Esophagitis Ulceration Stricture formation Bleeding or fistula formation (rare) Dysplasia and adenocarcinoma (very rare)

@Neet_pg_bot

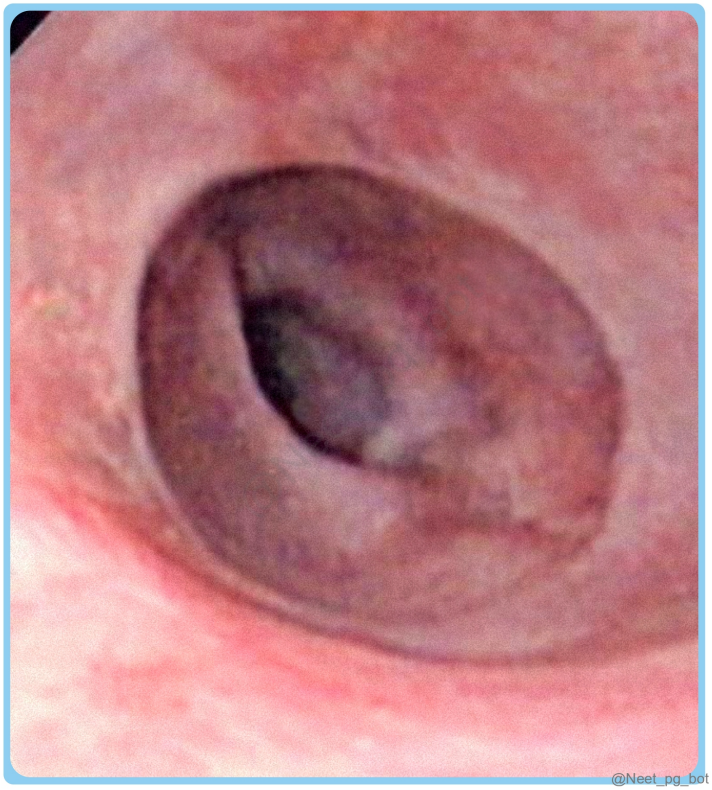
Q10: A 48-year-old man has intermittent dysphagia to solids with occasional food impaction. Endoscopy shows a thin ring, as shown in the image, at the gastroesophageal junction. What is the diagnosis? (Q890292)

A. Esophageal web

B. Achalasia

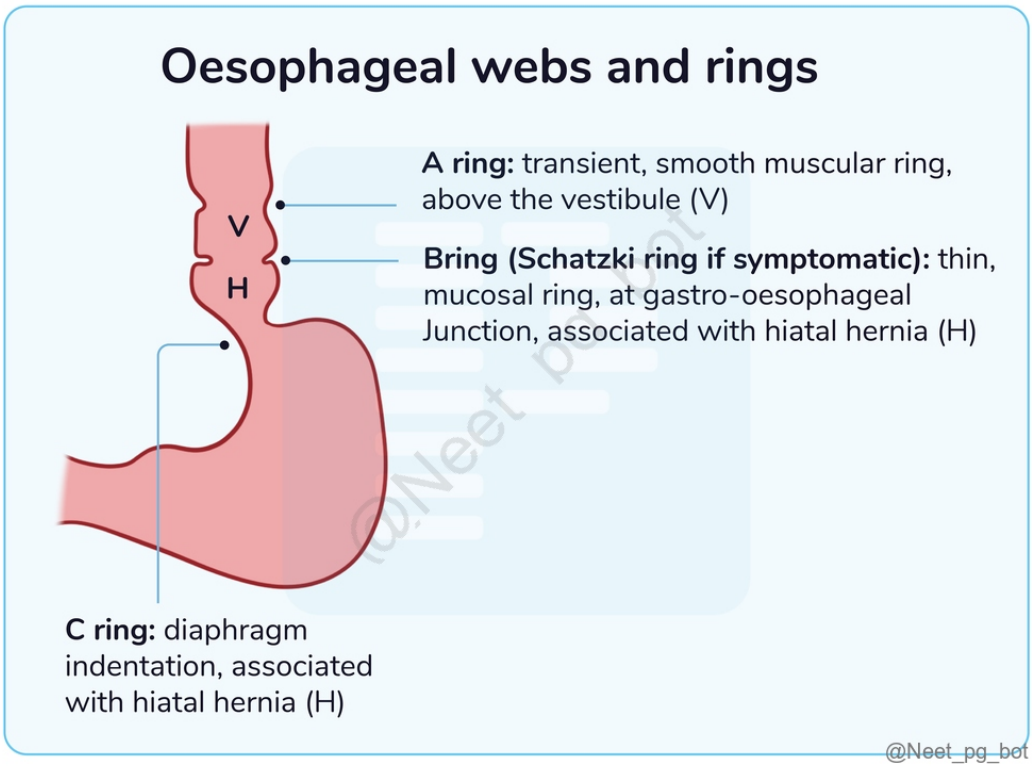
C. Schatzki ring

D. Type A ring



Correct Answer: C. Schatzki ring

Explanation: Schatzki ring presents with intermittent, non-progressive, solid dysphagia and is located at the gastroesophageal junction . Oesophageal Webs and Rings: Oesophageal webs (Option A): Found in the proximal oesophagus Covered by stratified squamous epithelium . Oesophageal rings: Found in the distal oesophagus near the gastroesophageal junction. Ring Type Location Structure Type A ring (Option D) Above the gastroesophageal junction Muscular ring formed by distal esophageal muscle Type B ring (Schatzki ring) At the gastroesophageal junction Thin mucosal ring causing luminal narrowing Type C ring Below the gastroesophageal junction Indentation produced by the diaphragm (not a true ring) Schatzki rings are the most common type of ring and can cause symptoms if luminal narrowing occurs. Achalasia (Option B): Achalasia results from failure of lower esophageal sphincter relaxation due to loss of inhibitory neurons in the myenteric plexus. It causes progressive dysphagia to both solids and liquids , rather than intermittent dysphagia.



References:

https://www.ncbi.nlm.nih.gov/books/NBK539771/

https://radiopaedia.org/articles/schatzki-ring

↑ *Back to this question in Part A*

@Neet_pg_bot

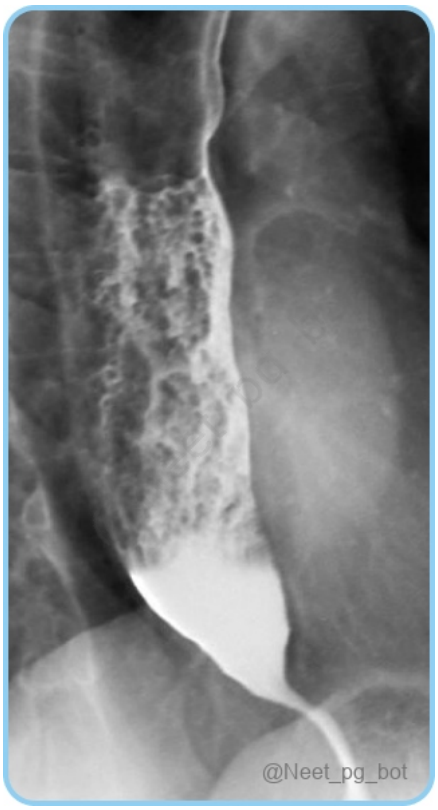
Q11: A 40-year-old man from rural South America presents with progressive dysphagia to solids and liquids and chronic constipation. Imaging shows findings as shown. What is the mechanism of his oesophageal disease? (Q890295)

A. Degeneration of nitric oxide-producing neurons

B. Autoimmune destruction of inhibitory neurons

C. Destruction of the myenteric plexus

D. Smooth muscle fibrosis



Correct Answer: C. Destruction of the myenteric plexus

Explanation: This clinical presentation is typical of secondary achalasia caused by Chagas disease (American trypanosomiasis) . The disease is caused by Trypanosoma cruzi , which infects and destroys the Auerbach (myenteric) plexus of the gastrointestinal tract. Loss of the myenteric plexus results in: Failure of esophageal peristalsis Impaired relaxation of the lower esophageal sphincter (LES) Progressive dilation of the esophagus (megaesophagus) Chagas disease can also affect other regions containing the myenteric plexus , including the colon (megacolon) and occasionally the duodenum and ureters . Chagas Disease Cause: Trypanosoma cruzi infection Transmission: Triatomine (“kissing”) bug Mechanism: Destruction of Auerbach (myenteric) plexus Major GI manifestations: Megaesophagus Megacolon Degeneration of nitric oxide-producing neurons (Option A) : Seen in primary achalasia. Autoimmune destruction of inhibitory neurons (Option B) : Proposed in idiopathic achalasia. Smooth muscle fibrosis (Option D) : Seen in systemic sclerosis (hypotensive LES).

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 689

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following statements regarding primary achalasia is incorrect? (Q890298)

A. Degeneration of nitric oxide-producing inhibitory neurons

B. May involve degeneration of the dorsal motor nucleus of the vagus

C. Not associated with autoimmune conditions

D. Loss of LES relaxation

Correct Answer: C. Not associated with autoimmune conditions

Explanation: Primary achalasia is thought to have an immune-mediated component, supported by associations with autoimmune disorders and immunoregulatory gene polymorphisms. Primary Achalasia: Motility disorder characterised by failure of the lower esophageal sphincter (LES) relaxation (Option D) and absence of normal esophageal peristalsis. The underlying mechanism is degeneration of inhibitory neurons in the Auerbach (myenteric) plexus , particularly those producing nitric oxide (NO) and vasoactive intestinal peptide (VIP) . (Option A) May involve: Extraesophageal vagus nerve Dorsal motor nucleus of vagus (Option B) Possible immune-mediated mechanism: Association with HSV-1 exposure Immunoregulatory gene polymorphisms Coexistence with autoimmune disorders (e.g., Sjögren syndrome, autoimmune thyroid disease)

@Neet_pg_bot

Q13: Which of the following statements regarding eosinophilic esophagitis is incorrect? (Q890302)

A. Commonly associated with atopic disorders

B. Characterised by superficial intraepithelial eosinophils

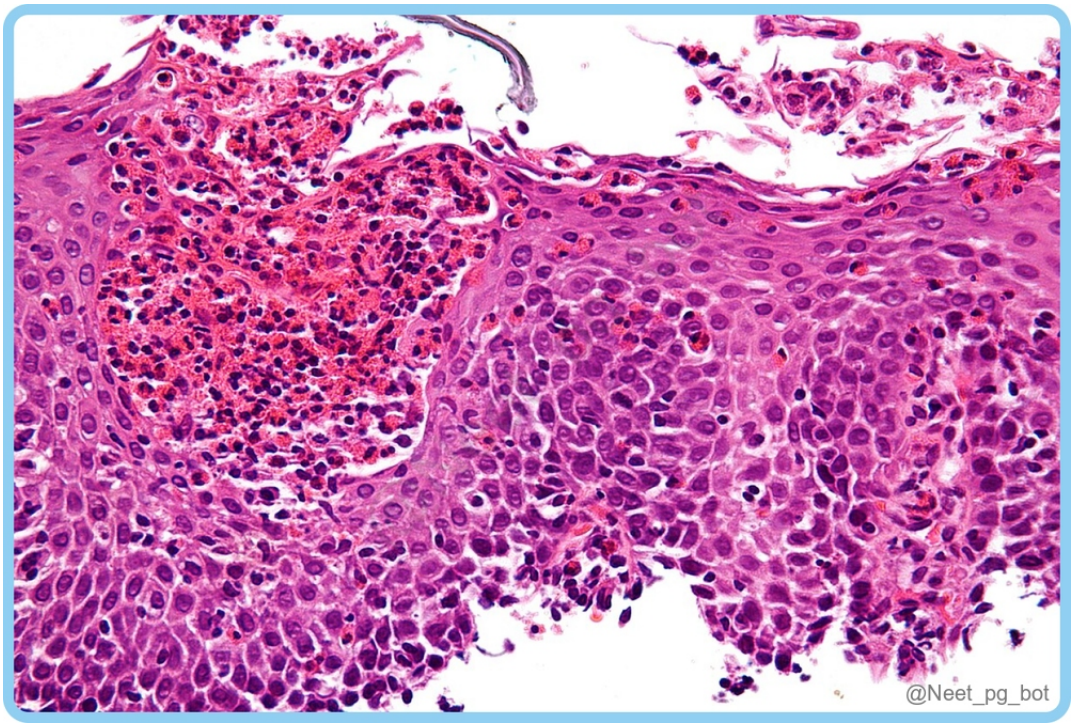
C. Strongly associated with Barrett's oesophagus

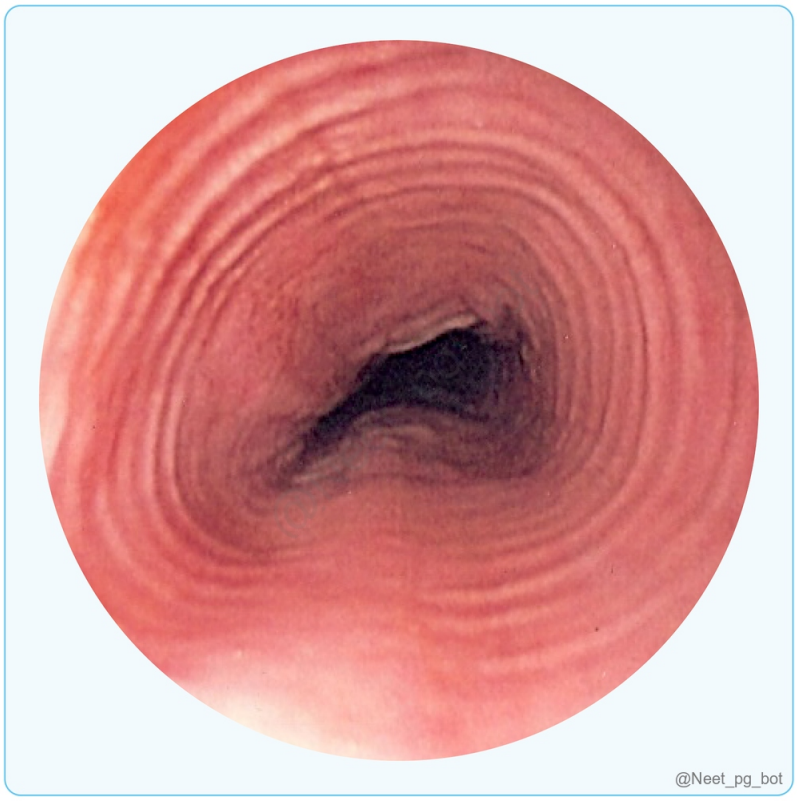
D. Endoscopic dilation relieves dysphagia but not inflammation

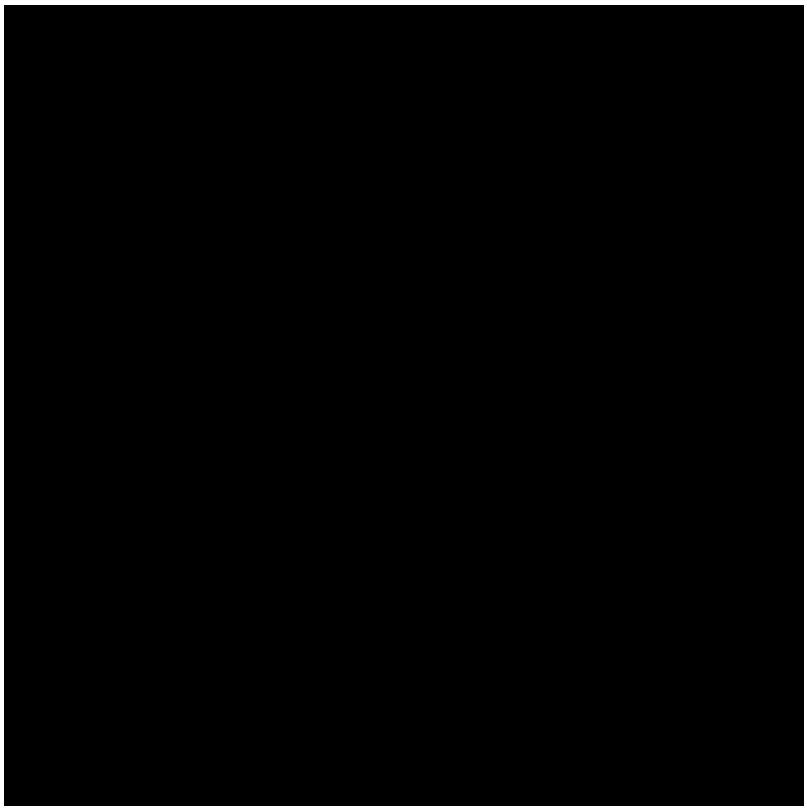
Correct Answer: C. Strongly associated with Barrett's oesophagus

Explanation: Eosinophilic esophagitis has no association with Barrett's oesophagus . Eosinophilic Esophagitis (EoE): Chronic, immune-mediated oesophageal inflammation associated with atopy . (Option A) Associations: Asthma, allergic rhinitis, atopic dermatitis, and mild peripheral eosinophilia. Not associated with Barrett's oesophagus. Symptoms: Dysphagia, food impaction GERD-like symptoms Vomiting & feeding intolerance (infants) Histology: ■ Numerous superficial intraepithelial eosinophils (Option B) Clusters/sheets + intercellular edema Not specific → exclude GERD, Crohn disease, infections Endoscopy: “Feline oesophagus” (stacked rings) ■ ■■ Linear furrows, strictures Treatment: Empiric elimination of cow’s milk and related dairy products

Pharmacologic treatment: Proton pump inhibitors Topical corticosteroids IL-4/IL-13 receptor antagonist Dilation for strictures (does not reduce inflammation) (Option D)







References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 690, 691

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following statements regarding Mallory-Weiss tear is incorrect? (Q890305)

A. Usually longitudinal and located near the GEJ

B. Commonly result from severe retching or vomiting

C. Transmural perforation of the oesophageal wall

D. Most cases resolve without surgical intervention

Correct Answer: C. Transmural perforation of the oesophageal wall

Explanation: Mallory-Weiss tears are mucosal lacerations , not transmural perforations. Transmural rupture characterises Boerhaave syndrome. Mallory-Weiss tear: Longitudinal mucosal laceration at the gastroesophageal

junction (GEJ). (Option A) At or across GEJ May extend into the proximal stomach Feature Boerhaave Syndrome Mallory-Weiss Syndrome Definition Oesophageal perforation Mucosal laceration near the gastroesophageal junction Cause Forceful vomiting Forceful vomiting, retching, coughing, or straining (Option B) Location The lower part of the oesophagus (left side) Gastroesophageal junction Symptoms Vomiting, chest pain, subcutaneous emphysema, pleural effusion, fever, tachycardia, tachypnea, and a crunching sound on heart auscultation Vomiting, hematemesis, upper abdominal pain, hypotension, tachycardia Complications Pleural effusion, increased morbidity and mortality if delayed diagnosis and treatment Rarely massive bleeding, associated with portal hypertension Diagnosis Clinical evaluation, imaging studies Clinical evaluation, endoscopy Treatment Drainage, closure of perforation, and supportive measures Endoscopic methods (multipolar electrocoagulation, epinephrine injection, band ligation), angiographic transarterial embolisation, and rarely surgery Prognosis Poor if not treated promptly Usually conservative (Option D) Rarely requires surgery

Q7 (p. 1919)	*Q8 (p. 1921)*	*Q9 (p. 1923)*	*Q10 (p. 1924)*	*Q11 (p. 1924)*	*Q12 (p. 1925)*
Q13 (p. 1926)	*Q14 (p. 1928)*	*Q15 (p. 1930)*	*Q16 (p. 1931)*	*Q17 (p. 1932)*	*Q18 (p. 1934)*
Q19 (p. 1934)	*Q20 (p. 1935)*	*Q21 (p. 1936)*			

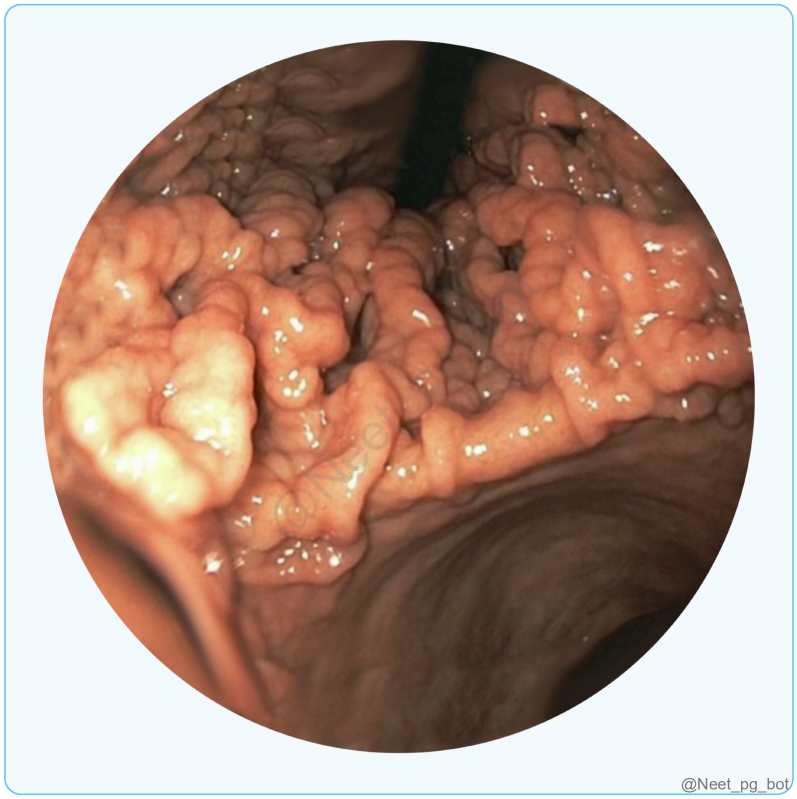
Q1: A 45-year-old patient presents with persistent abdominal discomfort, nausea, weight loss, and occasional diarrhoea. He was recently diagnosed with a viral infection. The following gross image of the gastric mucosa is observed upon upper gastrointestinal endoscopy. Which of the following is correct regarding the patient's condition? (Q845222)

A. Associated with excessive secretion of TNF-α.

B. Histopathologically, villous atrophy is observed.

C. Increases the risk of gastric carcinoma.

D. More common in females and can cause protein-losing enteropathy.



Correct Answer: C. Increases the risk of gastric carcinoma.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The endoscopic picture reveals thickened or giant gastric folds (referred to as Cerebriform rugae) seen in Menetrier's disease. Menetrier's disease is more common in males. (Option D ruled out) It is associated with an increased risk of gastric adenocarcinoma. (Option C). It is caused due to elevated secretions of a mediator called TGF-α. (Option A ruled out) Histopathology reveals elongated, cystic foveolar mucous cell hyperplasia. (Option B ruled out) Menetrier's disease: Menetrier's disease is a rare, acquired premalignant condition characterized by massive overgrowth of the gastric mucous cells (foveolar hyperplasia). Pathophysiology and Associations: TGF-α Overexpression: The disease is caused by the elevated secretion of Transforming Growth Factor-alpha (TGF-α), which activates the epidermal growth factor receptor. CMV Association: In children, the condition is often acute and strongly associated with Cytomegalovirus (CMV) infection; it usually resolves spontaneously after the infection clears. H. pylori Association: In adults, there is a recognized association with Helicobacter pylori infection, though it typically follows a more chronic course than the pediatric form. Anatomical and Endoscopic Findings: Cerebriform Rugae: Endoscopy reveals giant, thickened gastric folds that resemble the gyri of the brain. Antrum Sparing: A classic diagnostic hallmark is that these giant folds typically involve the fundus and body (corpus) of the stomach while sparing the antrum . Protein-Losing Gastropathy: The excessive mucus production leads to significant protein loss, often resulting in hypoalbuminemia and peripheral edema. Pathology and Risk: Histopathology: Shows elongated, "corkscrew" cystic foveolar mucous cell hyperplasia with a concomitant decrease in parietal (acid-producing) cells. Malignancy Risk: It is considered a premalignant state that increases the overall risk of developing gastric adenocarcinoma .

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 771, 772

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 60-year-old man presents with vague abdominal discomfort and early satiety. Imaging reveals a large mass in the gastric fundus. He undergoes surgical resection of the mass, and histopathology confirms a gastrointestinal stromal tumor (GIST). Which of the following factors is a favorable prognostic indicator of this condition? (Q845244)

A. Tumor size > 10 cm

B. Epithelioid cell type

C. Gastric location

D. Intestinal location

Correct Answer: C. Gastric location

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Prognostic factors of GISTs Features Good prognosis Bad prognosis Tumor size < 5cm >10cm (Option A) Mitotic rate < 5 per HPF >10 per HPF Location Gastric Intestinal (Jejunum, Ileum, Rectum) (Option D) Cell type Spindle cell type Epithelioid cell type (Option B) Mutations Wild type GIST (Lack mutations in KIT, PDGFR) Specific PDGFRA mutations, such as the D842V mutation in exon 18 Treatment Responds to Tyrosine kinase inhibitors. Resistant to Tyrosine kinase inhibitors.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 778

https://www.uptodate.com/contents/clinical-presentation-diagnosis-and-prognosis-of-gastrointestinal-stromal-tumors

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following markers will help confirm the diagnosis of GIST in C-kit negative cases? (Q845242)

A. CD34

B. DOG1

C. S-100

D. CD117

Correct Answer: B. DOG1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: 3 markers for GIST: CD117 (C-kit) expression is a hallmark of GISTs and it is the most sensitive marker on immunohistochemistry. (Option D) CD34: Non-specific marker of GIST. (Option A) DOG1: Most specific and specific marker in C-Kit negative cases. (Option B) S-100(Option C): S100 is a marker commonly associated with neural and melanocytic tumors, not typically expressed in GISTs.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 778

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following is the most common mutation found in GIST (Gastrointestinal Stromal Tumor)? (Q845238)

A. KIT mutation

B. PDGFRA mutation

C. SDH mutation

D. BRAF mutation

Correct Answer: A. KIT mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Genetic mutations in GIST: KIT (C-KIT or CD117) mutation is the most common found in GIST. (Option A) PDGFRA mutation (Platelet-Derived Growth Factor Receptor Alpha) (Option B): Seen in a subset of GIST SDH mutation (Succinate Dehydrogenase) (Option C): Usually GIST is seen in pediatric patients when SDH mutation occurs.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 779

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 55-year-old man with intermittent abdominal pain, nausea, and early satiety has a palpable epigastric mass. Imaging shows a well-defined, heterogeneously enhancing stomach mass, and endoscopic biopsy reveals CD117-positive spindle cells. What is the likely origin of this condition? (Q845236)

A. Cajal cells

B. Goblet cells

C. Paneth cells

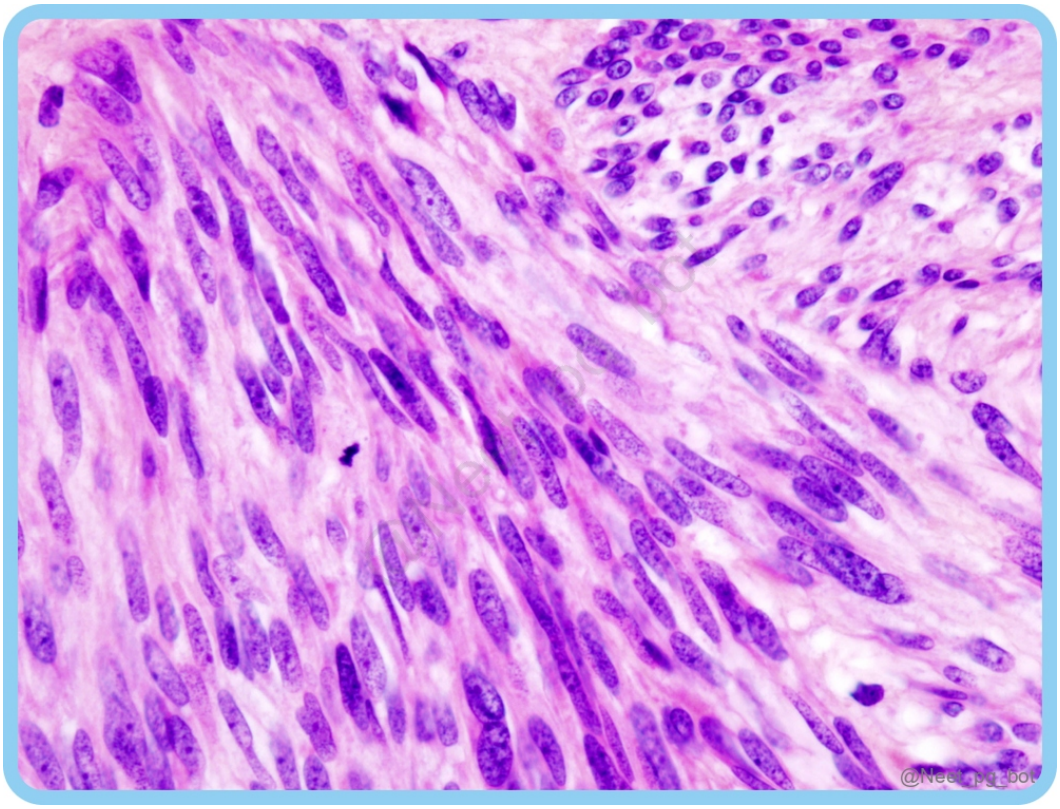
D. G cells

Correct Answer: A. Cajal cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Gastrointestinal Stromal Tumor (GIST): Cells of origin Cajal cells (Pacemaker cells of GIT) Location Stomach > Intestine GIST is the most common mesenchymal tumor of stomach. Mutations Most common- c-KIT/CD117 Others: PDGFR S uccinate dehydrogenase (SDH)- S mall baby(Pediatric GIST) Mechanism c-KIT mutation- Increase in tyrosinase kinase activity Markers Most sensitive marker of GIST: CKIT/CD117 Most specific marker of GIST: DOG1 Treatment Surgery Tyrosine Kinase inhibitors- Imatinib



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 778

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 55-year-old male presents with episodes of flushing, sweating, and colicky abdominal pain. Upper gastrointestinal endoscopy reveals a yellow-tan intramural mass in the stomach. Biopsy revealed sheets of uniform cells with scant granular cytoplasm. What is the most likely diagnosis? (Q845234)

A. Carcinoid tumor

B. Gastric outlet obstruction

C. Hypertrophic pyloric stenosis

D. Crohn's disease

Correct Answer: A. Carcinoid tumor

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the patient's presentation and histological findings, the most likely diagnosis is a Carcinoid tumor that originates from scattered neuroendocrine cells in the GIT. Carcinoid tumor arises from neuroendocrine cells. They present with symptoms like flushing, bronchospasm, abdominal pain, diarrhea, and occasionally weight loss due to the secretion of vasoactive substances like serotonin , leading to carcinoid syndrome . Gastric outlet obstruction (Option B): Can be caused by hypertrophic pyloric stenosis in children. Metabolic abnormalities like metabolic alkalosis and paradoxical aciduria are seen. Hypertrophic pyloric stenosis is a congenital condition where an olive-shaped lump can be palpated in the child's abdomen. Crohn's disease (Option D): Crohn's disease is a chronic granulomatous inflammation that affects the entire gastrointestinal tract (most commonly intestine), characterized by non-caseating granulomas in intestine and stomach.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 777, 778

↑ *Back to this question in Part A*

@Neet_pg_bot

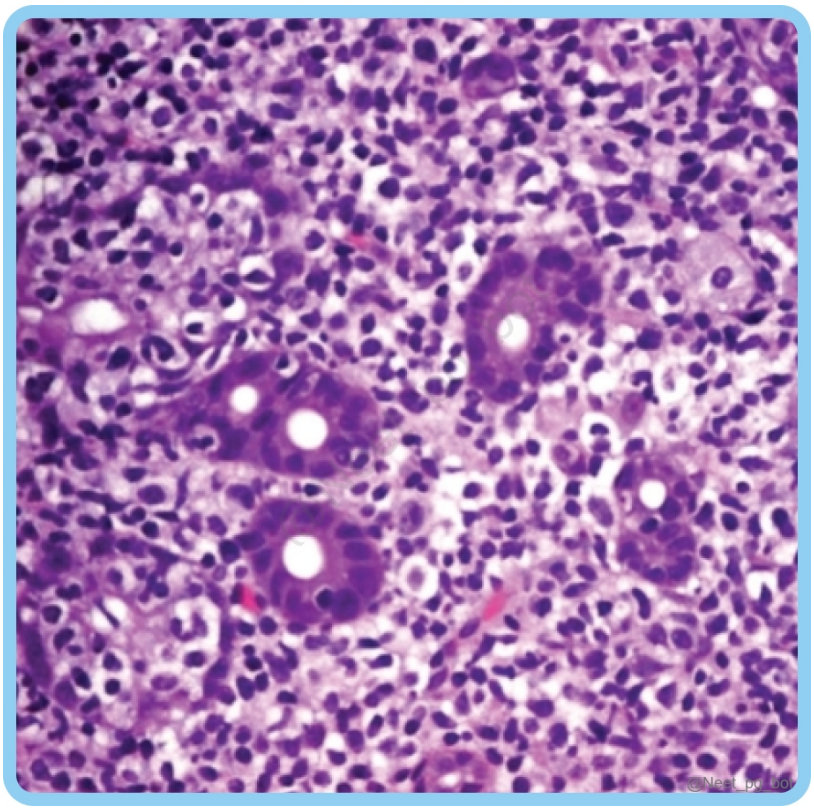
Q7: A 48-year-old female presents with recurrent abdominal pain, bloating, and early satiety for the past few months. Endoscopic biopsy revealed lympho-epithelial lesions with infiltration of small lymphoid cells. Which of the following statements is true regarding this condition? (Q845233)

A. Dense neutrophilic infiltrate

B. Reactive-appearing T-cell follicles seen

C. Plasmacytic differentiation seen

D. Presents as discrete small nodules in the GI tract



Correct Answer: C. Plasmacytic differentiation seen

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Plasmacytic differentiation seen The given presentation and biopsy findings suggest gastric MALT lymphoma , a type of non-Hodgkin lymphoma originating from the stomach's mucosa-associated lymphoid tissue (MALT). Biopsy finding: Lympho-epithelial lesions with infiltration of small lymphoid cells. Lympho → malignant lymphoid (B-cells) infiltrate. Epithelial → invasion and destruction of gastric glands by these malignant lymphocytes. It is characterised by a dense lymphocytic infiltrate in the lamina propria , creating lympho-epithelial lesions indicative of B-cell involvement (Option A ruled out) . Gastric MALToma involves B-cell follicles and not T-cell follicles (Option B ruled out) . Gastric lymphoma usually causes diffuse thickening , not a discrete polyp/nodule. (Option D ruled out) Gastric MALToma belongs to the category of Marginal Zone Lymphomas (MZL). The major causes include: H. pylori infection , where chronic antigenic stimulation leads to lymphoid proliferation and eventually neoplastic transformation. C hromosomal translocation t(11;18)(q21;q21) , which creates the API2–MALT1 fusion gene . This fusion activates NF-κB signaling, resulting in uncontrolled B-cell survival.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 777

↑ *Back to this question in Part A*

@Neet_pg_bot

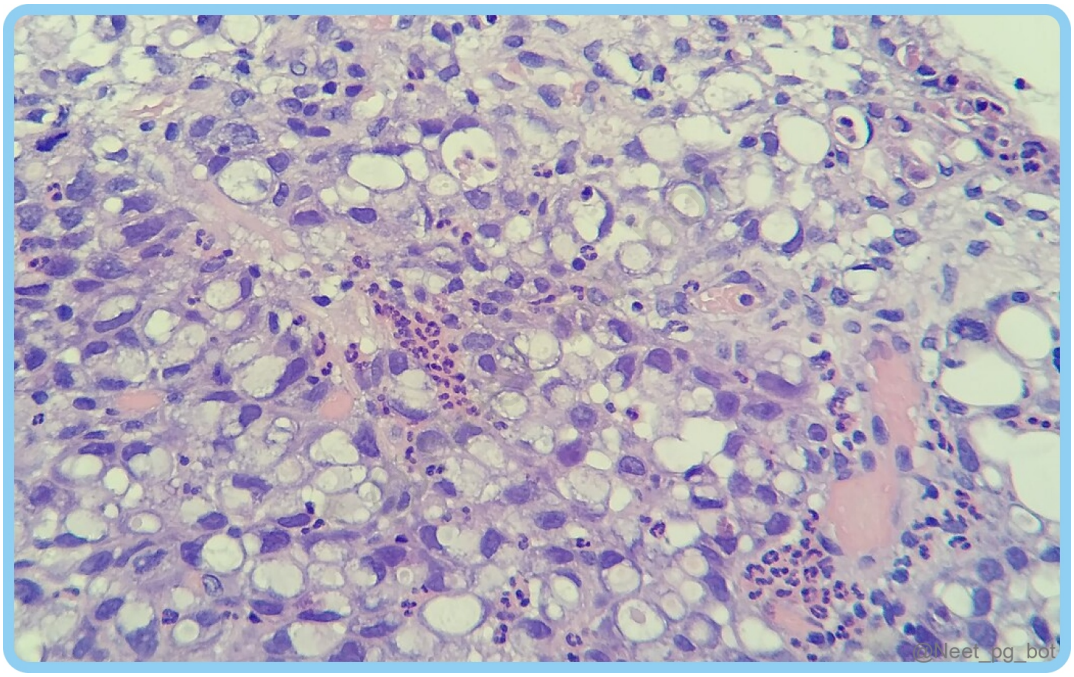
Q8: A 45-year-old female has a history of intermittent epigastric discomfort, nausea, and early satiety. Upper endoscopy reveals gastric wall thickening with a leather bottle appearance. Biopsy of the lesion shows signet ring cells infiltrating the gastric mucosa. What is the most likely diagnosis? (Q845228)

A. Intestinal-type gastric adenocarcinoma

B. Diffuse-type gastric adenocarcinoma

C. Peptic ulcer disease

D. Gastric lymphoma



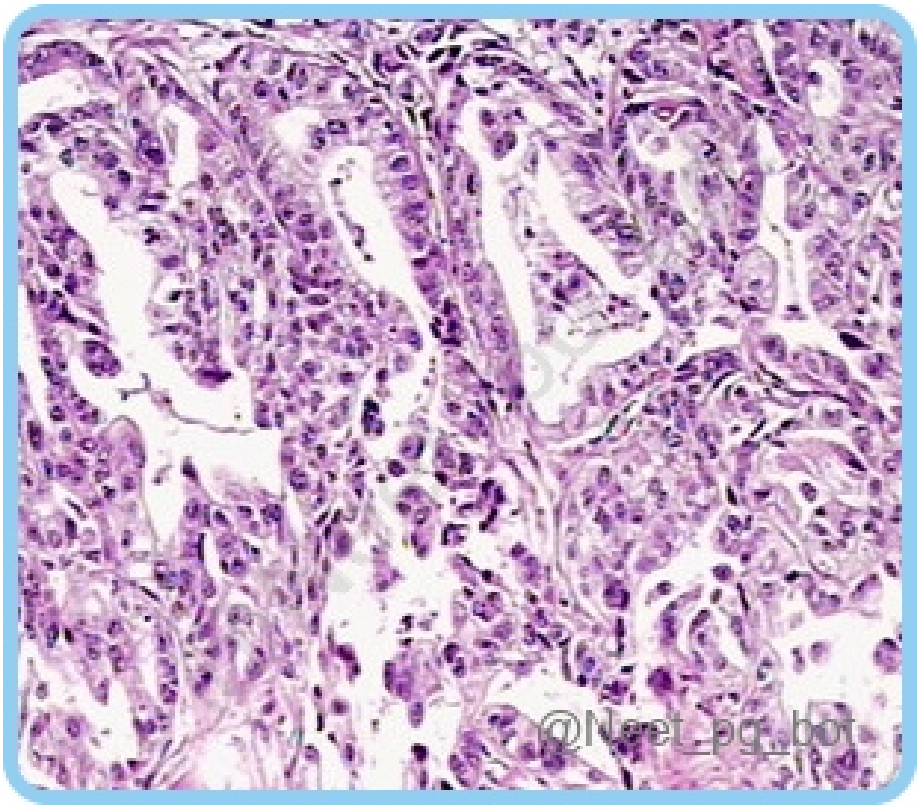
Correct Answer: B. Diffuse-type gastric adenocarcinoma

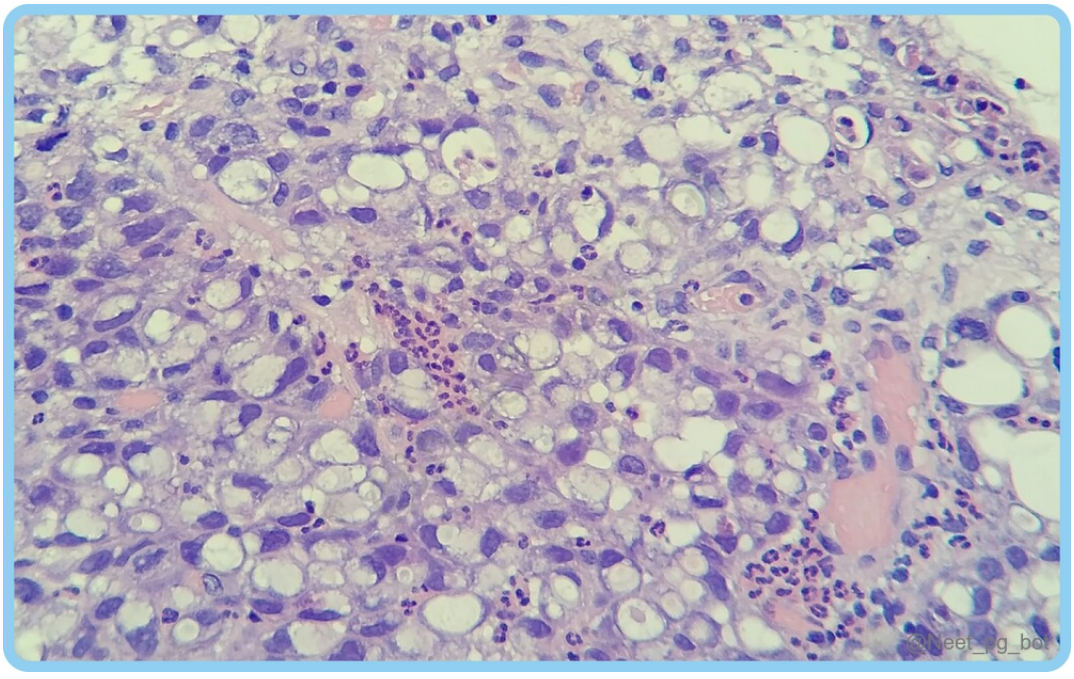
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Diffuse-type gastric adenocarcinoma The given findings suggest diffuse-type gastric adenocarcinoma, characterised by diffuse thickening of the gastric wall and signet ring cells infiltrating the gastric mucosa. Lauren classification: Features Intestinal type Gastric adenocarcinoma (Option A) Diffuse-type gastric adenocarcinoma (Option B) Location Predominantly in the antrum or pyloric region Diffuse involvement of gastric body and fundus Risk factors H. pylori infection, high intake of smoked/pickled foods, smoking, chronic gastritis, old age CDH1 gene mutation, younger age. Genetically diffuse type gastric adenocar shows loss of E-cadherin (CDH1) gene Appearance on endoscopy Ulcerative, polypoid masses (localised growth) Thickening of gastric wall (due to diffuse infiltration). Linitis plastica (leather bottle appearance) Histology Well-differentiated glandular structures with intestinal metaplasia. Signet ring cells and infiltration of poorly cohesive cells into the

gastric mucosa. Seen because cells are filled with mucin. Prognosis Better Poorer Peptic Ulcer Disease (PUD) (Option C) don't show signet ring cells on biopsy.. Gastric Lymphoma (Option D): Usually a maltoma which shows Lympho-Epithelial lesion (LEL).





References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 775 - 776

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 60-year-old male presents with a history of epigastric pain, unintentional weight loss, and early satiety over the past few months. An upper GI endoscopy revealed a nodular mass on the gastric wall, and a biopsy revealed well-differentiated glandular structures with intestinal metaplasia. Which of the following is least likely associated with this condition? (Q845226)

A. Helicobacter pylori (H. pylori) infection

B. APC gene mutation

C. CDH-1 gene mutation

D. High intake of smoked or pickled foods

Correct Answer: C. CDH-1 gene mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and biopsy revealing well-differentiated glandular structures with intestinal metaplasia suggest the diagnosis of ‘ Intestinal type of gastric adenocarcinoma ’, which has no significant association with CDH-1 gene mutation. Mutations in the CDH1 gene (E-cadherin), associated with hereditary diffuse gastric cancer (HDGC), can lead to an increased risk of diffuse-type gastric cancer but not related to the intestinal type of gastric cancer. Risk factors for intestinal type of gastric adenocarcinoma: Helicobacter pylori (H. pylori) infection (Option A) High intake of smoked or pickled foods (Option D) APC gene mutation (Option B) : Associated with familial adenomatous polyposis (FAP), which causes adenomas in the entire GI tract. Feature Intestinal-Type Diffuse-Type Microscopic Pattern Cohesive cells form glandular/tubular structures Poorly cohesive cells; often includes Signet Ring Cells Gross Morphology Bulky, exophytic masses or well-demarcated ulcers Infiltrative growth; leads to thickened wall (Linitis Plastica) Primary Location Distal stomach (Antrum/Lesser Curvature) Gastric body/Cardia; can involve the whole stomach Major Risk Factors H. pylori, smoking, diet (nitrates/high salt) Primarily Genetic ; CDH1 mutations Pathogenesis Stepwise progression (Correa Pathway) from metaplasia Arises de novo ; no defined precursor lesions Demographics Older age (mean 55+); more common in males Younger age; equal sex distribution or slight female predilection Spread Pattern Primarily Hematogenous (e.g., to the Liver) Primarily Peritoneal or transmural dissemination Surgical Margin Typically 4-5 cm proximal margin Requires much wider margins (8-10 cm) or total gastrectomy Prognosis Relatively better Poor; highly aggressive

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 775

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following is NOT a recognised risk factor for gastric adenocarcinoma? (Q845225)

A. Alcohol

B. Hot beverages

C. Blood group O

D. H. pylori

Correct Answer: C. Blood group O

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Blood group O is not a specific risk factor for gastric adenocarcinoma, but blood group A is a recognised risk factor. Bloog group O patients are at increased risk of Peptic ulcer disease. Blood group A patients are at increased risk of Adenocarcinoma of stomach (gastric adenoma) . The risk factors for gastric adenocarcinoma include : Alcohol (Option A) Smoking Hot beverages (Option B) Smoked and salted food Pernicious anemia Adenomatous polyps Blood group A H. pylori infection (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 774

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 45 y/o male presents with recurrent episodes of abdominal pain and persistent heartburn. Upper gastrointestinal endoscopy reveals multiple duodenal ulcers. Lab investigations show elevated serum gastrin levels (> 1000 pg/ml). Which features are most likely associated with the patient's condition? (Q845223)

A. Presence of gastrin-secreting tumors in the stomach

B. Presence of erosive esophagitis and hiatal hernia

C. Hyperplasia of parietal cells within the stomach

D. Association with MEN2 gene mutation

Correct Answer: C. Hyperplasia of parietal cells within the stomach

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The characteristic features described in the scenario, including recurrent abdominal pain, heartburn, multiple duodenal ulcers, and elevated serum gastrin levels, strongly suggest a diagnosis of Zollinger-Ellison syndrome. Gastrinomas most commonly arise in the duodenum or pancreas, rather than in the stomach. (Option A ruled out) Mechanism: A gastrinoma secretes excess gastrin, which stimulates the parietal cells, leading to their hyperplasia. The hyperplastic parietal cells then cause marked acid hypersecretion, and the resulting excess acid leads to multiple, refractory peptic ulcers, often located distal to the duodenal bulb. (Option C) Presence of erosive esophagitis and hiatal hernia (Option B): These features are commonly associated with gastroesophageal reflux disease (GERD), not Zollinger-Ellison syndrome. Association with MEN2 gene mutation (Option D): Gastrinomas are sporadic in 75% of cases. Approximately 25% of patients with gastrinomas have MEN1 (not MEN2).

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 773

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which cells are primarily responsible for secreting neutral mucin that forms a protective layer in the stomach? (Q845197)

A. Parietal cells

B. Chief cells

C. Foveolar cells

D. Enterochromaffin cells

Correct Answer: C. Foveolar cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The neutral mucin that forms the protective mucosal layer in the stomach is mainly secreted by 'Foveolar cells' located in the topmost layer of the stomach mucosa and acts as a barrier. Cells of the stomach and their function Cells Functions Parietal cells (Option A) Secrete hydrochloric acid (HCl) and intrinsic factor. Chief cells (Option B) Secrete pepsinogen (Inactive precursor of the pepsin). Enterochromaffin cells (Option D) Release of serotonin and histamine to regulate gastric functions.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 764

↑ *Back to this question in Part A*

@Neet_pg_bot

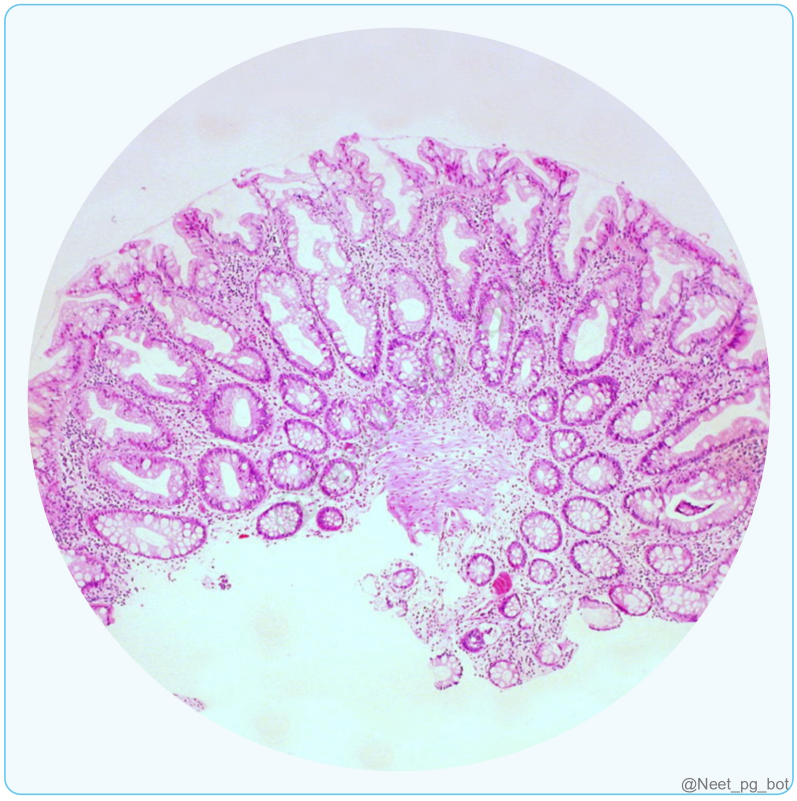
Q13: A 58-year-old female presents with recurrent epigastric discomfort and intermittent nausea. Histopathological examination of gastric biopsy samples reveals irregular, cystically dilated, and elongated foveolar glands. She also has a history of untreated H. pylori infection. What type of lesions is most likely to be associated with these findings? (Q845219)

A. Hyperplastic polyps

B. Gastric adenomas

C. Inflammatory fibroid polyps

D. Juvenile polyps

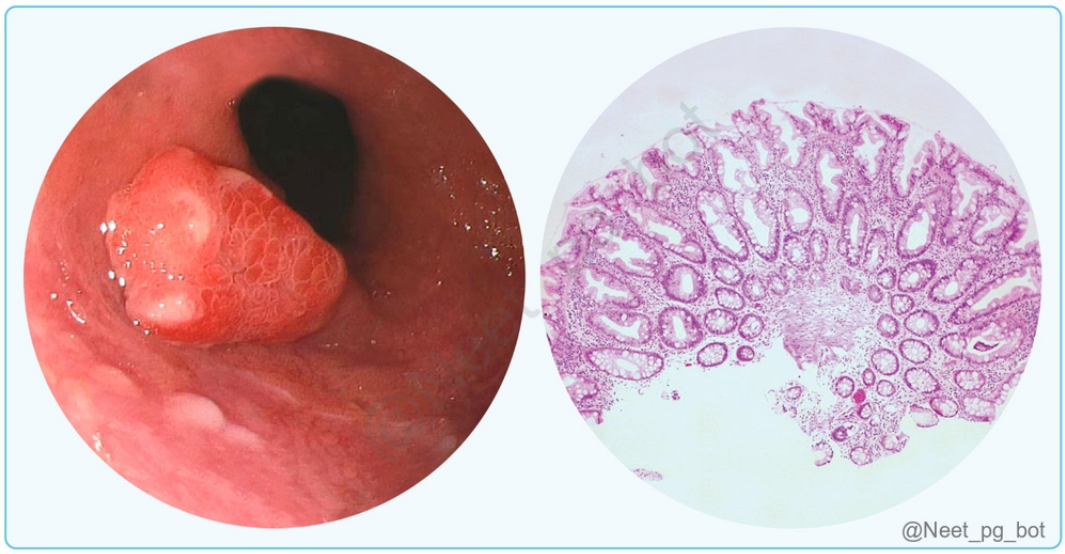


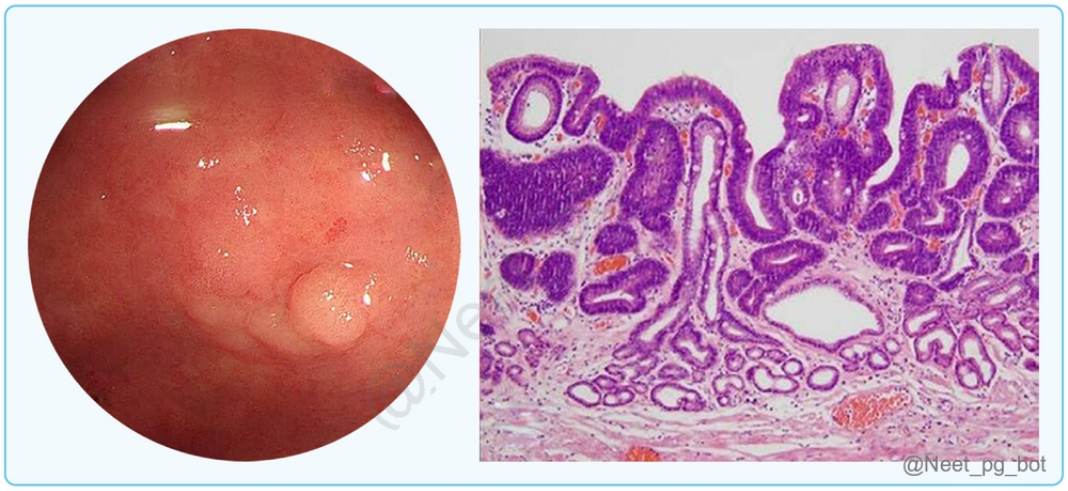
Correct Answer: A. Hyperplastic polyps

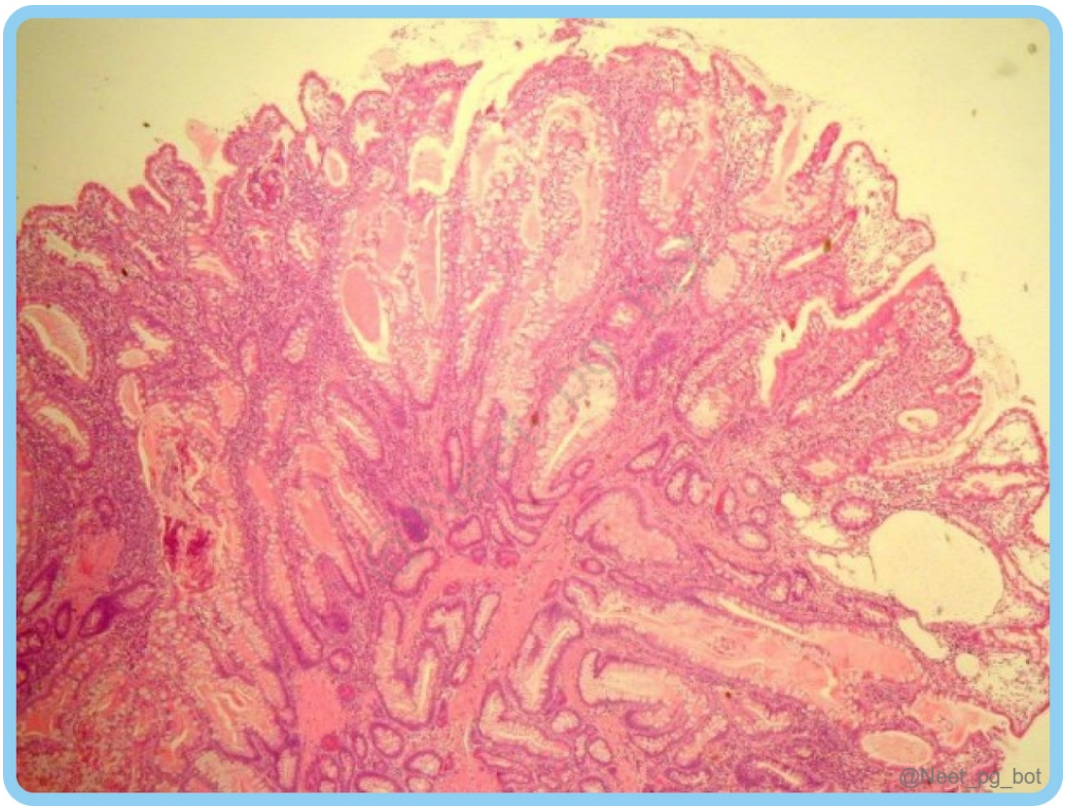
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the patient's symptoms, endoscopic findings, and history of untreated H. pylori infection, hyperplastic (or inflammatory) polyps are the most likely associated lesion. Hyperplastic Polyps: Frequently associated with H. pylori infection . Hypertrophy leads to the formation of multiple layers and an increase in foveolar cells. The risk of dysplasia increases with size, especially in pedunculated polyps >1 cm in diameter. Gastric adenomas (Option B) These are associated with APC gene mutation which increasestheir association with Familial Adenomatous Polyposis (FAP) syndrome. Lesions >2 cm carry a high risk of adenocarcinoma. Inflammatory fibroid polyps (Option C) Rare benign lesions in the GI tract, mostly sporadic, but some are familial (PDGFRA gene mutations). Peutz-Jeghers polyps (Option D) Oral or mucocutaneous pigmentations and jejunal polyps are seen with Peutz-Jeghers polyps. These are not common in stomach but if occurs then are known as arborising or christmas tree polyps. Associated with STK11 mutations.







References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 773, 774, 809, 810

https://www.uptodate.com/contents/gastric-polyps

↑ *Back to this question in Part A*

@Neet_pg_bot

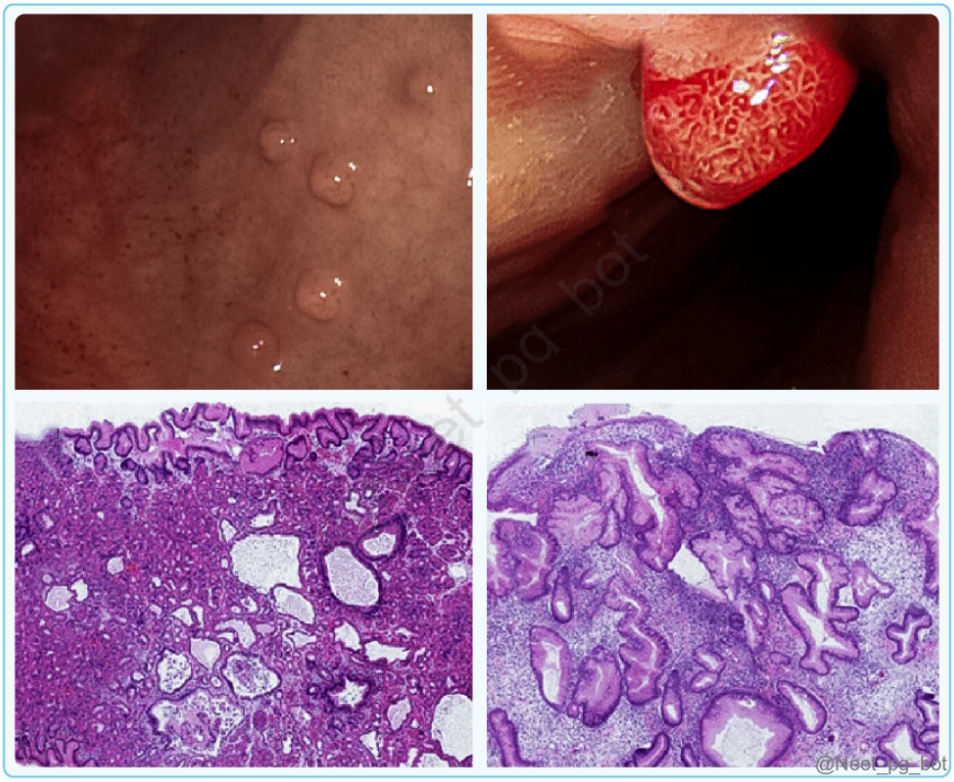
Q14: A 60-year-old man on long-term proton pump inhibitor therapy for acid reflux undergoes an upper gastrointestinal endoscopy for recurrent epigastric discomfort. The endoscopy reveals smooth-surfaced lesions in the gastric body and fundus. Which statement about these findings is likely correct? (Q845215)

A. PPIs decrease gastrin secretion, reducing the risk of fundic gland polyps

B. Fundic gland polyps are commonly associated with H. pylori infection.

C. Composed of cystically dilated glands lined by parietal, chief, and foveolar cells.

D. Sporadic fundic gland polyps carry a significant risk of neoplasia.



Correct Answer: C. Composed of cystically dilated glands lined by parietal, chief, and foveolar cells.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's presentation of smooth-surfaced lesions in the gastric body and fundus and a history of long-term proton pump inhibitor therapy suggest Fundic gland polyps. Histologically, they are characterised by irregular, cystically dilated glands lined by parietal, chief, and foveolar cells, with minimal inflammation. (Option C) Incorrect options: PPIs decrease gastrin secretion, reducing the risk of fundic gland polyps (Option A): Proton pump inhibitors (PPIs) inhibit acid production, leading to increased gastrin secretion, which can contribute to the growth of fundic gland polyps. Fundic gland polyps are commonly associated with H. pylori infection (Option B): H. pylori infection is more associated with hyperplastic polyps. Sporadic fundic gland polyps carry a significant risk of neoplasia(Option D): Sporadic fundic gland polyps are usually benign with very low malignant potential.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 773

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which type of gastritis is associated with a distinctive endoscopic appearance characterised by thickened folds, small nodules, and central aphthous ulceration affecting the entire stomach? (Q845214)

A. Eosinophilic gastritis

B. Lymphocytic gastritis

C. Granulomatous gastritis

D. Chemical gastritis

Correct Answer: B. Lymphocytic gastritis

Explanation: The clinical presentation with thickened folds, nodules, and central aphthous ulcers throughout the stomach suggests lymphocytic (varioliform) gastritis, characterized by increased intraepithelial T lymphocytes and often linked to celiac disease. Eosinophilic gastritis (Option A): It shows dense eosinophil infiltration in the gastric mucosa and muscularis, mainly in the antrum or pylorus. It is often linked to allergies in children and lacks the characteristic endoscopic features described. Granulomatous gastritis (Option C): It contains granulomas and is caused by conditions like Crohn's disease, sarcoidosis, and infections. It is not linked to the described endoscopic appearance. Chemical gastritis (Option D): Chemical gastritis, or reactive gastropathy, is mucosal damage caused by irritants such as NSAIDs, alcohol, or bile reflux, leading to inflammation, erosion, and ulcers.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 769

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 45-year-old female presents with chronic epigastric pain, nausea, and occasional vomiting. Upper gastrointestinal endoscopy reveals diffuse mucosal atrophy. Biopsy confirms chronic gastritis. Which of the following is a characteristic feature of Chronic Gastritis Type A? (Q845212)

A. Predominantly affects the antrum of the stomach

B. Autoimmune destruction of parietal cells

C. Associated with H. pylori infection

D. Increased risk of gastric carcinoma

Correct Answer: B. Autoimmune destruction of parietal cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Characteristic Chronic Gastritis Type A Chronic Gastritis Type B Location Fundus and body of the stomach Antrum and pyloric region of the stomach (Option A) Aetiology Autoimmune H. pylori infection or NSAID use Pathophysiology Autoimmune destruction of parietal cells (Option B) H. pylori-induced inflammation of gastric mucosa (Option C) Autoantibodies Autoantibodies against parietal cells and Antibodies against intrinsic factors (Vit B12 absorption: Megaloblastic anemia) Not autoimmune; may have H. pylori antibodies. Intrinsic factor Reduced due to parietal cell destruction. It may be normal unless atrophic gastritis is present. Gastric acid production Autoantibodies against parietal cells lead to decreased/absent HCl secretion and ↑gastrin synthesis. Normal to increased acid secretion due to H. pylori. Histological findings Lymphocytic and plasma cell infiltrate. Neutrophilic infiltrate, lymphoid follicles. Complications Pernicious anaemia, gastric carcinoid, adenocarcinoma. Peptic ulcers, gastric adenocarcinoma, MALToma. Risk of gastric carcinoma Low Increased, especially with H. pylori infection (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 766, 767

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: A 55-year-old patient presents with recurrent epigastric pain and signs of gastrointestinal bleeding. An upper endoscopy reveals gastric ulcers, and a biopsy is performed for further evaluation. Which stain is best for identifying the causative organism in this condition? (Q845210)

A. Z-N stain

B. Wright stain

C. Modified Giemsa stain

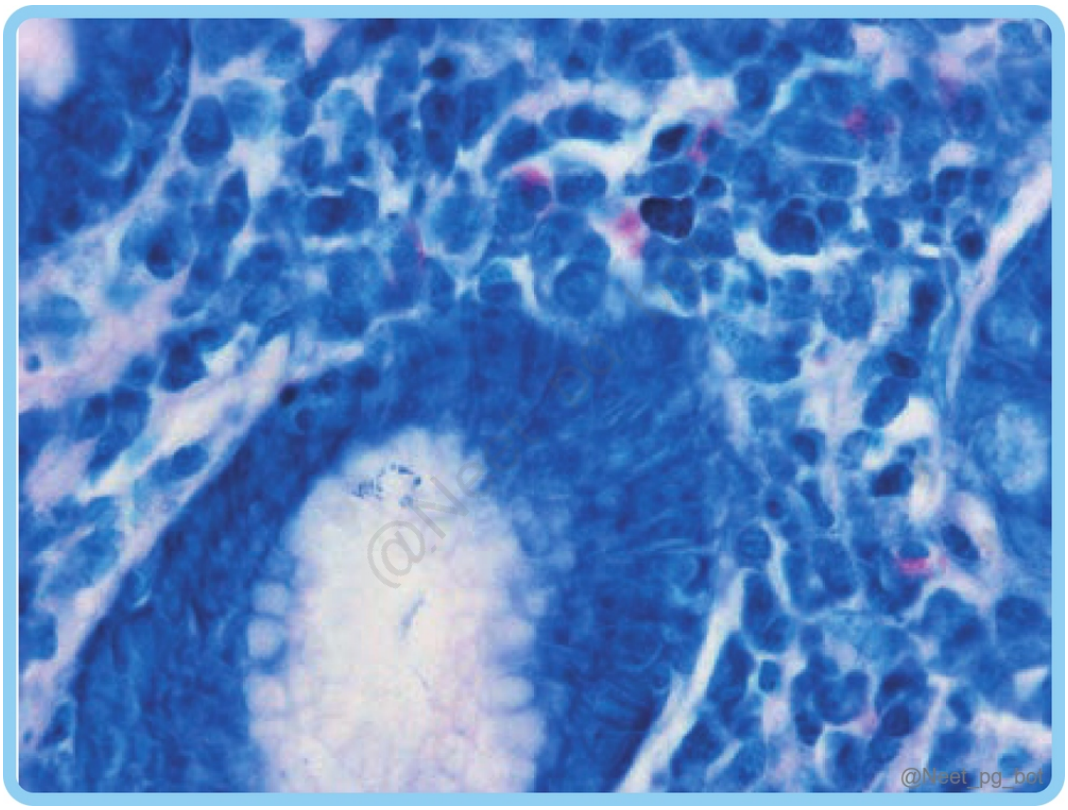
D. Gram stain

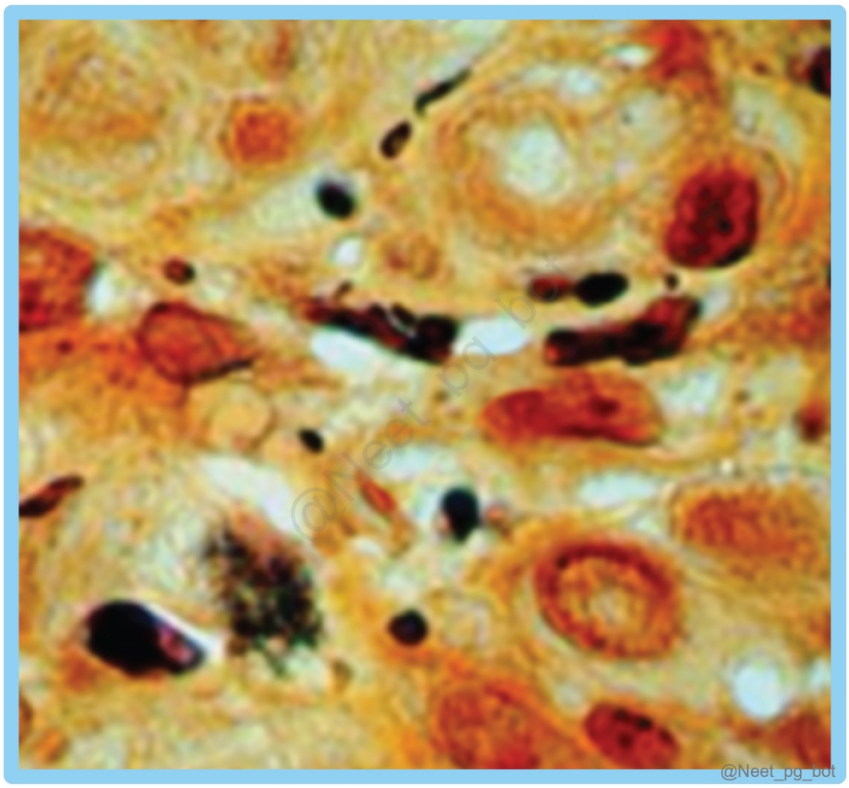
Correct Answer: C. Modified Giemsa stain

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical presentation suggests peptic ulcer disease (PUD), and the organism involved in this condition is Helicobacter pylori . 3 stains for H. pylori: Warthin-Starry silver stain Steiner stain Modified Giemsa stain Modified Giemsa stain Warthin Starry silver stain





References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 768

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: Which of the following is NOT a protective factor against Peptic Ulcer Disease? (Q845208)

A. Mucus

B. Bicarbonate

C. COX-1

D. Pepsin

Correct Answer: D. Pepsin

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Pepsin is not considered a protective factor for peptic ulcer disease (PUD). Excessive pepsin activity, especially in the presence of acid, can lead to tissue damage and ulcer formation. Therefore, pepsin is considered a contributing factor to ulceration rather than a protective factor against PUD. Peptic Ulcer Disease Protective factors Damaging factors Mucus (Option A) Bicarbonate (Option B) COX 1 (Option C) HCl Pepsin H.pylori Mucus and bicarbonate form a protective lining along the stomach wall, protecting it from the acids secreted by the stomach and parietal cells. COX-1 is a gastroprotective enzyme, and its inhibition by NSAIDs such as aspirin can lead to peptic ulcer disease (PUD) as a side effect.

Q19: A 45-year-old man experiences recurrent upper abdominal pain worsened after meals, unresponsive to over-the-counter antacids. Which of the following is NOT typically a risk factor for the patient’s presentation? (Q845206)

A. Helicobacter pylori infection

B. Cocaine use

C. Cigarette smoking

D. Obesity

Correct Answer: D. Obesity

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's presentation may raise suspicion for gastrointestinal conditions like peptic ulcer disease (PUD). Risk factors of PUD: .Helicobacter pylori infectiojn (Option A ruled out) Any substabce abuse like alcohol, cigarette smoking (Option C ruled out) , cocaine use (Option B ruled out) , tobacco. Obesity is not typically a common risk factor for PUD. (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 770

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 55-year-old female with traumatic brain injury undergoes emergency craniotomy and is now intubated in the neurosurgical ICU. She suddenly develops hematemesis despite stabilisation. What is the most likely cause of the patient's bleeding? (Q845205)

A. Curling ulcer

B. Cushing ulcer

C. Gastric antral vascular ectasia (GAVE)

D. Dieulafoy lesions

Correct Answer: B. Cushing ulcer

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: In the given scenario, the patient's acute onset hematemesis following a traumatic brain injury and neurosurgical intervention suggests the likely development of a stress-related ulcer, particularly a Cushing ulcer. Feature Cushing's Ulcers (Option B) Curling Ulcers (Option A) Location Usually found in the stomach (cardia), oesophagus, or duodenum Typically occur in the proximal duodenum Associated condition Elevated intracranial pressure (e.g., head trauma, intracranial haemorrhage) Severe burns (involving >30% of body surface area) or trauma Pathogenesis Increased vagal activity stimulates gastric acid secretion, leading to ulcer formation. Result from decreased mucosal blood flow due to systemic hypotension or stress-induced vasoconstriction Ulcer

characteristics Deep ulcers; increased risk of perforation. Superficial ulcers.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 766

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A 55-year-old male presents to the gastroenterology clinic with complaints of persistent abdominal pain, nausea, and unintentional weight loss over the past three months. His medical history is significant for peptic ulcer disease and he is a former smoker. An upper endoscopy reveals multiple gastric lesions, and a biopsy is taken for histological examination. The results indicate the presence of gastric adenocarcinoma, and positive for Helicobacter pylori. Which protein produced by Helicobacter pylori is primarily associated with this condition? (Q845199)

A. Urease

B. CagA

C. SRC

D. SHP2

Correct Answer: B. CagA

Explanation: CagA (Cytotoxin-associated gene A): CagA, secreted by H.pylori alters signaling pathways in the gastric epithelial cells, leading to increased inflammation and cell proliferation, leading to the development of gastric cancer. Urease(Option A): This enzyme helps H. pylori survive in the acidic environment of the stomach by neutralizing gastric acid. Although urease is important for colonization and inflammation, it does not have a direct role in the mechanisms leading to gastric cancer. SRC and SHP2 are involved in the downstream pathways of CagA signaling, but are not produced by H.pylori. (Options C and D).

[09_Gastrointestinal Tract] 041 Intestinal Polyps And Intestinal Carcinoma - I — Quick Jump

Q1 (p. 1937) *Q2 (p. 1938)* *Q3 (p. 1939)* *Q4 (p. 1941)* *Q5 (p. 1942)* *Q6 (p. 1943)*
Q7 (p. 1945) *Q8 (p. 1946)* *Q9 (p. 1947)* *Q10 (p. 1948)* *Q11 (p. 1949)* *Q12 (p. 1950)*
Q13 (p. 1951) *Q14 (p. 1952)*

Q1: During a routine colonoscopy of a 60-year-old male, a small polyp is identified in the colon. Subsequent biopsy results confirm the presence of a hyperplastic polyp. Which characteristic is typically associated with this condition? (Q845256)

A. Commonly found in the right colon

B. Pathogenesis involves increased epithelial cell turnover

C. Lacks malignant potential

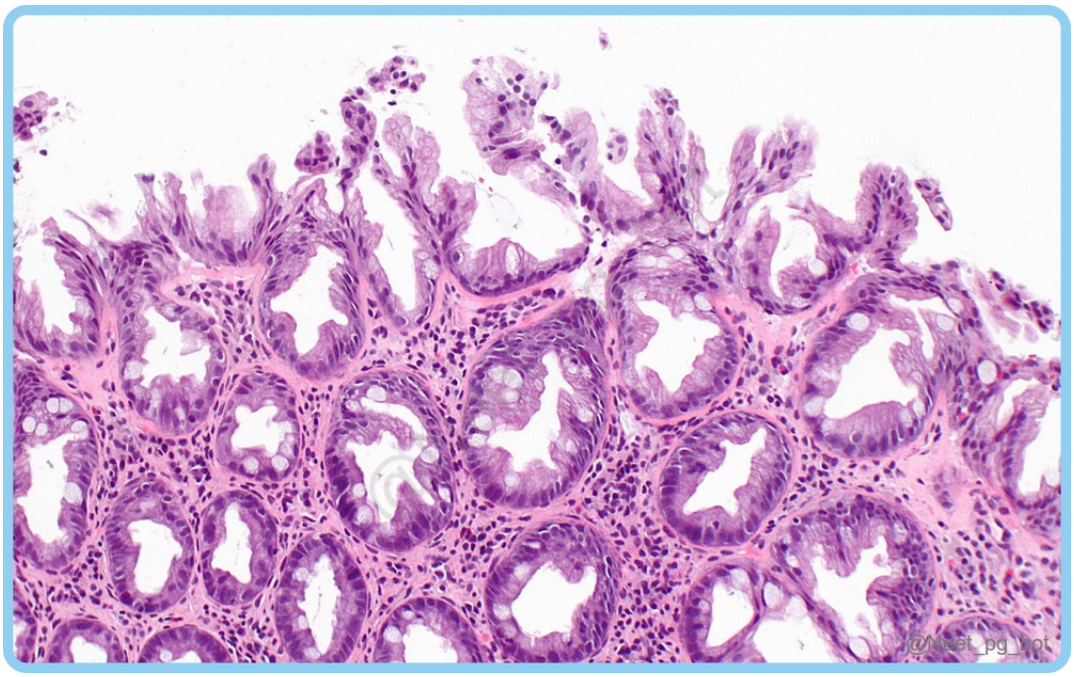
D. Histologically composed of immature goblet cells

Correct Answer: C. Lacks malignant potential

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The characteristic of hyperplastic polyps is that they lack malignant potential. Hyperplastic polyps: Lacks malignant potential Benign epithelial proliferations occurring commonly in the 6th-7th decade. Formed due to decreased epithelial cell turnover and delayed shedding, resulting in a piling up of goblet and absorptive cells. (Option B) Usually less than 5 mm with a smooth, nodular appearance and commonly found in the left colon. (Option A) Mature goblet cells and absorptive cells with serrated surface architecture are hallmark findings. (Option D)



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 807

↑ *Back to this question in Part A*

@Neet_pg_bot

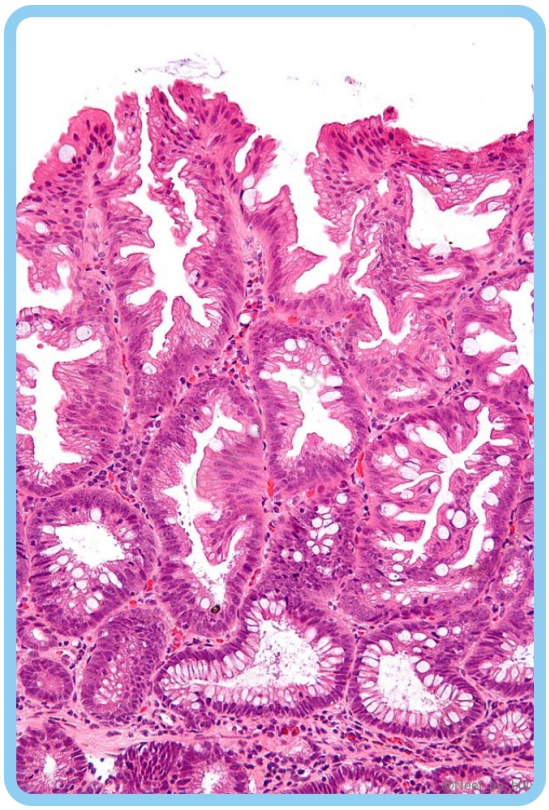
Q2: A 55-year-old man undergoes a routine colonoscopy. During the procedure, a polyp is discovered. Histological examination reveals serrated architecture, as shown in the image. Which of the following is true about this polyp? (Q845259)

A. It has malignant potential

B. Predominantly found in the left colon

C. Serrated architecture is limited to the surface of the lesions

D. Do not require surveillance or follow-up after detection



Correct Answer: A. It has malignant potential

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above image shows serrations throughout the full length of the glands including crypt base which is suggestive of sessile serrated adenoma which has malignant potential. Sessile Serrated Adenomas (SSA): Exhibit serrated architecture throughout the full length of the gland while hyperplastic polyps have serrated architecture only in the upper third of the crypt. (Option C) It has malignant potential More commonly located in the right colon. (Option B) Lack typical cytologic features of dysplasia found in other adenomas. Early precursor lesions in the serrated neoplasia pathway. Associated with BRAF-mutated colorectal carcinomas. Require follow-up surveillance for monitoring changes or growth. (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 811, 812, 807

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 4-year-old girl presents to the OPD with complaints of rectal bleeding and abdominal pain for the past six months. Investigations reveal approximately 40 hamartomatous colon polyps. The biopsy shows cystic spaces with dilated glands filled

with mucin and inflammatory debris. What is the most likely diagnosis for this patient? (Q845265)

A. Familial adenomatous polyposis

B. Adenocarcinoma colon

C. Juvenile polyposis syndrome

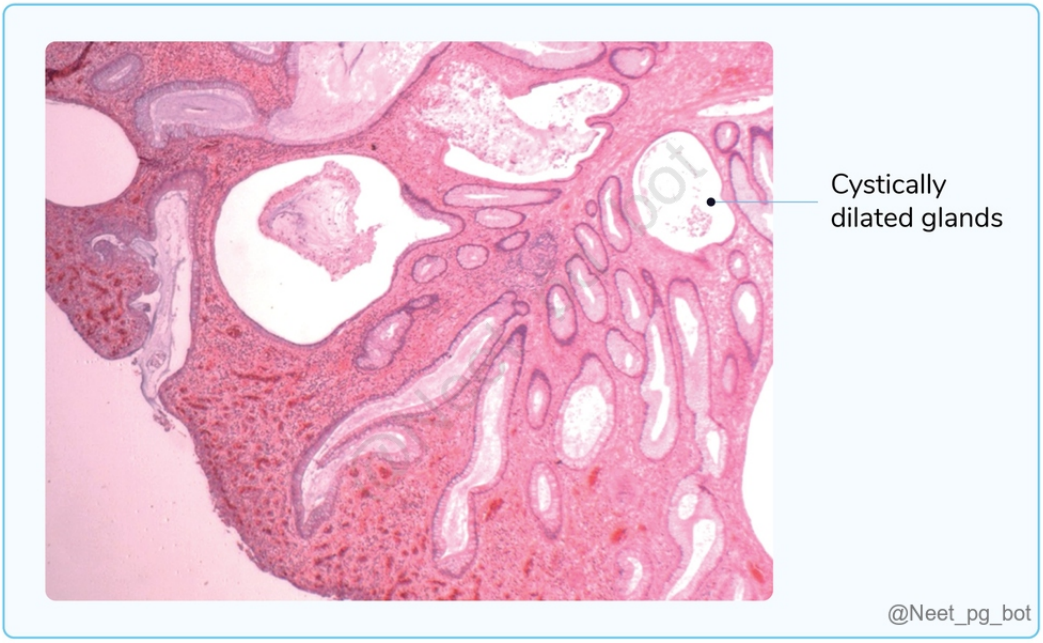
D. Sessile Serrated Adenoma

Correct Answer: C. Juvenile polyposis syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical presentation and investigation findings suggests a possible diagnosis of Juvenile Polyposis Syndrome (JPS). Juvenile polyposis Syndrome Primarily affects children under 5 years old. Autosomal dominant inheritance Can be sporadic or syndromic. Sporadic: Single polyps. Syndromic: 3-100 polyps. Linked to mutations in the SMAD4 and BMPR1A genes, part of the TGF-β signaling pathway. Pedunculated polyp which is usually less than 3 cm in diameter. Contains cystic spaces filled with mucin and inflammatory debris. Extra-intestinal manifestations include congenital malformations, digital clubbing.



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 808-809

↑ *Back to this question in Part A*

@Neet_pg_bot

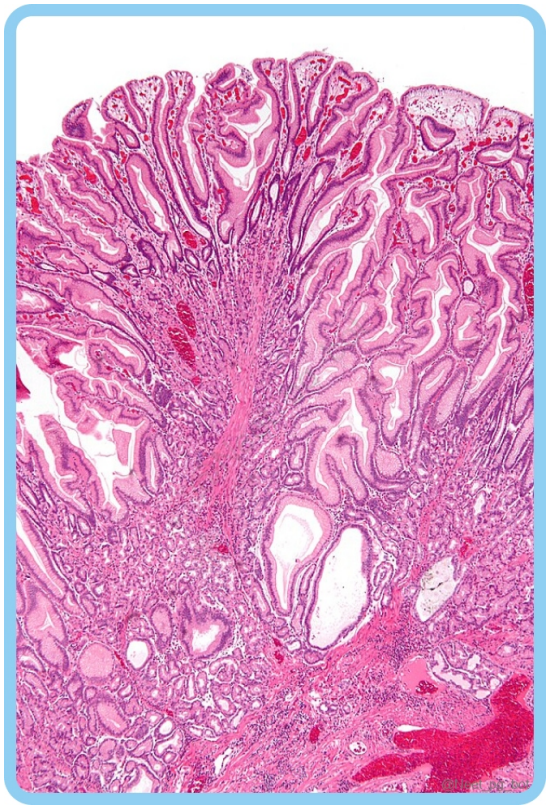
Q4: A 13-year-old female presents to the OPD due to abdominal pain and blood in stools. On examination, she had pigmented macules on her lips and oral mucosa. Endoscopy reveals multiple large, pedunculated polyps in the small intestine which shows an arborizing pattern of smooth muscle and glands lined by normal epithelium. Which of the following statements is incorrect about this condition? Autosomal dominant disorder Polyps are more common in the colon Increased risk of developing colon, pancreatic, and breast cancers Gain-of-function mutation in STK11 gene (Q845268)

A. 1 and 2

B. 2 and 4

C. 3 and 4

D. 1 and 3



Correct Answer: B. 2 and 4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical scenario and histological findings point towards the diagnosis of Peutz-Jeghers syndrome. Peutz-Jeghers syndrome : Autosomal dominant disorder. (statement 1) Caused by a loss of function mutation in the STK11 gene (statement 4) Presents around 11 years of age. Characterized by: Gastrointestinal hamartomatous polyps especially in the small intestine (statement 2) Mucocutaneous hyperpigmentation (macules on lips, nostrils, buccal mucosa, and extremities). Polyps are large, pedunculated, and lobulated. Histology - an arborizing pattern of smooth muscle and glands lined by normal epithelium. Significantly increased cancer risk (statement 3) Gastrointestinal tract, pancreas, breasts, gonads, and uterus. Lifetime cancer risk estimated at 40%

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 809

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 58-year-old female presents with weight loss, nail changes, alopecia, and skin hyperpigmentation. Colonoscopy reveals multiple hamartomatous polyps in the intestine. Family history is negative for intestinal cancers. What is the most likely diagnosis? (Q845281)

A. Tuberous sclerosis

B. Bannayan-Ruvalcaba-Riley Syndrome

C. Cowden syndrome

D. Cronkhite-Canada Syndrome

Correct Answer: D. Cronkhite-Canada Syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and multiple noncancerous polyps in the colon, coupled with a lack of family history of similar symptoms suggests Cronkhite-Canada Syndrome (CCS). Cronkhite-Canada syndrome Rare, non-hereditary condition Mean age of presentation: >50 years Characterized by: Widespread non cancerous/hamartomatous gastrointestinal polyposis Cutaneous changes - alopecia, hyperpigmentation) Nail dystrophy Polyps: Symptoms: Malabsorption, diarrhea, weight loss Tuberous sclerosis (Option A) is a neurocutaneous disorder resulting from mutations in the TSC1 (hamartin) or TSC2 (tuberin) genes. Patients exhibit neurological symptoms like seizures, along with skin abnormalities. The syndrome also includes hamartomatous polyps in the intestine. Bannayan-Ruvalcaba-Riley Syndrome (Option B) is a genetic condition characterized by macrocephaly, intestinal hamartomatous polyps and pigmented maculae of the glans penis. Cowden syndrome (Option C) is caused by mutation of PTEN gene on chromosome 10. It is associated with multiple hamartomatous polyps, benign skin tumors like trichilemmoma and an increased risk of breast, thyroid, and endometrial cancers.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 809

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 20-year-old man with a family history of colorectal carcinoma presents with chronic abdominal discomfort and occasional rectal bleeding.Upon further evaluation, a mutation in APC gene is identified leading to a diagnosis of Familial Adenomatous Polyposis. Which of the following statement is true regarding FAP? (Q845282)

A. Mutation in 6th chromosome

B. 50 % risk of colon cancer if untreated

C. Presence of a minimum of 100 polyps

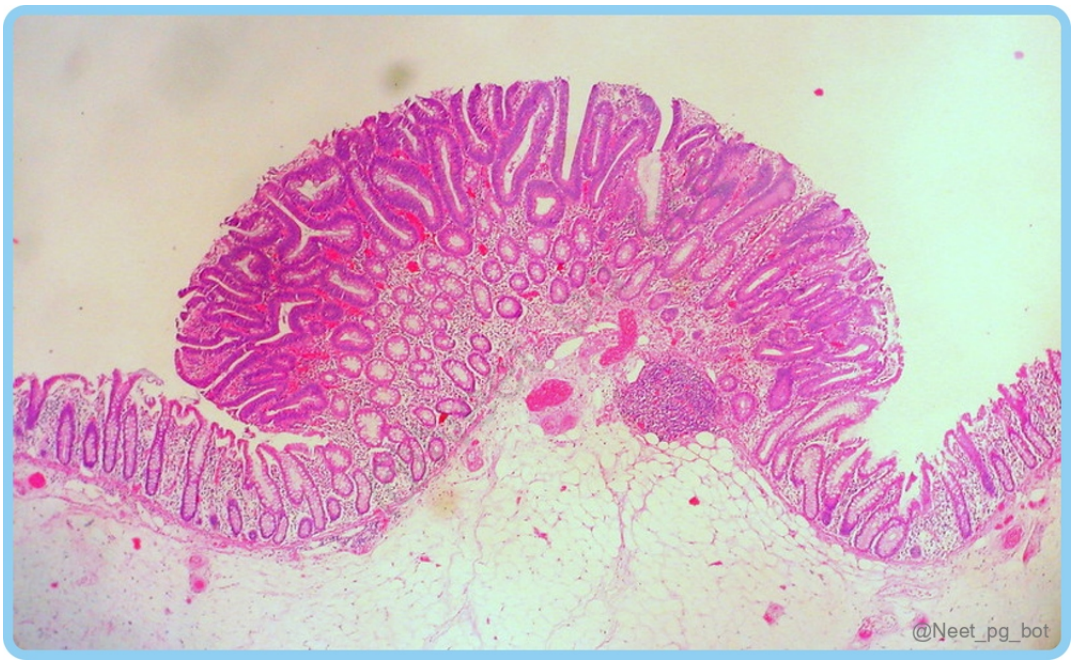
D. Congenital atrophy of the retinal pigment epithelium

Correct Answer: C. Presence of a minimum of 100 polyps

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Classic FAP is characterized by the presence of a minimum of 100 polyps Familial Adenomatous Polyposis (FAP) Autosomal dominant disorder caused by APC gene mutations on chromosome 5 (Option A) Numerous intestinal polyps develop Classic FAP: Diagnosed with at least 100 polyps (Option C) Almost 100% risk of colorectal cancer if untreated (Option B) Commonly develops by 30 years, almost always by 50 years Attenuated FAP (AFAP): Primarily affects the proximal colon Fewer polyps (average <30 polyps) Associated with congenital hypertrophy of the retinal pigment epithelium (Option D) Standard treatment: Prophylactic colectomy to prevent colorectal cancer Post-colectomy risks: Cancer at extracolonic sites, including the ampulla of Vater and stomach



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 812

https://www.uptodate.com/contents/clinical-manifestations-and-diagnosis-of-familial-adenomatous-polyposis?

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 28-year-old woman presents with a history of unexplained weight loss along with multiple sebaceous cysts on her face and scalp. She has a family history of colorectal cancer. Upon further examination, she is found to have a bony lesion on her jaw. What is the most likely diagnosis? (Q845283)

A. Turcot syndrome

B. Gardner syndrome

C. Lynch syndrome

D. MUTYH Associated Polyposis (MAP)

Correct Answer: B. Gardner syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical findings given suggest Gardner syndrome as a possible diagnosis. Gardner syndrome An autosomal dominant condition Characterized by colonic polyposis and extracolonic manifestations Due to mutations in APC gene Predisposition to colo-rectal cancer present Extracolonic manifestations include Osteomas (commonly in skull and mandible) Supernumerary teeth Epidermoid cysts Fibromas Thyroid and desmoid tumors Supernumerary teeth Option A) Turcot syndrome: Turcot syndrome can also arise from mutations in APC genes. But, there is association with brain tumors along with colorectal cancer Option C) Lynch syndrome: AKA HNPCC(hereditary non polyposis colorectal cancer) Autosomal dominant condition due to mutations in MLH 1 and MSH 2 Characterized by increases risk of colorectal cancer, endometrial, ovarian, uterus and Pancreatic cancers Option D) MUTYH Associated Polyposis (MAP) Rare autosomal recessive disorder due to mutations in the MUTYH gene. Occurs later in life compared to other polyposis syndromes Involves fewer than 100 polyps and individuals with MAP have an increased risk of colorectal cancer. Unlike Gardner syndromes, MAP is not associated with osteomas or epidermoid cysts.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 809, 813

Gardner syndrome - UpToDate

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 6 cm polyp is identified in the descending colon during a routine colonoscopy. Histological examination reveals villous architecture with high-grade dysplasia. Based

on this scenario, which factors most strongly correlate with the risk of malignancy in colorectal adenomas? (Q845284)

A. Presence of villous architecture

B. Size of the adenoma

C. Histologic grade of dysplasia

D. Location within the gastrointestinal tract

Correct Answer: B. Size of the adenoma

Explanation: The size of colorectal adenomas is the most critical factor associated with the risk of malignancy. Larger adenomas are most likely to develop into invasive carcinoma Adenomas larger than 4 cm in diameter have nearly a 40% chance of containing invasive cancer. Villous architecture (Option A) : Villous adenomas are associated with a higher incidence of cancer than tubular adenomas, but this correlation primarily arises from their larger size rather than their architectural characteristics alone. Histologic grade of dysplasia(Option C): High-grade dysplasia within an individual polyp increases its risk of harboring cancer. However, histologic grade of dysplasia is not the primary factor correlating with the overall risk of malignancy across adenomas. Gastrointestinal tract location (Option D): While certain types of polyps may have preferences for specific locations within the gastrointestinal tract (e.g., sessile serrated lesions are more common in the right colon), location alone is not the strongest predictor of malignancy in colorectal adenomas.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 810 - 811

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A patient underwent genetic testing after being diagnosed with colon cancer. Testing reveals a mutation associated with Hereditary Nonpolyposis Colorectal Cancer (HNPCC). Which of the following genes is defective in this patient? (Q845285)

A. SMAD4, BMPR1

B. STK11

C. APC, MUTYH

D. MLH1, MSH2

Correct Answer: D. MLH1, MSH2

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hereditary Nonpolyposis Colorectal Cancer (HNPCC), also known as Lynch syndrome, is caused by inherited mutations in DNA mismatch repair (MMR) genes: MSH2 and MLH1. Genes mutation Manifestation MLH1, MSH2 (Option D) Results in microsatellite instability Causes cluster of cancer: Colorectal, Endometrial, Ovarian, Pancreatic cancers Colon cancer develops at a young age and it usually occurs in the right side SMAD4 and BMPR1 (Option A) Juvenile polyposis syndrome STK11 (Option B) Peutz-Jeghers syndrome APC gene (Option C) Familial Adenomatous Polyposis(FAP), sporadic colon cancer, Gardner syndrome and Turcot syndrome MUTYH (Option C) MUTYH-associated polyposis.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 809, 813

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 55-year-old male presents to the clinic with complaints of recurrent abdominal discomfort and changes in bowel habits over the past few months. Further investigation with colonoscopy confirmed the presence of adenocarcinoma. Which of the following factors is most closely associated with this condition? (Q845286)

A. Use of aspirin

B. Estrogen replacement therapy

C. High intake of unabsorbable vegetable fiber

D. High consumption of red meat

Correct Answer: D. High consumption of red meat

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: High consumption of red meat is associated with increased risk of adenocarcinoma of the colon Factors increasing the risk Factors decreasing the risk Low fiber, high fat diet High intake of red meat and processed meat Increased calorie intake and obesity Family history of colon cancer Personal history of adenomas Smoking and alcohol Inflammatory bowel disease Lynch syndrome FAP Acromegaly Pelvis irradiation Streptococcus bovis septicemia Ureterosigmoidoscopy High fiber diet Intake of fish (omega-3 fatty acids), fruits and vegetables (Vit A, C, E) NSAID use, particularly Aspirin Folic acid Calcium Hormone replacement therapy

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 814

https://www.uptodate.com/contents/epidemiology-and-risk-factors-for-colorectal-cancer

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 55-year-old female presents with abdominal pain, changes in bowel habits, unintended weight loss. A previous colonoscopy showed a polyp, but a recent one confirmed colorectal adenocarcinoma. Which gene mutations are characteristically associated with development of colorectal adenocarcinoma? (Q845287)

A. APC, TGFBR2, SMAD2, and BAX

B. TP53, BRAF, TGFBR2, and BAX

C. APC, KRAS, SMAD4 and TP53

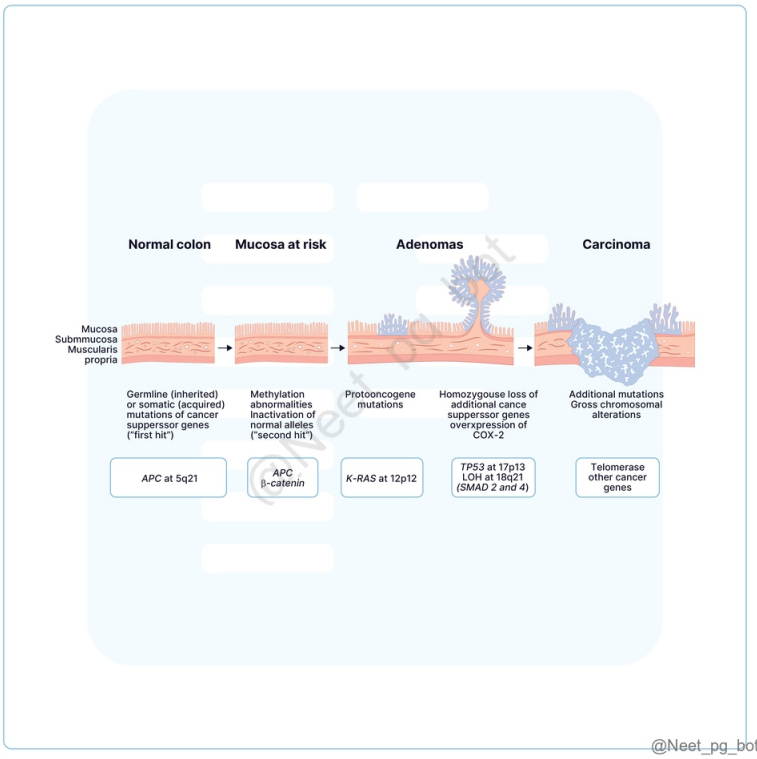
D. APC, KRAS, TP53, and MYC

Correct Answer: C. APC, KRAS, SMAD4 and TP53

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The genes associated with development of colorectal carcinoma are APC, KRAS, SMAD4 and TP53. Adenoma-Carcinoma Sequence: Accounts for up to 80% of sporadic cancers. APC Gene Mutations: Leads to β-catenin accumulation and Wnt pathway activation. "First hit": Sporadic inactivation of APC. "Second hit": Loss of second APC copy KRAS Mutations: Promote growth and prevent apoptosis. SMAD2 and SMAD4 Mutations: Disrupt TGF-β pathway, causing uncontrolled proliferation. TP53 Mutations: Occur in later stages of tumor progression.



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 815

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 45-year-old female presents with abdominal pain, changes in bowel habits, and weight loss. Her mother and aunt were diagnosed with endometrial and ovarian cancer in their 50s. A colonoscopy and a biopsy confirm well-differentiated adenocarcinoma. Which genetic pathway is most likely associated with adenocarcinoma in this patient? (Q845290)

A. APC/β-catenin pathway

B. TGF-β signaling pathway

C. DNA mismatch repair pathway

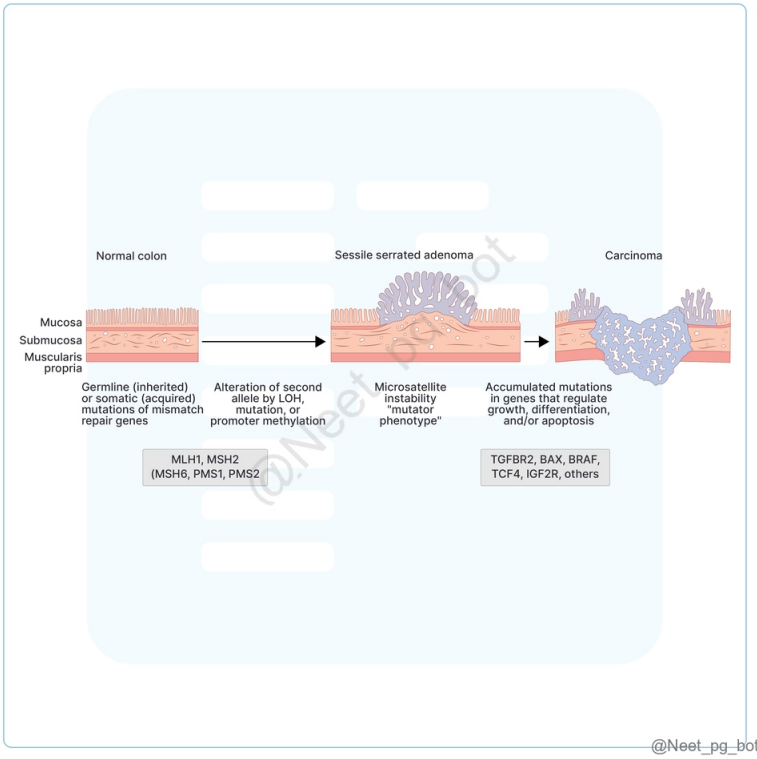
D. BAX pathway

Correct Answer: C. DNA mismatch repair pathway

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient's family history of endometrial and ovarian cancer, combined with her well-differentiated adenocarcinoma, suggests Lynch syndrome (HNPCC) which is associated with DNA mismatch repair pathway Lynch syndrome occurs due to germline mutations in DNA mismatch repair (MMR) genes resulting in microsatellite instability (MSI) Option A: APC/β-catenin pathway: This is commonly associated with the classic adenoma-carcinoma sequence in colorectal adenocarcinoma. Options B & D): TGF-β signaling pathway and pro-apoptotic protein BAX regulate cell growth, differentiation, and apoptosis. While these signalling pathways are alterations in colorectal cancer, they are not commonly associated with MSI or Lynch syndrome.



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 815

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following is the most common site of metastasis for colon adenocarcinoma? (Q845291)

A. Brain

B. Lungs

C. Bones

D. Liver

Correct Answer: D. Liver

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The liver is the most common site of distant metastasis for colon adenocarcinoma. This is due to the portal venous drainage of the colon, which allows cancer cells to spread easily to the liver. Other sites :Lymph nodes, lungs, and bones can metastasize Prognostic factors Depth of invasion Lymph node metastases. Colon adenocarcinoma: Prevalence It is the most common (M/c) type of intestinal carcinoma. Risk Factors High fat, low fiber, alcohol, smoking, FAP, HNPCC (Lynch Syndrome), and inflammatory bowel diseases (Ulcerative Colitis, Crohn's). Protective Factors Omega-3 fatty acids and NSAIDs are considered protective. Diagnostic Gold Standard Biopsy and Histopathology. Prognostic Factors Lymph node metastasis and the depth of invasion. Pathogenic Mechanisms: Colonic adenocarcinoma develops through multistep carcinogenesis via several distinct pathways: Adenoma-Carcinoma Sequence (Mnemonic: AK53): Involves a progression from APC mutation (2 Hits) → KRAS → p53, SMAD 2 & 4 → Telomere activation. Sessile Serrated Adenoma (SSA) Pathway: Characterized by MMR (Mismatch repair gene) defects (MLH1, MSH2,6, PMS1,2) leading to Microsatellite Instability (MSI) and BRAF mutation. CIMP-BRAF: Features CpG island hypermethylation phenotype (CIMP) leading to MSI and BRAF mutation without an initial MMR mutation. CIMP-KRAS: Involves CIMP leading to KRAS mutation; notably, this pathway does not involve MSI or MMR mutations. Clinical presentation by location: Feature Proximal (Right-Sided) Distal (Left-Sided) Appearance Proliferative mass with a "cauliflower" appearance. "Napkin ring" appearance. Primary Symptoms Occult blood loss leading to Iron Deficiency Anemia (IDA). Occult bleeding and significant changes in bowel habits. Diagnosis and Staging: Barium Enema: May show a characteristic "apple core" deformity . Tumor Marker: CEA (Carcinoembryonic antigen) is the primary marker used. Screening: Occult blood testing in stool is performed using the Guaiac test . Staging System: Duke's staging is utilized to categorize the extent of the cancer.

↑ *Back to this question in Part A*

@Neet_pg_bot

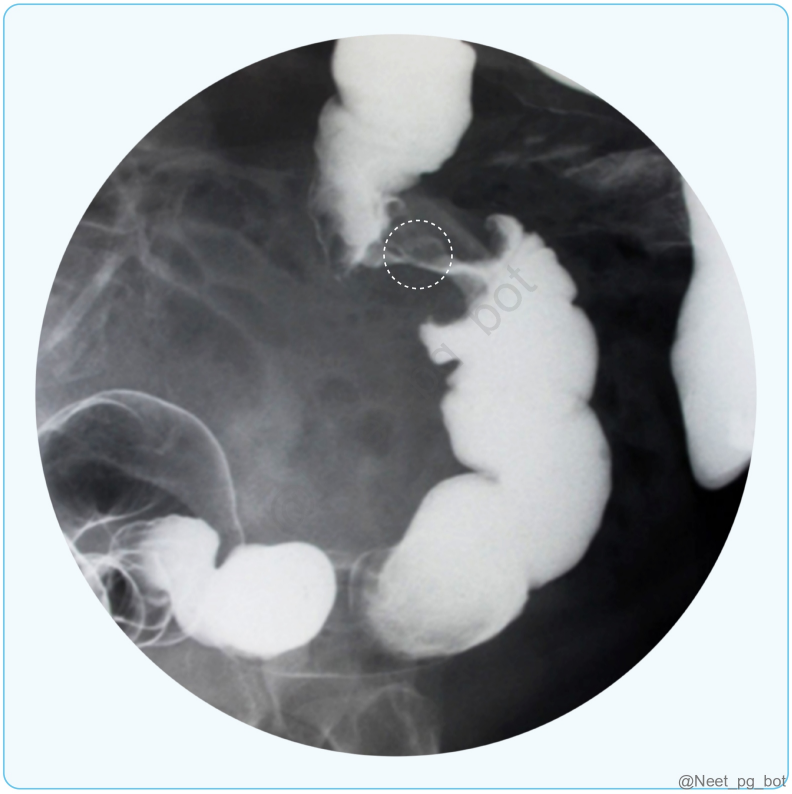
Q14: A 60-year-old male presents with abdominal pain, altered bowel habits and 5kg weight loss in one month. A barium enema study showed the following finding. Which of the following statements is true about the patient's condition? (Q845293)

A. Presents asweakness due to iron deficiency anemia

B. Leads to a napkin-ring constriction and luminal narrowing

C. Growth tends to be polypoidal (growth is into the wall of the intestine?)

D. HPE commonly shows signet-ring cells



Correct Answer: B. Leads to a napkin-ring constriction and luminal narrowing

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Distal colorectal carcinoma leads to formation of a napkin ring constriction and luminal narrowing which can be seen as an apple core appearance on barium enema study Proximal adenocarcinoma (masses on the caecum and ascending colon) Grow as polypoidal and exophytic masses which extend along one wall. (Option C) Present with occult anemia, causing late-stage weakness. (Option A) Distal Adenocarcinoma Equally distributed along the colon. Lesions are annular, causing napkin-ring constrictions and luminal narrowing.(Option B) Barium study - apple core appearance Present early with changes in bowel habits, Hematochezia, cramping, left lower quadrant pain. Cell Composition: Tall columnar cells resembling dysplastic epithelium in adenomas. Mucinous Adenocarcinoma:Contains signet-ring cells producing abundant mucin. They are rare and associated with poor

prognosis. (Option D)

Q13 (p. 1973) *Q14 (p. 1974)*

Q1: A 47-year-old male presents with chronic diarrhoea, unintentional weight loss, joint pain, pallor, and generalised weakness. Upper GI endoscopy and biopsy revealed characteristic histopathological findings suggestive of Whipple's disease. Which of the following histopathological features would have led to the diagnosis? (Q845296)

A. Foamy macrophages filled with PAS-positive granules

B. Villous atrophy and blunting of the small intestinal mucosa

C. Lymphoplasmacytic infiltrate in the lamina propria

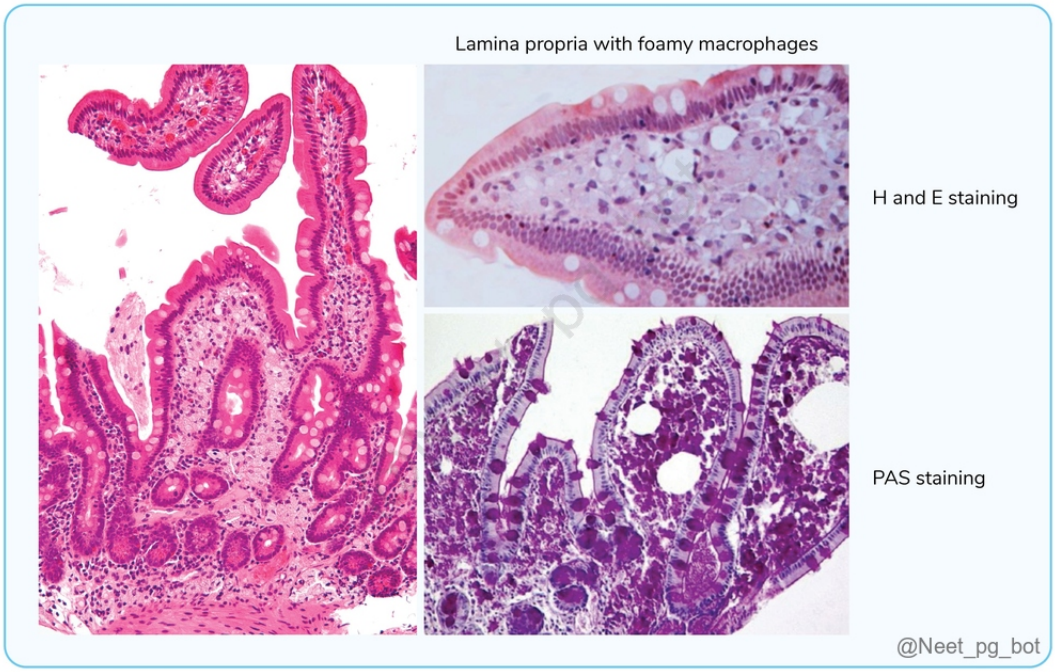
D. Presence of caseating granulomas and acid-fast bacilli

Correct Answer: A. Foamy macrophages filled with PAS-positive granules

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Whipple's disease is a malabsorption problem: Nothing will get absorbed from the intestine, especially fats, leading to Steatorrhea. Whipple’s disease: Feature



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 794

↑ *Back to this question in Part A*

@Neet_pg_bot

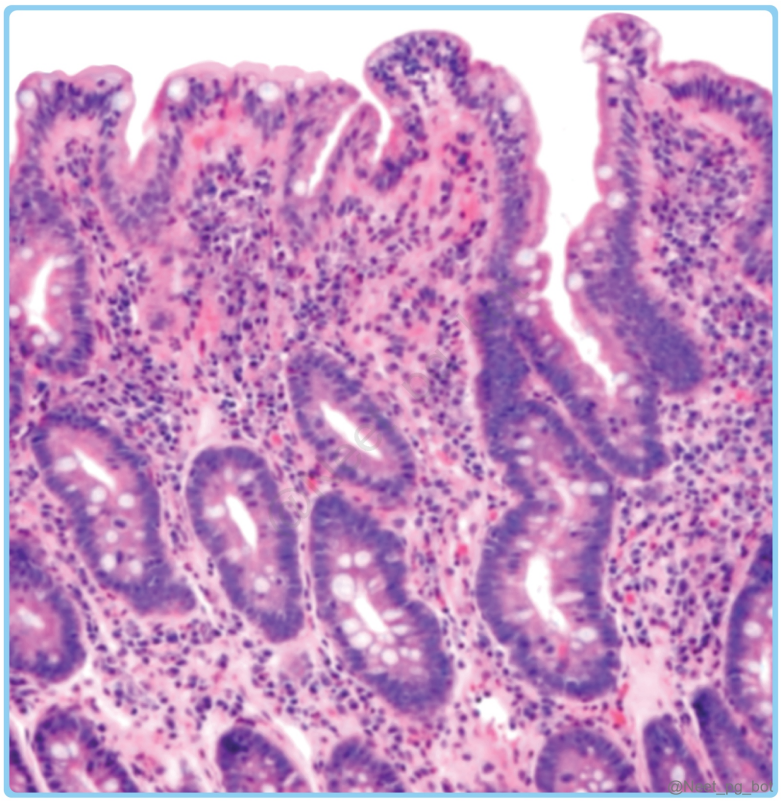
Q2: A 35-year-old female presents with chronic diarrhoea, abdominal bloating, and unintended weight loss. She reports discomfort after consuming gluten-containing foods. Laboratory tests show elevated tissue transglutaminase (tTG) and anti-endomysial antibodies (EMA) levels, prompting a small intestinal biopsy via upper endoscopy. Which of the following combinations of histopathological features will be seen in this condition? Intraepithelial CD8+ T Lymphocytes Crypt hyperplasia Villous atrophy Decreased mitotic activity Inflammatory cell infiltration in lamina propria (Q845302)

A. 1, 2, 3

B. 1, 2, 3, 4

C. 2, 4, 5

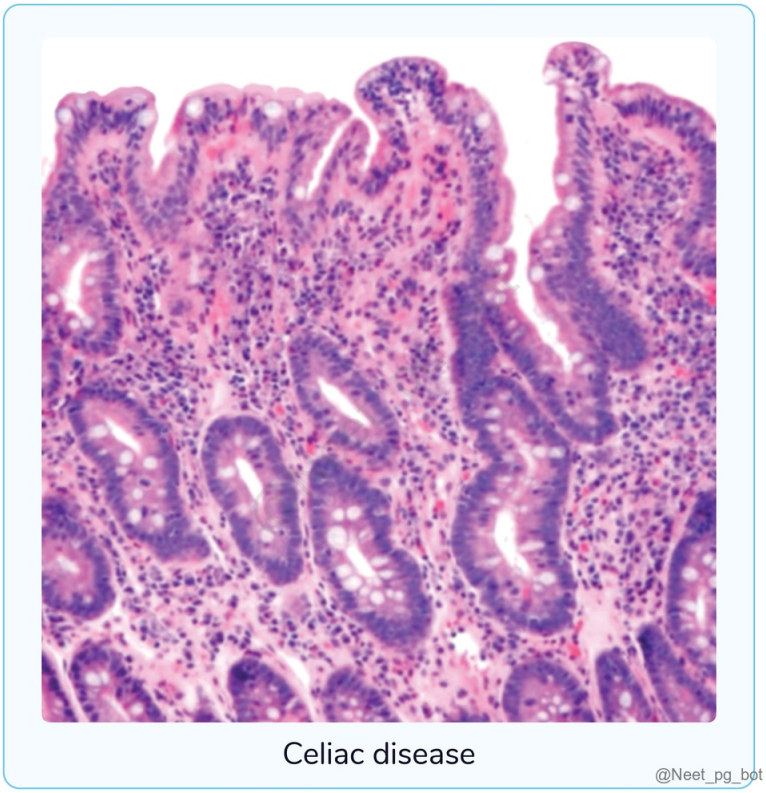
D. 1, 2, 3, 5



Correct Answer: D. 1, 2, 3, 5

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical scenario is classic for Celiac disease , an autoimmune disorder triggered by gluten ingestion , confirmed by: Positive anti-tTG and anti-EMA antibodies Small bowel biopsy is the gold standard for diagnosis Marsh criteria of celiac disease: Because the antibodies are formed due to consumption of gluten, they first attack the villi of intestine (Villous atrophy) Histopathological features in Celiac disease: Feature Seen in Celiac?



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 785

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 45-year-old woman presents to the clinic with a history of chronic abdominal pain and diarrhoea, worsening notably after consuming wheat-based foods. Physical examination reveals signs suggestive of malabsorption. Considering celiac disease as a possible diagnosis, which of the following statements regarding its pathogenesis is NOT correct? (Q845306)

A. Gliadin peptides in the lamina propria are deamidated by tissue transglutaminase.

B. HLA-DR2 or HLA-DR8 significantly influences celiac disease susceptibility.

C. Gliadin peptides may induce epithelial cells to express IL-15, activating CD8+ lymphocytes.

D. Type 1 diabetes, Sjögren syndrome, and IgA nephropathy are associated with celiac disease.

Correct Answer: B. HLA-DR2 or HLA-DR8 significantly influences celiac disease susceptibility.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Celiac disease (aka celiac sprue or gluten-sensitive enteropathy) is an immune-mediated condition triggered by consuming foods containing gluten, such as barley, rye, oats, and wheat. It is influenced by HLA-DQ2 or HLA-DQ8 , not HLA-DR2 or HLA-DR8 Gliadin is released when these patient consumes gluten. Pathogenesis of Celiac disease: Gliadin peptides ↓ Deamidated by Tissue transglutaminase (TTG) enzyme of intestine ↓ IL-15 expression ↓ CD8+ t-lymphocytes activated ↓ Epithelial damage Genetic variations may link celiac disease to other immune disorders, such as type 1 diabetes, thyroiditis, Sjogren syndrome, and IgA nephropathy. (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 784, 785

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 35-year-old female who recently returned from a tropical region presents with persistent diarrhoea, weight loss, fatigue, anaemia, and vitamin deficiencies, along with a small intestine biopsy findings of villous atrophy and chronic mucosal inflammation. Which part of the gastrointestinal tract is typically NOT affected in this condition? (Q845307)

A. Duodenum

B. Jejunum

C. Ileum

D. Colon

Correct Answer: D. Colon

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario, with a history of returning from a tropical region and biopsy findings, points towards diagnosing Tropical enteropathy or Environmental enteropathy that does not affect the colon. This disease often occurs after E. coli infection. Tropical sprue: Predominantly affects the small intestine(duodenum, jejunum, and ileum) and presents with Iron deficiency anemia or megaloblastic anemia. Part of the small intestine Nutrient absorbed Duodenum Iron Jejunum Folic acid Ileum Vitamin B12

@Neet_pg_bot

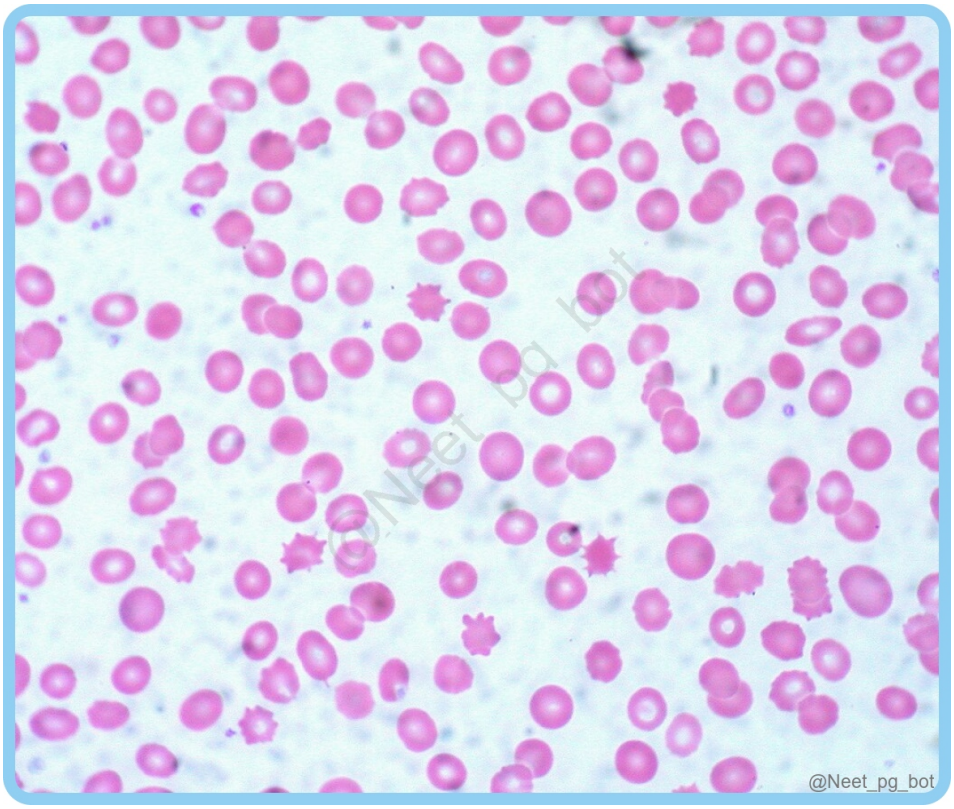
Q5: A 6-month-old infant presents with failure to thrive, chronic diarrhoea, and poor weight gain. A peripheral blood smear revealed a characteristic appearance, as shown in the image below. Biochemical investigations reveal very low levels of triglycerides, cholesterol, and fat-soluble vitamins. Which genetic mutation is most likely responsible for these findings? (Q845309)

A. APOB gene mutation

B. MTTP gene mutation

C. MYO5B gene mutation

D. LPL gene mutation



Correct Answer: B. MTTP gene mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical scenario and peripheral smear findings suggest Abetalipoproteinemia, caused by a mutation in Microsomal triglyceride transfer protein (MTTP), which is required for the transfer of lipids to nascent apolipoprotein B polypeptide in the endoplasmic reticulum. Abetalipoproteinemia: Aetiology Mutation in Microsomal triglyceride transfer protein (MTTP) Presentation Extremely low cholesterol and triglycerides Malabsorption of fat-soluble vitamins. Intestine shows lipid vacuoles because of problem in lipid transfer. Biochemical investigation Low triglyceride cholesterol levels Low fat soluble vitamin levels Symptoms Presents in infancy with failure to thrive, diarrhoea, and steatorrhea. Peripheral smear Presence of acanthocytes -RBCs with peripheral spikes

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 4-week-old infant presents with severe watery diarrhoea and failure to thrive since birth. Stool studies are negative for pathogens. A small bowel biopsy shows villous atrophy, cytoplasmic inclusion bodies within enterocytes, and reduction of microvilli on the enterocyte surface. Which of the following statements is true

regarding this condition? (Q845310)

A. It is characterised by the absence of ganglion cells in the distal part of the colon.

B. It is associated with mutations in the MYO5B or STX3 genes.

C. Histological findings include villous atrophy and crypt hyperplasia.

D. It is commonly caused by rotavirus infection, which leads to persistent diarrhoea.

Correct Answer: B. It is associated with mutations in the MYO5B or STX3 genes.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation suggests Microvillous Inclusion Disease (MVID). It is a rare autosomal recessive disorder characterised by severe, intractable watery diarrhoea from early infancy. It presents with inclusion bodies and reduction in microvilli. Aetiology: Mutations in the MYO5B or STX3 genes. It is characterised by the absence of ganglion cells in the distal part of the colon (Option A): Seen in Hirschsprung disease. Histological findings include villous atrophy and crypt hyperplasia (Option C): Seen in celiac disease or gluten insensitivity. It is commonly caused by rotavirus infection, which leads to persistent diarrhoea (Option D): Stool studies are negative for pathogen in this case.

@Neet_pg_bot

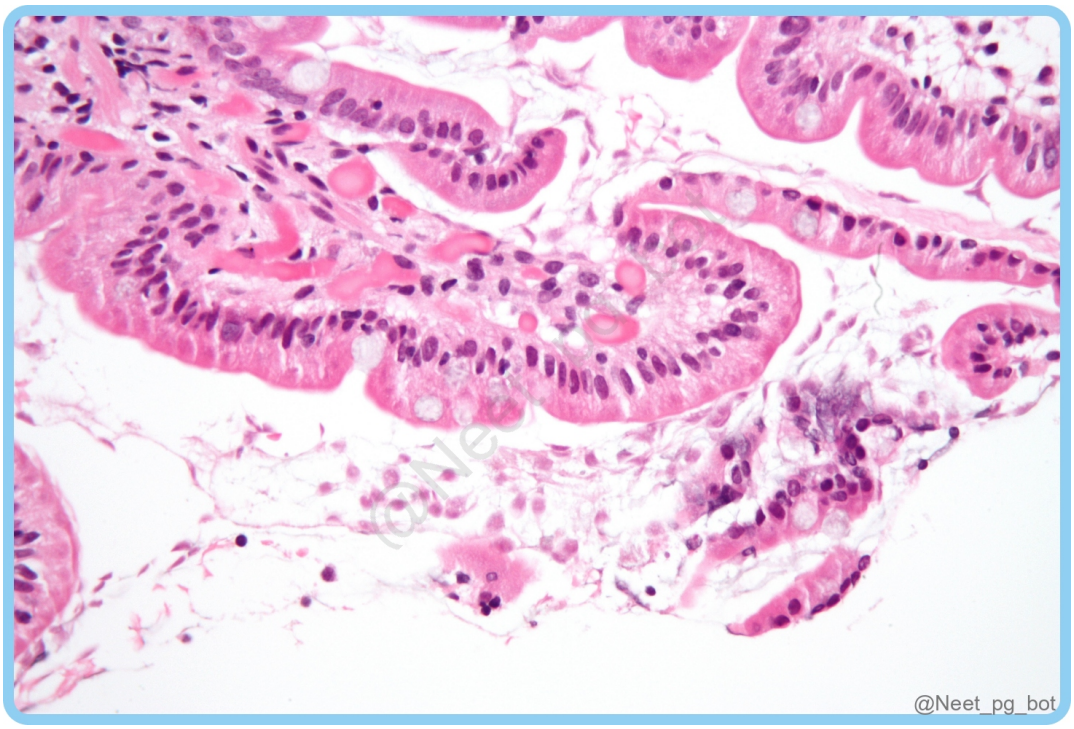
Q7: A 28-year-old female presents with foul-smelling, greasy diarrhoea, bloating, and abdominal cramps following a hiking trip in a remote area. Stool microscopy reveals cysts containing motile trophozoites. A duodenal biopsy shows luminal organisms, as shown in the image, without tissue invasion. Based on the clinical presentation and biopsy findings, what is the most likely causative organism? (Q845312)

A. Cryptosporidium

B. Tropheryma whipplei

C. Entamoeba histolytica

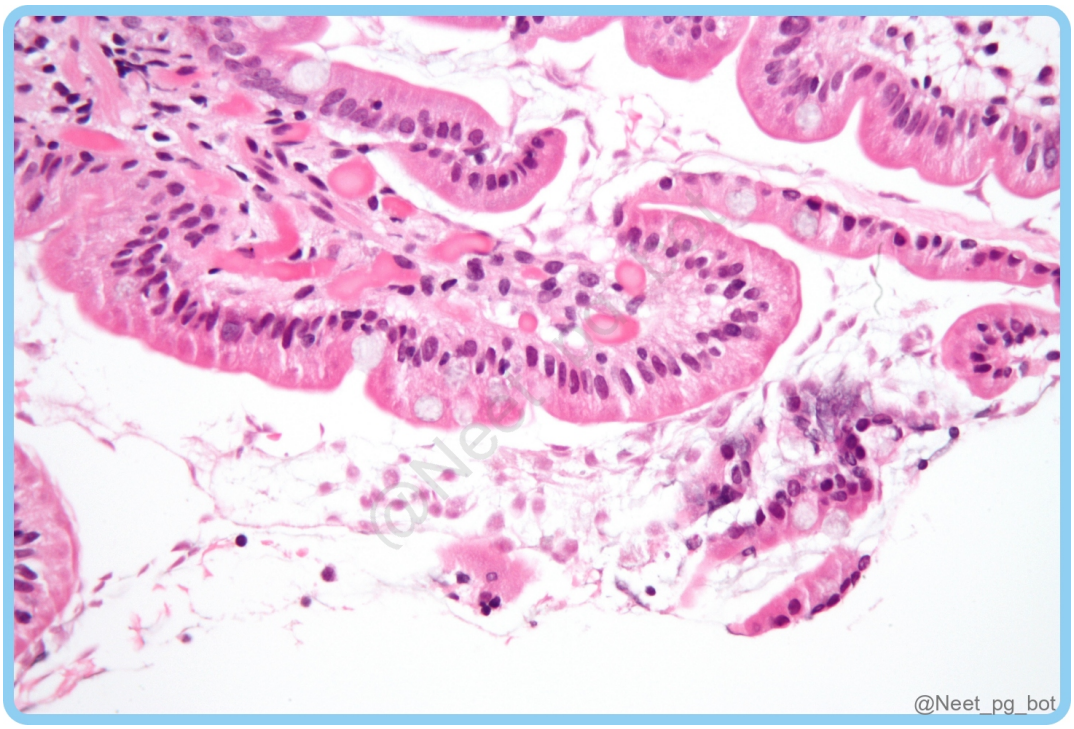
D. Giardia lamblia



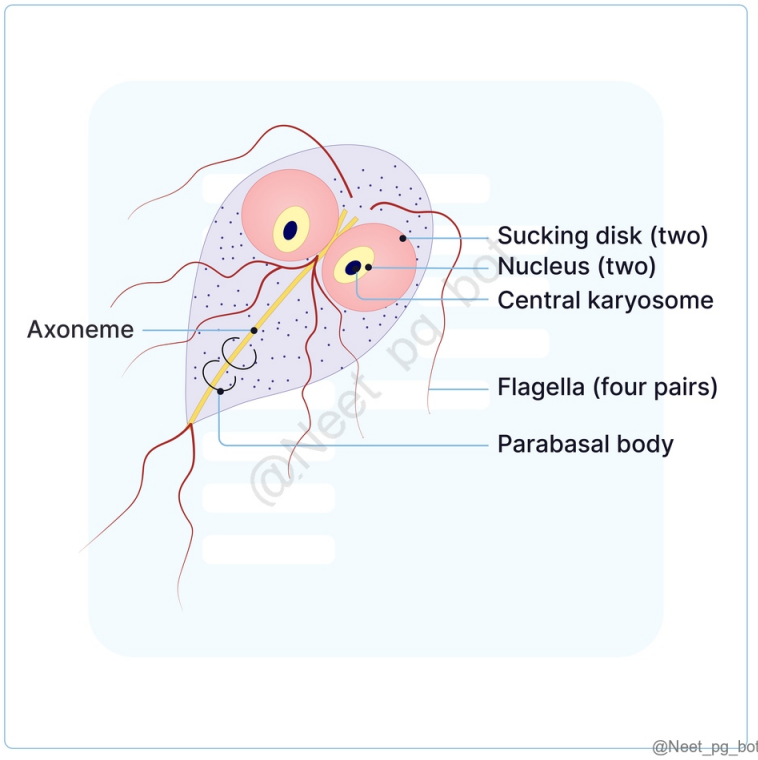
Correct Answer: D. Giardia lamblia

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The scenario is of Giardia lamblia infestation Giardia lamblia: Definition Flagellated protozoan parasite Commonly associated with contaminated water sources. Symptoms Foul-smelling-greasy diarrhoea Bloating Abdominal cramps. Biopsy findings Luminal organisms attached to the intestinal epithelium Blunting of the villi and inflammation without tissue invasion. Giardia trophozoites on biopsy are often described as resembling "falling leaves" {{caption_text}} Cryptosporidium (Option A) Coccidian parasite Usually present along brush border of the intestine. Causes watery diarrhoea, especially in immunocompromised individuals Tropheryma whipplei (Option B) Causes Whipple's disease Histology: PAS-positive foamy macrophages in the intestinal mucosa Entamoeba histolytica (Option C) Protozoan parasite It causes amoebic ulcer in intestine identified by flask shaped ulcers.



@Neet_pg_bot



Sucking disk (two)
Nucleus (two)
Central karyosome
Axoneme
Flagella (four pairs)
Parabasal body

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which type of ulcer is characterised by flask shaped, multiple punched-out ulcers with undermined edges and necrotic bases on histopathological examination? (Q845325)

A. TB ulcer

B. Typhoid ulcer

C. Amoebic ulcer

D. Peptic ulcer

Correct Answer: C. Amoebic ulcer

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: On histopathological examination, amoebic ulcers caused by Entamoeba histolytica present as multiple punched-out ulcers with undermined edges and necrotic bases (flask-shaped ulcers). The ulcers often have surrounding inflammation and contain trophozoites of Entamoeba histolytica. When Entamoeba histolytica goes to liver: It breaks the liver tissue into brown coloured pus known as Encovy sauce appearance TB ulcer (Option A): Transverse ulcer in direction. Typhoid ulcer (Option B): Longitudinal ulcer in direction.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 767, 791

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 60-year-old patient presents with severe diarrhoea and abdominal pain after completing a course of broad-spectrum antibiotics for a respiratory infection. Stool studies detect the presence of Clostridioides difficile (C. difficile) toxin. A colonoscopy revealed diffuse yellowish plaques covering the colonic mucosa, as shown in the image. Which inflammatory cell type predominantly infiltrates the lamina propria and surface epithelium in this condition? (Q845329)

A. Lymphocytes

B. Eosinophils

C. Neutrophils

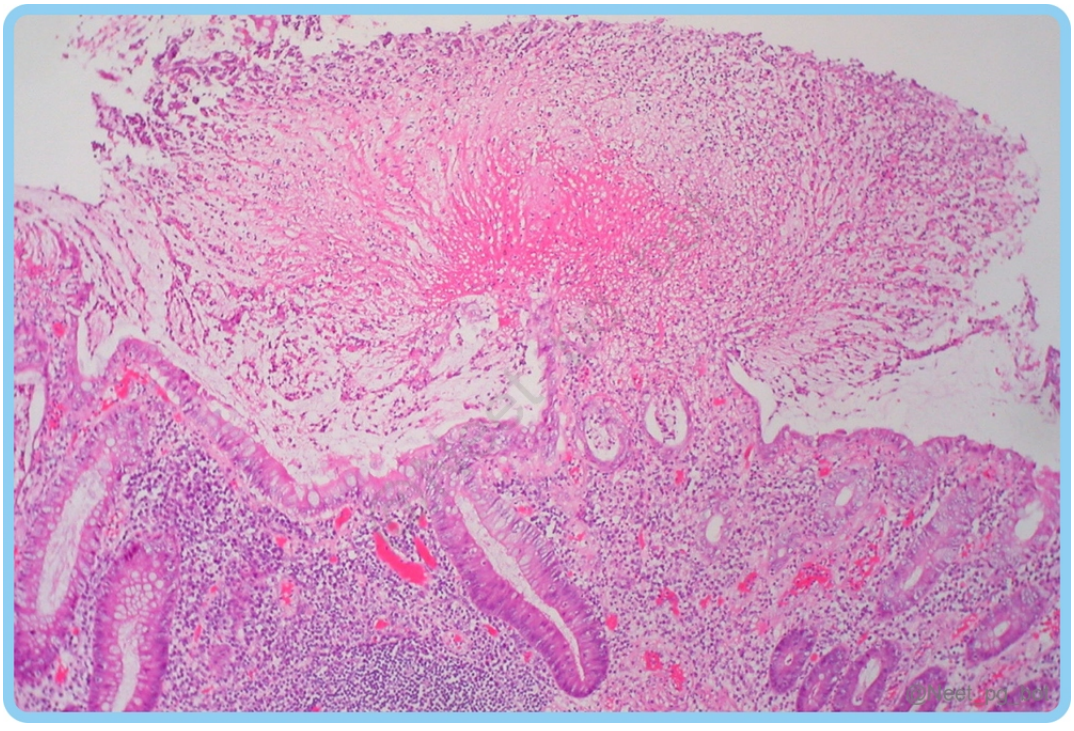
D. Plasma cells

Correct Answer: C. Neutrophils

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical condition suggests Pseudomembranous enterocolitis (PMEC). Pseudomembranous: On colonoscopy, diffuse yellowish plaques covering the colonic mucosa are seen. Enterocolitis: Inflammation of intestine Long term antibiotics alters the gut flora and makes person prone to C. difficile infection, which damages the intestine and forms pseudomembrane. Necrosis and damaged cells are always associated with neutrophilic infiltrations (Option C) Patient presents with watery diarrhoea (rarely can present with bloody diarrhoea), Caused by 2 toxins of C. difficile: Toxin A and Toxin B On biopsy: Classical volcano like erruptions Drug of choice: Vancomycin ± Metronidazole New drug: Fidaxomicin



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 793

↑ *Back to this question in Part A*

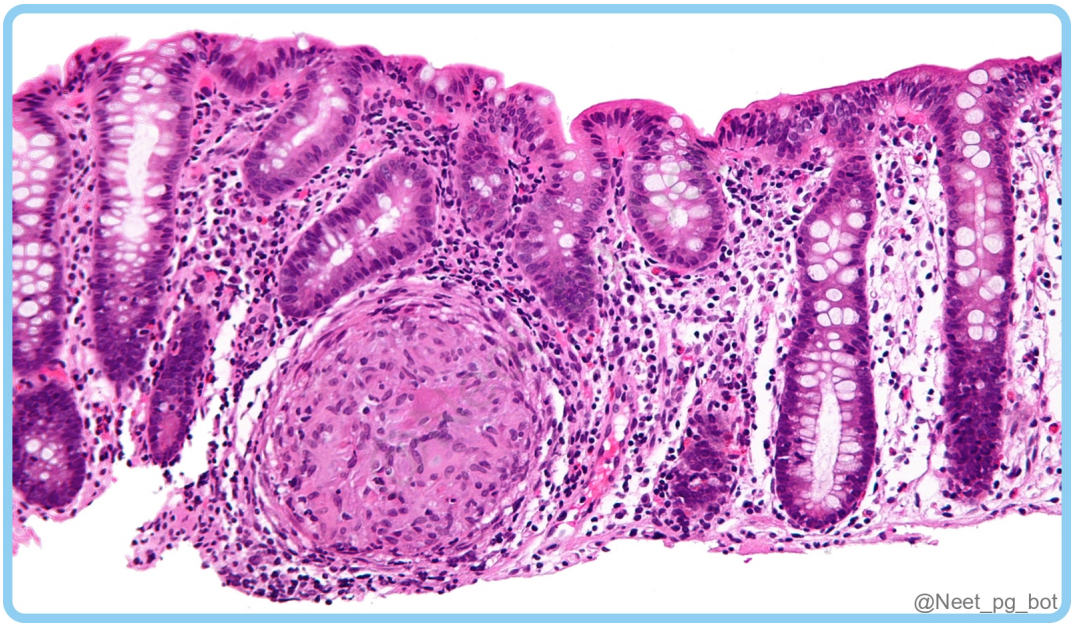
Q10: A 32-year-old man presents with chronic abdominal pain, diarrhoea, weight loss, and occasional blood in the stool. A colonoscopy reveals skip lesions with areas of normal mucosa alternating with segments, cobblestoning and deep linear fissuring ulcers in the patchy terminal ileum and colon. The histopathological findings from the affected area are shown below. What histopathological features are observed in this patient's condition? (Q845333)

A. Presence of noncaseating granulomas

B. Smooth transition between ulcerated and adjacent normal mucosa

C. Absence of metaplastic changes in the epithelium

D. Uniform distribution of inflammation throughout the affected areas

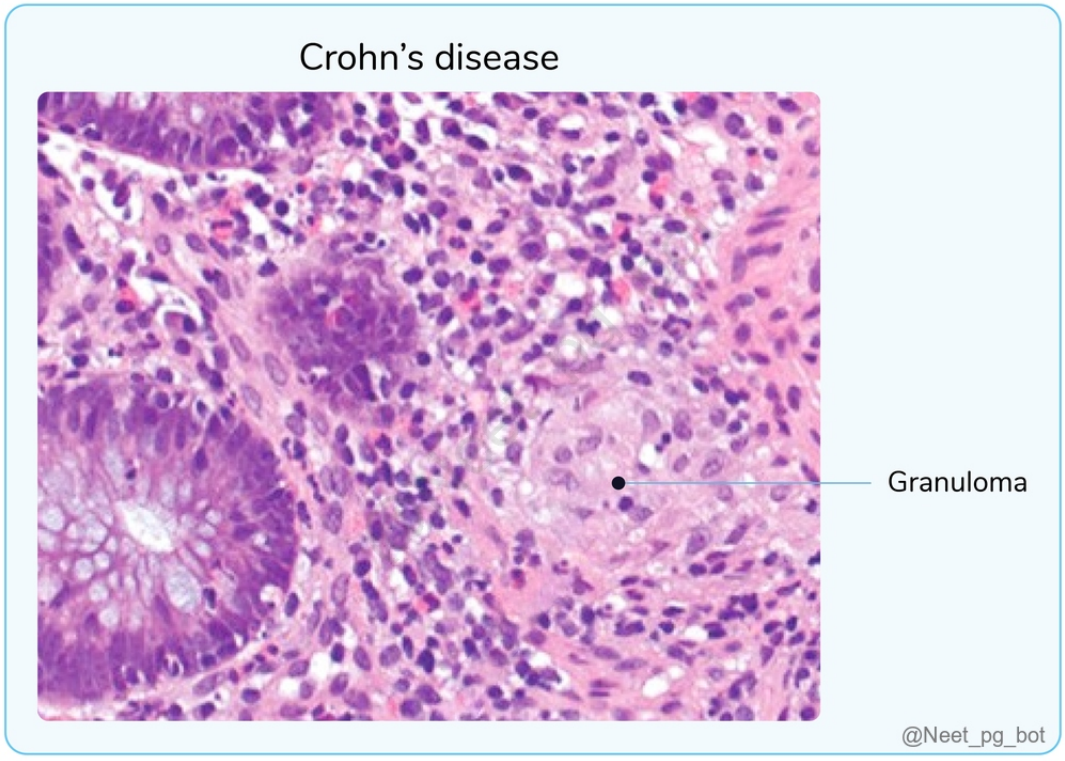


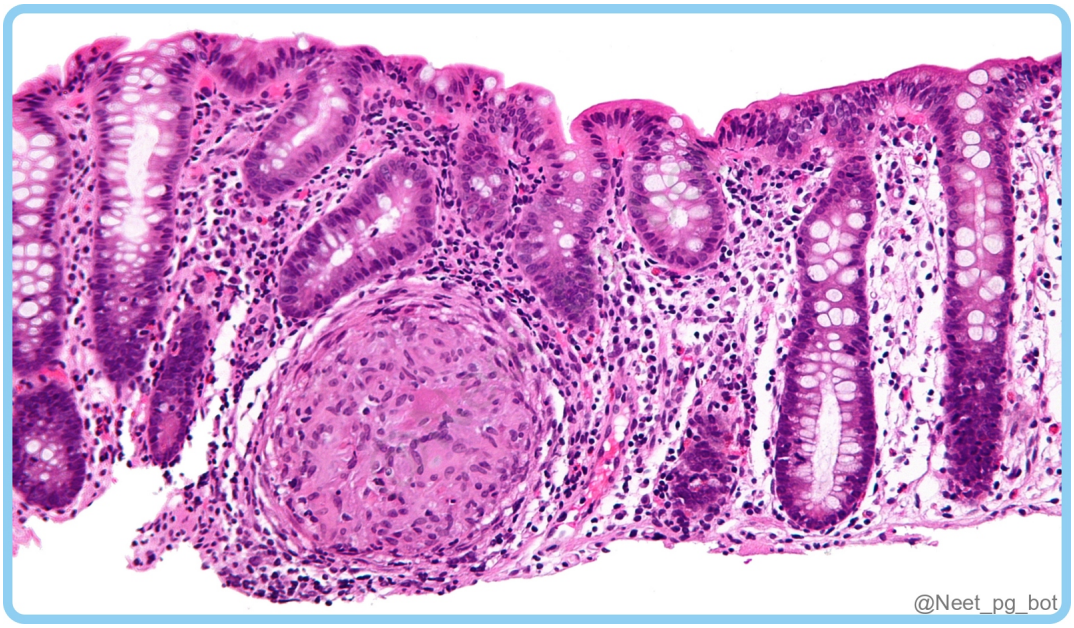
Correct Answer: A. Presence of noncaseating granulomas

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and biopsy findings showing noncaseating granulomas and skip lesions suggest Crohn’s disease. Noncaseating granulomas are round lesions with multinucleated giant cells within them.





References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 801

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 32-year-old male presents with a 6-month history of abdominal pain, diarrhoea, and weight loss. A colonoscopy reveals findings consistent with Crohn's diseaseWhat histological features would you observe in this patient's biopsy? (Q845339)

A. Inflammation is limited superficial layer

B. Fibrosis is not seen

C. Ulcers are limited to mucosa

D. Ulcers can extend beyond the mucosa

Correct Answer: D. Ulcers can extend beyond the mucosa

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Crohn’s disease presents with transmural inflammation, which causes deep ulcers. It is characterised by transmural inflammation and can affect the entire intestinal wall thickness, from the mucosa to the serosa, which can lead to fissures and fistulas. (Option A ruled out) Strictures or fibrosis are commonly seen in this condition (Option B ruled out) Ulcers are intially superficial and then goes deep extending to every layer of intestine. (Option C ruled out)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 799

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which statement is true regarding inflammatory bowel disease (IBD) pathogenesis? (Q845341)

A. NOD2 polymorphisms are closely associated with Crohn's disease in Asian populations.

B. ATG16L1 mutation promotes ATG16L1 degradation and enhances autophagy.

C. Dysbiosis is often established at disease presentation in IBD.

D. All of the above

Correct Answer: C. Dysbiosis is often established at disease presentation in IBD.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: "Dysbiosis" is an imbalance in gut microbiota marked by shifts in microbial populations and reduced diversity. It commonly occurs at inflammatory bowel disease (IBD) onset and leads to increased inflammation and impaired gut barrier, contributing to IBD progression. Patients with newly diagnosed, treatment-naïve IBD often show: Reduced diversity of gut microbiota Decreased beneficial bacteria (e.g., Firmicutes, Bacteroidetes) Increased pro-inflammatory species (e.g., Enterobacteriaceae) This suggests that dysbiosis occurs early in the disease process , though it may be both a cause and consequence of inflammation. Dysbiosis Triggers the IL-23/IL-17 Pro-inflammatory Axis: The shift toward pro-inflammatory bacterial species (like Enterobacteriaceae) stimulates innate immune cells (dendritic cells and macrophages) to secrete IL-23 . Role of IL-23: Acts as a critical survival factor for Th17 cells . Role of IL-17: Secreted by Th17 cells, it recruits neutrophils to the gut mucosa and promotes the release of other inflammatory cytokines (like TNF-α). Result: This pathway creates a "feed-forward" loop where immune activation further damages the gut barrier, worsening the dysbiosis. NOD2 polymorphisms are closely associated with Crohn's disease in Asian populations (Option A) : NOD2 polymorphisms are closely associated with Crohn's disease but not with Crohn's disease in Asian populations. ATG16L1 mutation promotes ATG16L1 degradation and enhances autophagy (Option B) : The ATG16L1 mutation limits autophagy rather than enhancing it by promoting ATG16L1 degradation.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 799-800

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following statements regarding ulcerative colitis and Crohn's disease is true? (Q845344)

A. Ulcerative colitis is characterised by skip lesions, whereas Crohn’s disease typically presents with continuous inflammation.

B. Cobblestone appearance is a feature seen in ulcerative colitis and Crohn's disease but is more commonly associated with Crohn's disease.

C. Ulcerative colitis typically begins in the rectum and extends proximally, whereas Crohn's disease can involve any part of the GI tract with rectal sparing.

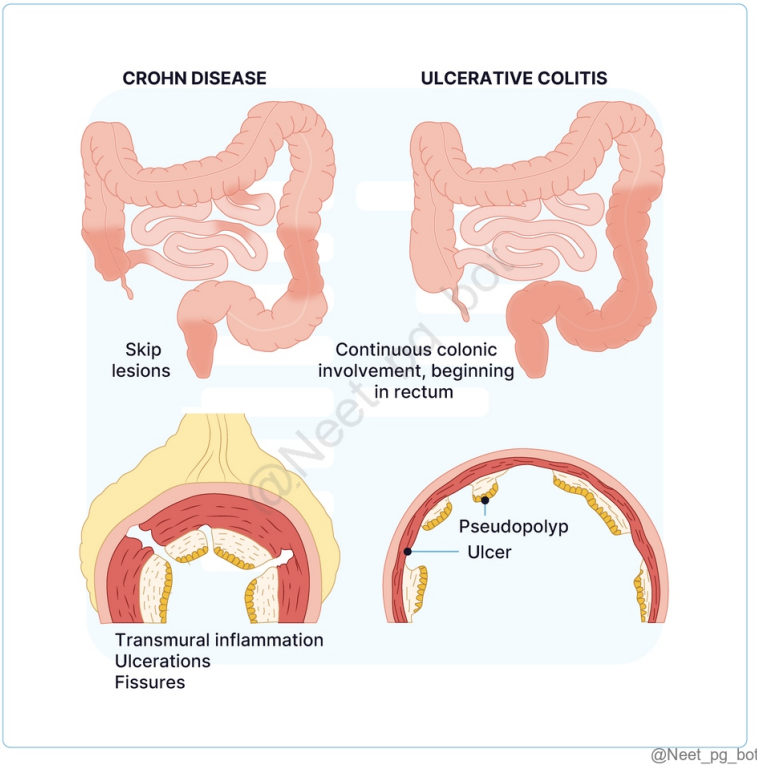
D. Fistulae, strictures, and abscesses are more commonly seen in ulcerative colitis than in Crohn's disease.

Correct Answer: C. Ulcerative colitis typically begins in the rectum and extends proximally, whereas Crohn's disease can involve any part of the GI tract with rectal sparing.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Features Ulcerative colitis Crohn’s disease Location Typically begins in the rectum and extends proximally affecting entire large and small intestines: Backwash ileitis Can involve any part of the GI tract: Primarily it starts most commonly from Ileum and then it can effect any part of GI tract in the forn of skip lesions. Distribution Diffused continuous lesion Patchy, with skip lesions . (Option A) Gross appearance Mucosal erythema and granularity Broad-based ulcers with a continuous pattern Pseudopolyps Mucosal atrophy Smooth, continuous inflammation Transmural inflammation Aphthous ulcers Cobblestone appearance (Option B) Fistulae, strictures, abscesses Creeping fat (mesenteric fat wrapping) Complications Toxic megacolon Colonic dilation Mucosal bridges. Strictures Fistulae Fissures (Option D)



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 798-805

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 32-year-old male presents to the outpatient clinic with a 5-day history of non-bloody, watery diarrhea. He reports that he recently returned from a hiking trip in a rural area where he drank water from a nearby stream. On examination, he appears dehydrated but is otherwise stable. A stool sample was sent for analysis, which revealed the presence of oocysts. Which of the following is the most likely cause

of this patient's gastrointestinal symptoms? (Q846629)

A. Cryptosporidium

B. Microsporidium

C. Giardia lamblia

D. Entamoeba histolytica

Correct Answer: A. Cryptosporidium

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Cryptosporidiosis is a significant cause of diarrhea worldwide. Cryptosporidium is known to cause non-bloody, watery diarrhea and is commonly associated with drinking contaminated water, particularly from untreated sources such as streams or lakes . The presence of oocysts in the stool supports this diagnosis C. hominis and C. parvum usually presents with waterry diarrhea and many times the patient is immunocompromised like HIV+. Oocysts are present in stool and measures 4-6µm. Cold ZN stain or Kinyoun stain is used to see oocytes. On biopsy of intestine, Cryptosporidium is found along the brush border of epithelium. Microsporidium (Option B): Rarely presents with oocysts in stool sample. Giardia lamblia (Option C): Do not have oocysts. Entamoeba histolytica (Option D): Do not have oocysts

Q1: Which of the following is a sensitive and specific marker of intestinal inflammation? (Q858080)

A. Procalcitonin

B. Fecal lactoferrin

C. Tissue transglutaminase IgA

D. High-sensitivity C-reactive protein

Correct Answer: B. Fecal lactoferrin

Explanation: Faecal lactoferrin is a sensitive and specific marker for intestinal inflammation , particularly in conditions like inflammatory bowel diseases (IBD). It is a glycoprotein released by the neutrophils. Fecal calprotectin and Fecal lactoferrin are both non-invasive biomarkers used to assess intestinal inflammation . They are particularly useful in the diagnosis and monitoring of IBD and in identifying and separating between inflammatory bowel disease (IBD) and non-inflammatory conditions like irritable bowel syndrome (IBS). Incorrect Options: Procalcitonin (Option A) is a biomarker produced in response to bacterial infections , particularly sepsis. It's used to monitor bacterial infections and guide antibiotic therapy. It is not specific for intestinal inflammation . Tissue transglutaminase IgA (Option C) is an antibody commonly used in the diagnosis of celiac disease , an autoimmune disorder where the ingestion of gluten leads to intestinal damage. It is not a marker for general intestinal inflammation . High-sensitivity C-reactive protein (Option D) is a more sensitive version of CRP, often used to assess the risk of coronary artery disease. It increases in response to generalised inflammation and does not specifically pinpoint conditions like IBD.

Harrison’s Principles of Internal Medicine, 21st Edition, Page 2475

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 12-year-old boy presents with multiple dark-brown macules around the lips and oral mucosa. Upper GI endoscopy shows numerous hamartomatous polyps in the jejunum. Which of the following statements regarding this condition are correct? Autosomal recessive inheritance Presence of congenital retinal pigmentation (CRPE) Loss-of-function mutation in the STK11 gene. Arborising pattern due to the proliferation of smooth muscle in the polyp histology (Q879201)

A. 1, 2

B. 1, 3, 4

C. 3, 4

D. 2, 3, 4

Correct Answer: C. 3, 4

Explanation: The presentation is classic for Peutz–Jeghers Syndrome (PJS) . Inheritance: Autosomal dominant (Statement 1 ruled out) Gene: STK11 - tumour suppressor, loss-of-function mutation (Statement 3) Clinical features: Multiple hamartomatous polyps (mainly jejunum, also stomach/colon) Mucocutaneous pigmentation – dark macules on lips, buccal mucosa, palms, genitalia, perianal area Complications: Intussusception, ↑ risk of GI, pancreatic, breast, ovarian, uterine cancers (~40%) Histology: Arborising pattern of smooth muscle, lamina propria, and glands with normal epithelium (Statement 4). ■ Congenital retinal pigmentation (Statement 2) is not a feature of PJS.

Robbins & Cotran, Pathologic Basis of Diseases, 10th Edition, Page 809,810

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following is a characteristic feature of Barrett's oesophagus? (Q859302)

A. Squamous metaplasia

B. Severe dysplasia

C. Intestinal metaplasia

D. Cuboidal metaplasia

Correct Answer: C. Intestinal metaplasia

Explanation: The primary cellular change seen in Barrett's oesophagus is metaplasia of squamous epithelium into intestinal/columnar epithelium. {{caption_text}} {{caption_text}} Incorrect Options: Squamous Metaplasia

(Option A) is the replacement of normal columnar epithelium with stratified squamous epithelium , typically due to chronic irritation (e.g., bronchial epithelium in smokers or the cervix). In Barrett's oesophagus , the reverse occurs, with squamous epithelium replaced by columnar epithelium . Severe Dysplasia (Option B) is disordered cellular growth and a precancerous condition . In Barrett's oesophagus , dysplasia (low-grade or high-grade) may arise as a progression from intestinal metaplasia toward adenocarcinoma , but it is not a defining feature-rather, a complication. Cuboidal Metaplasia (Option D) is not a recognised feature of Barrett's oesophagus or any other oesophagal condition. Barrett's oesophagus is specifically defined by intestinal metaplasia , with goblet cells present within the columnar epithelium.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 762, 272

↑ *Back to this question in Part A*

@Neet_pg_bot

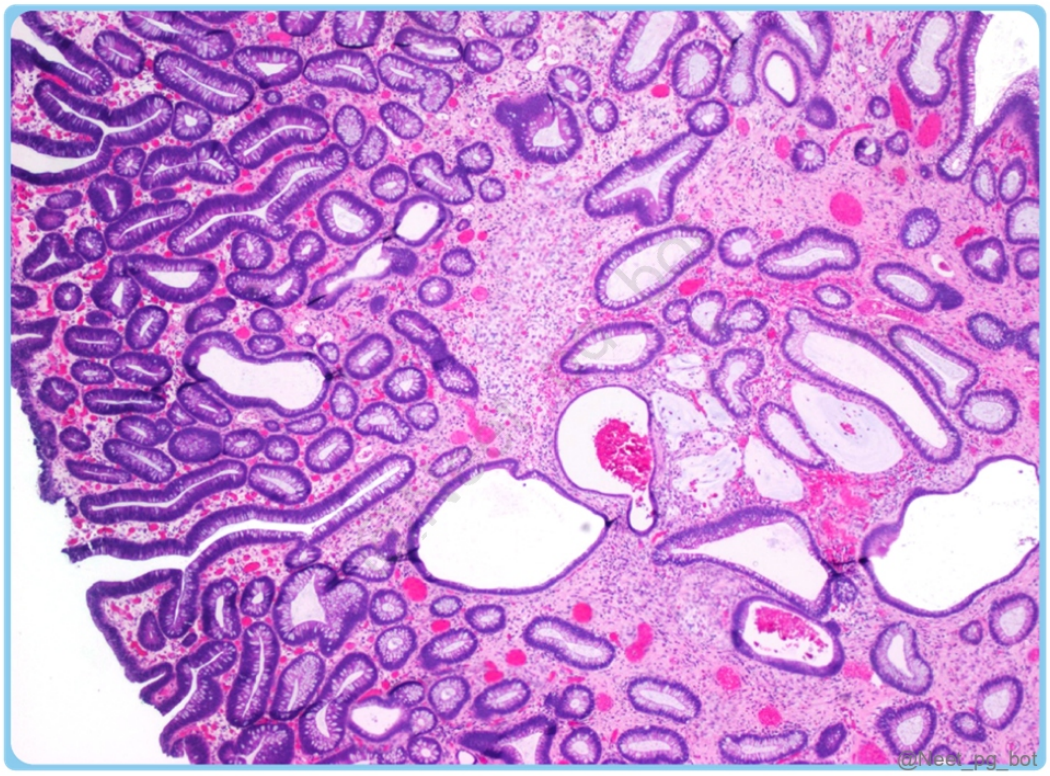
Q4: A 5-year-old child was admitted to the hospital with a history of prolapsing rectal mass and painless rectal bleeding. The histopathological image of the mass is shown below. What is the most likely diagnosis? (Q858520)

A. Peutz-Jegher syndrome

B. Villous adenoma

C. Juvenile polyp

D. Tubular adenoma



Correct Answer: C. Juvenile polyp

Explanation: The clinical presentation and HPE image showing characteristic cystically dilated crypts & glands are suggestive of Juvenile polyp. Juvenile Polyps: Occurrence : Common in children under 5 years old; can be sporadic or syndromic. Size & Appearance : Typically less than 3 cm, pedunculated, smooth-surfaced, reddish with cystic spaces. Histology : Dilated glands filled with mucin and inflammatory debris, mixed inflammatory infiltrates, and sometimes attenuated muscularis mucosae. {{caption_text}} Pathogenesis : Linked to mucosal hyperplasia ; mutations in SMAD4 and BMPR1A (TGF-β pathway). Dysplasia : Rare in sporadic polyps but present in juvenile polyposis syndrome. Complications : Juvenile polyposis syndrome can lead to colonic adenocarcinoma (30-50% risk by age 45). Peutz-Jeghers Syndrome (Option A) is an autosomal dominant condition characterised by hamartomatous polyps throughout the gastrointestinal tract. While rectal polyps may occur in this syndrome, the histopathological image seen in this case is more indicative of juvenile polyps. Villous Adenoma (Option B) are adenomatous polyps commonly seen in adults, characterised by finger-like projections with abundant mucin production. Tubular Adenoma (Option D) are common adenomatous polyps found in adults, characterized by glandular structures with tubular architecture.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 808,809

↑ *Back to this question in Part A*

@Neet_pg_bot

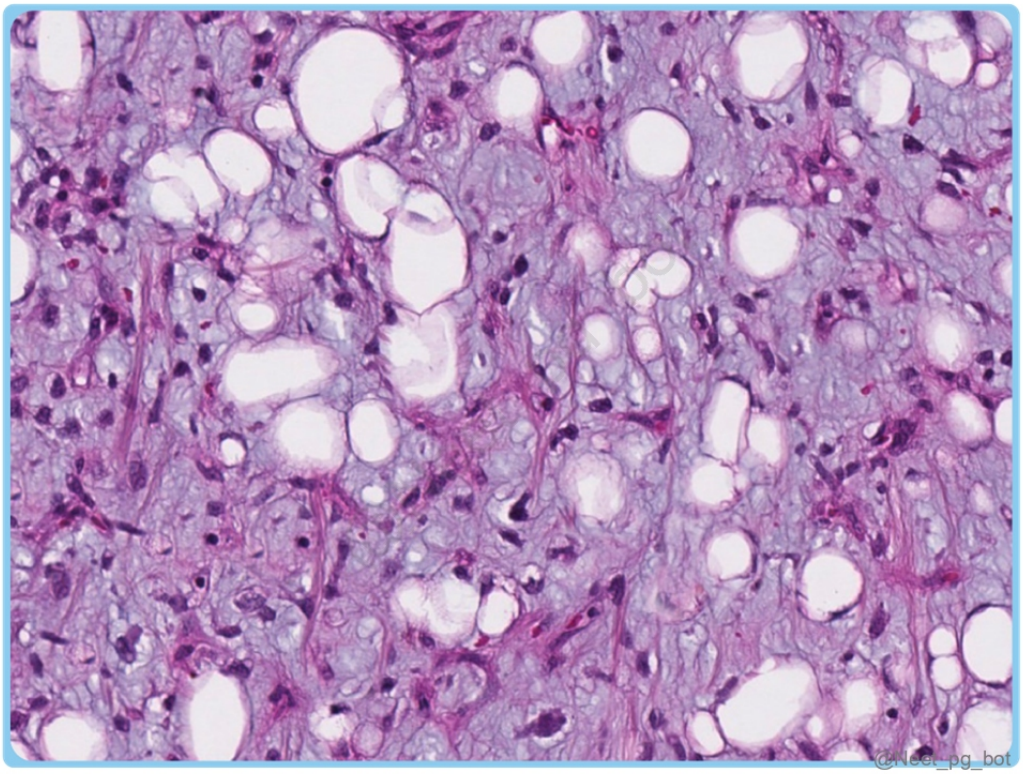
Q5: A 50-year-old man presented with a retroperitoneal mass. A biopsy of the lesion is shown in the image below. Molecular analysis revealed t(12;16). What is the most likely condition? (Q858516)

A. Myxoid liposarcoma

B. Lipoma

C. Spindle lipoma

D. Polymorphic lipoma



Correct Answer: A. Myxoid liposarcoma

Explanation: - Myxoid liposarcoma The presence of a retroperitoneal mass with the molecular finding of t(12;16) translocation & image showing abundant ground substance, with branching capillaries and few immature adipocytes, is highly suggestive of Myxoid liposarcoma . Liposarcoma, malignant tumours of adipose tissue, is the most common type of sarcoma in adults. These tumours typically arise in the deep soft tissues of the proximal extremities and retroperitoneum, commonly affecting individuals in their sixth and seventh decades of life. Pathogenesis: The three subtypes of liposarcoma—well-differentiated, myxoid, and pleomorphic—have distinct genetic abnormalities: Well-differentiated liposarcomas exhibit amplifications in the chromosome region 12q13–q15, which includes the p53 inhibitor MDM2. Myxoid liposarcomas are characterised by a fusion gene caused by a t(12;16) translocation, which arrests adipocyte differentiation, leading to uncontrolled proliferation of primitive cells. Pleomorphic liposarcomas display complex karyotypes without consistent genetic abnormalities. Histopathological findings: Well-differentiated liposarcomas are composed primarily of mature adipocytes with

scattered atypical spindle cells. Myxoid liposarcomas are characterised by a rich basophilic extracellular matrix, arborizing capillaries, and primitive cells at different stages of adipocyte differentiation, resembling fetal fat. Pleomorphic liposarcomas feature sheets of anaplastic cells with bizarre nuclei intermixed with varying numbers of immature adipocytes, called lipoblasts. Lipomas (Option B) are benign tumours made up of mature adipose tissue. They are typically well-defined and do not show the cellular atypia or genetic abnormalities associated with liposarcomas. Spindle Lipoma (Option C) is a benign variant of lipoma characterised by spindle-shaped cells within the fatty tissue. It lacks the genetic mutations seen in myxoid liposarcoma. Polymorphic Lipoma (Option D) , also referred to as pleomorphic lipoma, is a benign lipomatous tumour made of mature adipose tissue containing various cell types. It does not exhibit the specific t(12;16) translocation found in myxoid liposarcoma.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 1209

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 30-year-old female presents with chest pain, recurrent heartburn, and dysphagia. A barium swallow shows a bird beak sign. Which of the following statements is true regarding the condition in this patient? (Q854892)

A. Relaxation of LES

B. Increased peristalsis

C. Decreased release of NO and VIP in the distal esophagus

D. Decreased tone of LES

Correct Answer: C. Decreased release of NO and VIP in the distal esophagus

Explanation: The clinical presentation & the bird beak sign on barium swallow suggests achalasia , a condition characterized by the inability of the lower esophageal sphincter (LES) to relax and an absence of peristalsis in the distal esophagus. It is caused by a decreased release of nitric oxide (NO) and vasoactive intestinal peptide (VIP) , which are essential for smooth muscle relaxation. This results in increased tone of the LES and impaired peristalsis. Achalasia: Pathology: Incomplete LES relaxation/Increased LES tone/Aperistalsis of the esophagus Symptoms: Dysphagia (difficulty swallowing), Difficulty in belching, Chest pain Primary Achalasia: It is caused by degeneration of nitric oxide-producing neurons that normally induce LES relaxation. Degeneration of the extraesophageal vagus nerve or dorsal motor nucleus of the vagus may occur. Secondary Achalasia: Chagas disease (Trypanosoma cruzi infection) destroys the myenteric plexus, leading to peristalsis failure and esophageal dilation. Associated with conditions like: Diabetic autonomic neuropathy Infiltrative disorders (e.g., malignancy , amyloidosis , sarcoidosis) Systemic sclerosis Dorsal motor nuclei lesions (post-polio) Down syndrome or Allgrove syndrome (achalasia, alacrima, ACTH-resistant adrenal insufficiency). Some cases linked to HSV1 infection , immunoregulatory gene polymorphisms, Sjögren syndrome , or autoimmune thyroid disease , suggesting immune-mediated destruction of inhibitory esophageal neurons. Treatment: Laparoscopic myotomy

Pneumatic balloon dilation Botulinum neurotoxin (Botox) injections to inhibit cholinergic neuron contraction.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 757,758

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following is true about the pathogenesis of Hirschsprung disease? (Q854856)

A. Failure of migration of neural crest cells

B. Increase in ganglion cells

C. Visceral myopathy

D. Obstruction by inflammatory strictures

Correct Answer: A. Failure of migration of neural crest cells

Explanation: Hirschsprung disease arises when the migration of neural crest cells is arrested , causing a lack of ganglion cells (Option B ruled out) in the affected segment, leading to a lack of peristalsis in the affected bowel segment, causing functional obstruction and bowel dilation without inflammation or strictures (Option D ruled out) . This leads to aganglionosis, preventing peristalsis and causing bowel dilation. Morphology: Histopathological confirmation involves identifying the absence of ganglion cells, and acetylcholinesterase staining aids in diagnosis. The disease typically involves the rectum, with short-segment or long-segment Hirschsprung disease based on the extent of involvement. Clinical Features: Symptoms include failure to pass meconium, abdominal distension, constipation, and bilious vomiting. Complications such as enterocolitis, perforation, and peritonitis can occur. Surgical resection of the aganglionic segment is the primary treatment. Acquired Megacolon: Acquired Megacolon, seen in conditions like Chagas disease and ulcerative colitis , may share a similar pathophysiology with Hirschsprung disease, particularly in cases involving the loss of ganglion cells. Visceral myopathy (Option C) refers to smooth muscle dysfunction, which can affect gastrointestinal motility but is not the cause of Hirschsprung disease.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 755,766

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 20-year-old patient presents with a history of malabsorption, diarrhea, and poor appetite. A duodenal biopsy shows crypt hyperplasia, villi atrophy, and CD8+ cells in the lamina propria. What is the most probable diagnosis? (Q854843)

A. Environmental enteropathy

B. Celiac disease

C. Whipple’s disease

D. Chronic pancreatitis

Correct Answer: B. Celiac disease

Explanation: Celiac disease is an autoimmune disorder triggered by the ingestion of gluten in genetically predisposed individuals. The immune response leads to damage in the small intestine, causing malabsorption, diarrhea, and poor appetite. On histopathological examination, crypt hyperplasia, villous atrophy, and increased CD8+ T lymphocytes in the lamina propria are classic features of celiac disease. Celiac disease Definition Autoimmune disorder triggered by ingesting gluten-containing foods in genetically susceptible individuals. Synonym Gluten-sensitive enteropathy Celiac sprue Diagnosis Biopsy of the second part of the duodenum or proximal jejunum Serum markers Anti-tissue transglutaminase (tTG)-most sensitive Anti-endomysial antibodies (EMA)-most specific Histology Increased intraepithelial CD8+ T lymphocytes (intraepithelial lymphocytosis), Crypt hyperplasia (increased mitosis) Villous atrophy (reduced mucosal surface area, causing malabsorption) Inflammatory cells infiltration {{caption_text}} Environmental enteropathy (Option A) is a condition marked by chronic inflammation and structural changes in the small intestine. It is commonly seen in individuals from regions with poor sanitation and hygiene. Whipple's disease (Option C) is a rare bacterial infection caused by Tropheryma whipplei . It primarily affects the small intestine but can also involve other organs. The biopsy findings in Whipple's disease are different and typically show PAS-positive macrophages. Chronic pancreatitis (Option D) is characterised by persistent inflammation and fibrosis of the pancreas, leading to impaired pancreatic function. It can cause malabsorption, but the biopsy would not show the characteristic findings of celiac disease, such as villous atrophy and crypt hyperplasia.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 785

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following statements regarding Peutz-Jeghers syndrome is correct? An arborizing pattern of smooth muscle Loss of heterozygosity in STK11 gene Multiple GI polyps Autosomal recessive inheritance Congenital hypertrophy of retinal pigmental epithelium is seen (Q856473)

A. 2, 4, 5

B. 1, 2, 3

C. 1, 3, 4

D. 2, 3, 5

Correct Answer: B. 1, 2, 3

Explanation: Peutz-Jeghers Syndrome: Inheritance : Autosomal dominant. Age of Onset : Median age of 11 years. Key Features : Multiple GI hamartomatous polyps. Mucocutaneous hyperpigmentation (dark macules on lips, buccal mucosa, palms, genitalia, and perianal region). {{caption_text}} Polyps are most common in the small intestine but may also occur in the stomach, colon, bladder, and lungs. Complications: Risk of intussusception , potentially fatal. Increased cancer risk (lifetime risk ~40%), including cancers of the GI tract, testes, pancreas, breast, lung, ovarian, and uterus. Pathogenesis: It is caused by germline mutations in the STK11 gene, a tumour suppressor gene regulating cell polarization and growth. Somatic loss of the second STK11 gene copy in cancers. Morphology: Polyps are pedunculated and lobulated. Histology shows an arborizing network of smooth muscle, connective tissue, lamina propria, and glands. {{caption_text}} Congenital hypertrophy of retinal pigmental epithelium is not typically associated with Peutz-Jeghers syndrome . Congenital hypertrophy of the retinal pigment epithelium (CHTPE) is more commonly seen in other conditions, such as familial adenomatous polyposis (FAP) .

@Neet_pg_bot

Q10: The cells lining the isthmus of gastric pits are: (Q856472)

A. Chief cells

B. Stem cells

C. Parietal cells

D. Mucous cells

Correct Answer: B. Stem cells

Explanation: The isthmus of the gastric pits contains stem cells , which are responsible for replenishing the various cell types in the gastric mucosa. These stem cells differentiate into different types of gastric cells, including parietal cells, chief cells, and mucous cells, as they migrate along the pit. Cell Type Location Function Stem cells Isthmus of gastric pits Regenerate the various types of gastric epithelial cells. Parietal cells Fundus and body of the stomach It secretes hydrochloric acid (HCl) and intrinsic factors that are important for digestion and vitamin B12 absorption. Chief cells Fundus and body of the stomach Secrete pepsinogen, which is converted to pepsin in the acidic environment, to aid in protein digestion. Mucous cells Surface epithelium of the stomach lining and neck of gastric pits Secrete mucus to protect the stomach lining from the acidic environment and digestive enzymes. Endocrine cells (G cells) Antrum of the stomach Secrete gastrin, which stimulates acid secretion by parietal cells and gastric motility. Enteroendocrine cells Throughout the gastric mucosa Secrete various hormones such as somatostatin, serotonin, and histamine to regulate gastric functions.

@Neet_pg_bot

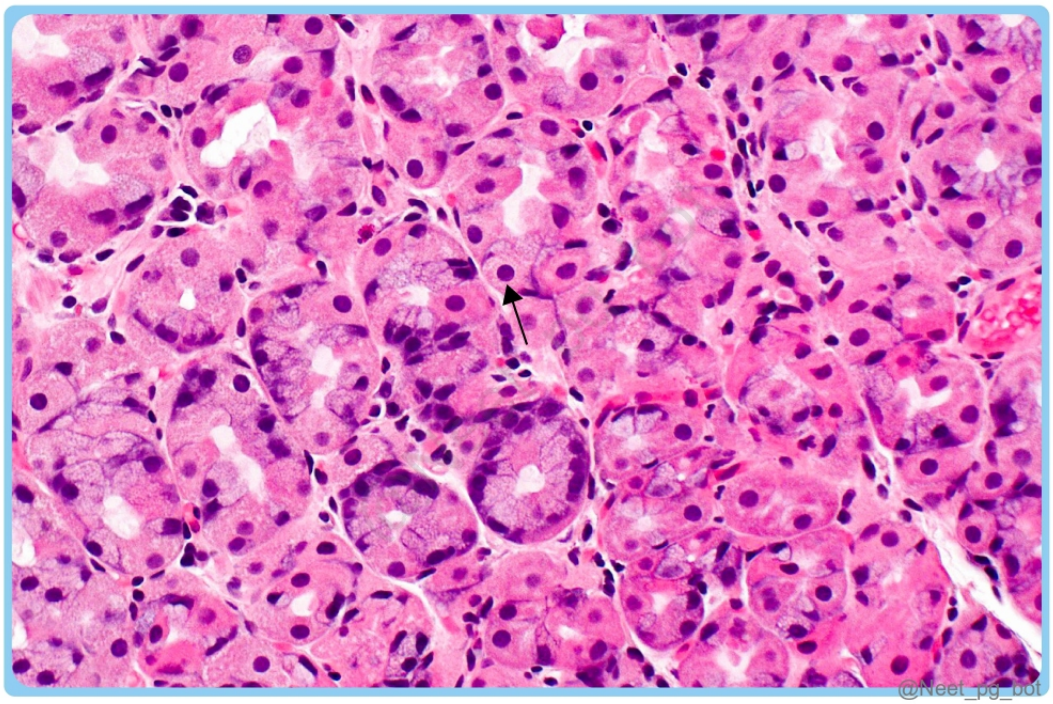
Q11: The absence of the structure will be present in all except: (Q856471)

A. Pernicious anemia

B. Autoimmune Metaplastic Atrophic Gastritis

C. Vitamin B12 Deficiency

D. Zollinger-Ellison syndrome



Correct Answer: D. Zollinger-Ellison syndrome

Explanation: The marked structure shows eosinophilic cells indicative of parietal cells. Zollinger-Ellison syndrome , which is characterized by excess gastrin secretion from tumours, is not related to the absence of parietal cells. Zollinger-Ellison syndrome: Cause : Gastrin-secreting neuroendocrine tumours (gastrinomas) located mainly in the small intestine or pancreas . {{caption_text}} Presentation : Duodenal ulcers Chronic diarrhoea Marked increase in oxyntic mucosal thickness due to parietal cell hyperplasia {{caption_text}} Gastrin also induces hyperplasia of the mucous neck and endocrine cells . Sporadic, solitary lesions in 75% of cases. Multiple endocrine neoplasia type 1 (MEN1) in 25% of cases and is associated with younger age, duodenal tumours, and metastasis. Treatment: Proton pump inhibitors (PPIs) block acid hypersecretion, promoting ulcer healing and preventing gastric perforation. Focus on treating the gastrinomas , which influence long-term survival. Pernicious Anemia (Option A) is an autoimmune disorder caused by the destruction of gastric parietal cells , leading to intrinsic factor deficiency. Since intrinsic factor is essential for vitamin B12 absorption in the intestines, its absence results in vitamin B12 deficiency . The loss of parietal cells is a hallmark of pernicious anaemia. Autoimmune Metaplastic Atrophic Gastritis (Option B) is an autoimmune condition that targets the parietal cells, causing hypochlorhydria (low stomach acid) and a decreased production of intrinsic factors. Vitamin B12 Deficiency (Option C) can arise from various causes, including pernicious anaemia or inadequate dietary intake. Pernicious anaemia occurs due to the loss or dysfunction of parietal cells , which produce intrinsic factors essential for vitamin B12 absorption. The resulting intrinsic factor deficiency impairs B12 absorption, leading to deficiency.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 773

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following is true about celiac disease? (Q856469)

A. Most common cause of malnutrition in developing countries

B. Can be diagnosed with CECT

C. Improves with food rich in carbohydrates

D. Increased risk of GI lymphoma

Correct Answer: D. Increased risk of GI lymphoma

Explanation: Celiac disease is an autoimmune disorder that affects the small intestine, triggered by the ingestion of gluten. It is associated with an increased risk of gastrointestinal lymphoma, particularly enteropathy-associated T-cell lymphoma (EATL). Celiac disease Definition Autoimmune disorder triggered by ingesting gluten-containing foods in genetically susceptible individuals. Synonym Gluten-sensitive enteropathy Celiac sprue Diagnosis Biopsy of the second part of the duodenum or proximal jejunum Serum markers Anti-tissue transglutaminase (tTG): Most sensitive Anti-endomysial antibodies (EMA): Most specific Histology Increased intraepithelial CD8+ T lymphocytes (intraepithelial lymphocytosis), Crypt hyperplasia (increased mitosis) Villous atrophy (reduced mucosal surface area, causing malabsorption) Inflammatory cells infiltration {{caption_text}} Celiac disease is more commonly diagnosed in developed countries (Option A) , particularly among populations of European descent, rather than being the leading cause of malnutrition in developing countries. CECT (contrast-enhanced computed tomography) is not used to diagnose celiac disease (Option B) . The diagnosis is typically based on clinical evaluation, serological tests (e.g., anti-tissue transglutaminase antibodies), and confirmation through a small bowel biopsy. Celiac disease does not improve with a carbohydrate-rich diet (Option C) . The primary treatment for celiac disease is a strict gluten-free diet, which requires avoiding foods containing gluten.

@Neet_pg_bot

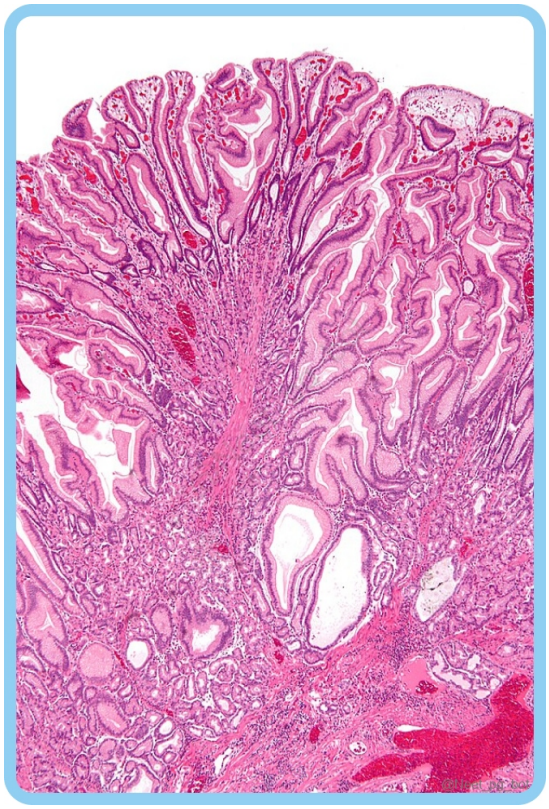
Q13: A 17-year-old boy presented with intussusception and was taken up for surgery. He was found to have multiple polyps. The resected section was sent for histopathology, and the whole mount image of the specimen is given below. Identify the lesion. (Q855425)

A. Tubulovillous adenoma

B. Hamartomatous polyp

C. Adenocarcinoma

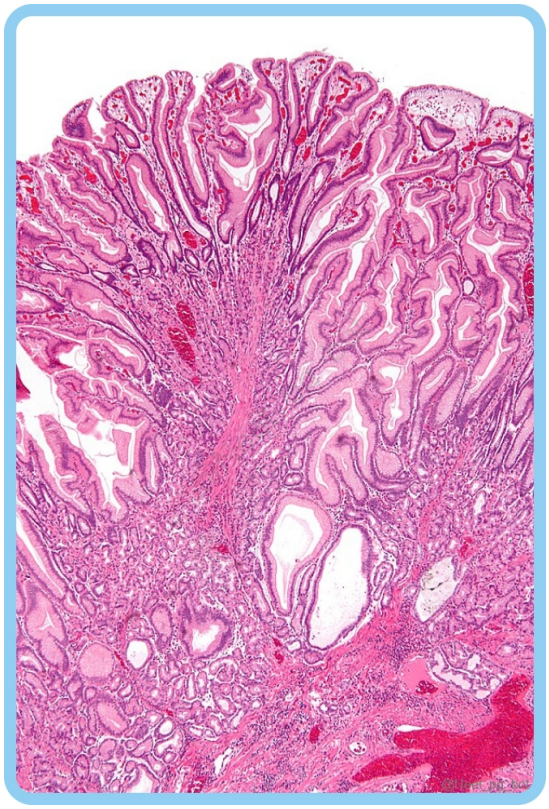
D. Hyperplastic polyp

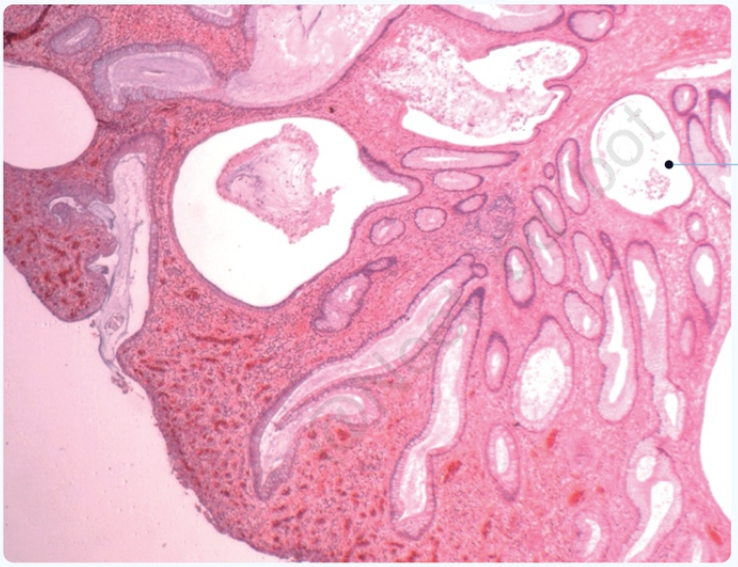


Correct Answer: B. Hamartomatous polyp

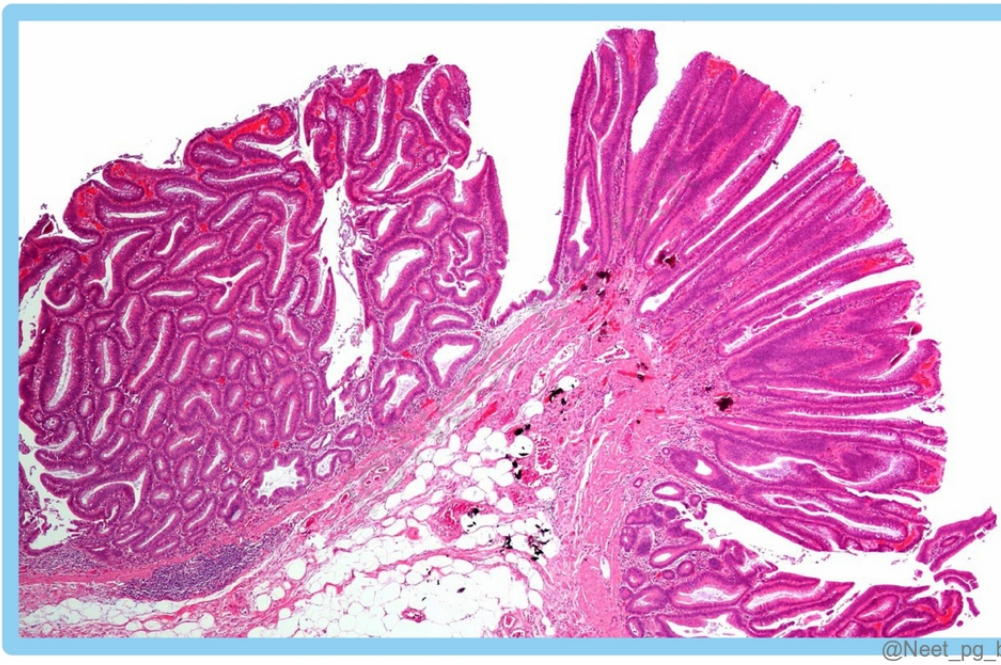
Explanation: The histopathological image reveals a Hamartomatous Polyps, characterized by an arborizing pattern of connective tissue, smooth muscle, glands, and lamina propria. They are non-neoplastic growths resulting from

the disorganized overgrowth of normal tissues within an organ. These polyps are often associated with genetic syndromes, including: Features Peutz-Jeghers syndrome (PJS) Juvenile polyposis syndrome (JPS) Inheritance pattern Autosomal dominant disorder Autosomal dominant inheritance Age Presents around 11 years of age Primarily affects children under 5 years old. Features Caused by a loss of function mutation in the STK11 gene Characterized by: Gastrointestinal hamartomatous polyps, especially in the small intestine Mucocutaneous hyperpigmentation (macules on lips, nostrils, buccal mucosa, and extremities). Polyps are large, pedunculated, and lobulated. Can be sporadic or syndromic. Sporadic: Single polyps. Syndromic: 3-100 polyps. Linked to mutations in the SMAD4 and BMPR1A genes, part of the TGF-β signalling pathway. Pedunculated polyp, which is usually less than 3 cm in diameter. Extra-intestinal manifestations include congenital malformations and digital clubbing. Microscopy An arborizing pattern of smooth muscle and glands lined by normal epithelium. {{caption_text}} Contains cystic spaces filled with mucin and inflammatory debris. {{caption_text}} Tubulovillous adenoma (Option A) is a premalignant lesion featuring both tubular and villous components, with the potential to progress to adenocarcinoma. However, the image does not display the typical characteristics of a tubulovillous adenoma, such as dysplasia or dysplastic cells within the epithelial lining. {{caption_text}} Adenocarcinoma (Option C) is a malignant tumour that originates from the glandular cells of an organ and is characterized by invasive growth and the presence of dysplastic cells. However, the image does not reveal features typical of adenocarcinoma, such as tissue infiltration or cytological atypia. {{caption_text}} Hyperplastic polyps (Option D) are non-neoplastic growths marked by an increase in the number of cells in the epithelial layer of an organ. They are typically small, sessile, and have a smooth surface. However, the image does not resemble the usual appearance of hyperplastic polyps, which are generally smaller and more uniform in size. {{caption_text}}

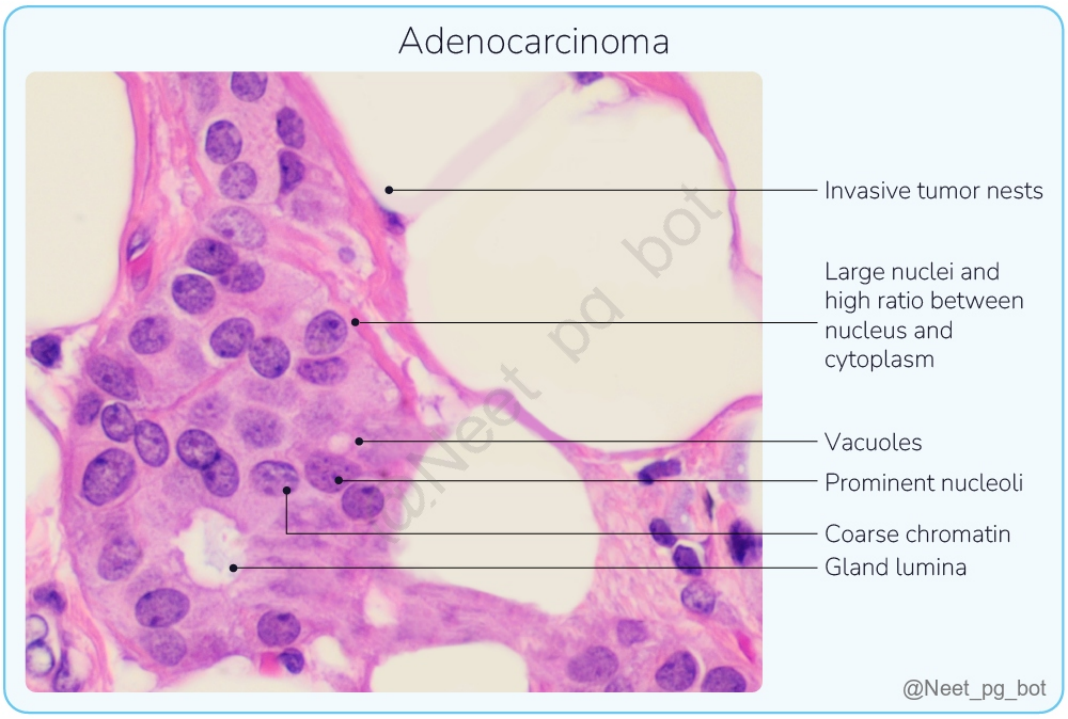


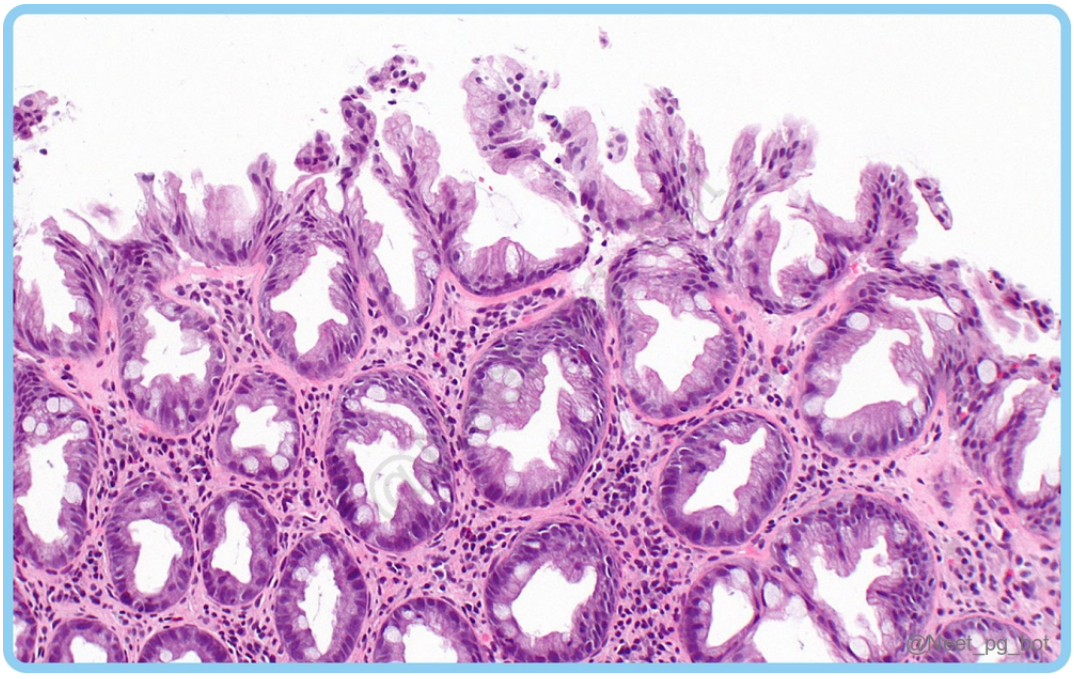


@Neet_pg_bot



@Neet_pg_bot





References:

Robbins & Cotran Pathological Basis of Diseases, 10th Edition, Page, 808-810.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following set of statements is true about familial adenomatous polyposis (FAP)? It is autosomal recessive. If not treated, 100% of the cases progress to adenocarcinoma of the colon. Polyps do not arise after puberty. It is associated with congenital hypertrophy of the retinal pigment epithelium. (Q855122)

A. 2 and 4

B. 1 and 4

C. 2 and 3

D. 3 and 4

Correct Answer: A. 2 and 4

Explanation: Familial Adenomatous Polyposis: (FAP) {{caption_text}} An autosomal dominant disorder caused by APC gene mutations on chromosome 5 (Statement 1) Numerous intestinal polyps develop. Classic FAP: Diagnosed with at least 100 polyps. There is almost 100% risk of colorectal cancer if untreated (Statement 2) Commonly develops in 30 years, almost always by 50 years (Statement 3) {{caption_text}} Attenuated FAP (AFAP): Primarily affects the proximal colon Fewer polyps (average <30 polyps) Associated with congenital hypertrophy of the retinal pigment epithelium (Statement 4) {{caption_text}} Standard treatment: Prophylactic colectomy to prevent colorectal cancer. Post-colectomy risks: Cancer at extracolonic sites, including the ampulla of Vater and stomach

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 812

↑ *Back to this question in Part A*

Q15: In Barrett’s oesophagus, which of the following epithelial transformations occurs? (Q866674)

A. Columnar to squamous epithelium

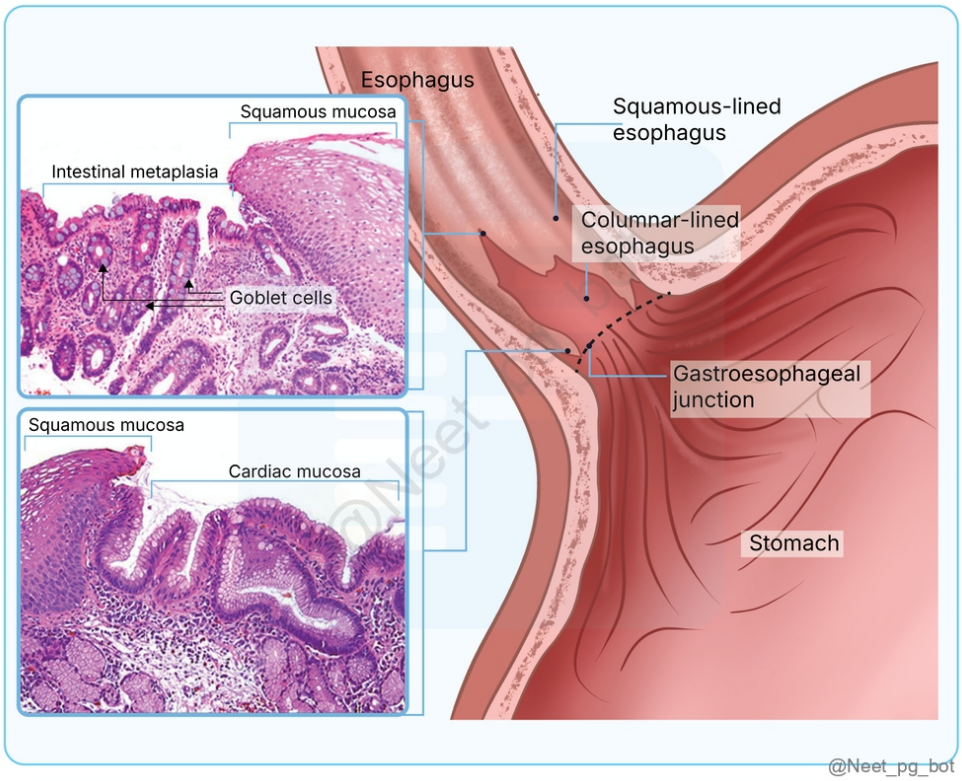
B. Squamous to intestinal columnar epithelium

C. Transitional to squamous epithelium

D. Cuboidal to columnar epithelium

Correct Answer: B. Squamous to intestinal columnar epithelium

Explanation: Barrett's oesophagus is a complication of chronic GERD, characterised by intestinal metaplasia (Option B) in the oesophageal squamous mucosa. It increases the risk of oesophageal adenocarcinoma. Occurs in 10% of individuals with symptomatic GERD. Affects up to 2% of the general population. Most common in white males, typically between ages 40 and 60. Cancer Risk: Increases the risk of oesophageal adenocarcinoma. The majority of oesophageal adenocarcinomas are associated with Barrett's oesophagus, but not all individuals with it will develop cancer. Recognised as red, velvety mucosa (Barrett's mucosa) extending upward from the gastroesophageal junction & alternating with pale squamous mucosa and light-brown gastric mucosa. Subclassified as long segment (≥3 cm) or short segment (<3 cm). Short-segment disease carries a lower cancer risk compared to long-segment disease. Intestinal-type metaplasia with goblet cells replacing squamous epithelium. Goblet cells are diagnostic of Barrett oesophagus and have distinct mucous vacuoles that stain blue with Alcian blue. This imparts the shape of a wine goblet to the remaining cytoplasm. Goblet cells are diagnostic , with pale blue mucous vacuoles resembling a wine goblet. Non-goblet columnar cells, like gastric-type foveolar cells, may also be present. Incorrect Options: Columnar to squamous (Option A): occurs in squamous metaplasia (e.g., chronic irritation in bronchi of smokers), not Barrett’s. Transitional to squamous (Option C): occurs in the bladder with chronic irritation (e.g., schistosomiasis). Cuboidal to columnar (Option D): not typical in Barrett’s; cuboidal epithelium is seen in small ducts/glands, not in the oesophagus.



Esophagus
Squamous mucosa
Intestinal metaplasia
Goblet cells
Squamous-lined esophagus
Columnar-lined esophagus
Gastroesophageal junction
Squamous mucosa
Cardiac mucosa
Stomach

@Neet_pg_bot

Q16: Which of the following diet is not advised in celiac sprue disease? (Q820577)

A. Rice

B. Wheat

C. Dhal

D. Ragi

Correct Answer: B. Wheat

Explanation: Correct Option B - Wheat: The diet not advised for individuals with celiac sprue disease is option B (Wheat), as it contains gluten, which can lead to harmful immune reactions and damage to the small intestine. Incorrect Options: Option A - Rice: Rice is generally considered safe for individuals with celiac sprue disease. It does not contain gluten, which is the protein responsible for triggering adverse reactions in people with celiac disease. Option C - Dhal (Lentils): Lentils are naturally gluten-free and are usually safe for individuals with celiac disease. However, it's important to ensure that lentils are not contaminated with gluten-containing grains during processing or cooking. Option D - Ragi: Ragi also known as finger millet is gluten free and can be used by individuals with celiac disease

References:

.

@Neet_pg_bot

Q17: Which of the following intestinal pathologies is associated with dermatitis herpetiformis? (Q860249)

A. Ulcerative colitis

B. Whipple’s disease

C. Celiac disease

D. Crohn’s disease

Correct Answer: C. Celiac disease

Explanation: Celiac Disease (also referred to as Gluten-sensitive Enteropathy or Celiac Sprue) is associated with Dermatitis herpetiformis. Celiac Disease Definition Autoimmune disorder triggered by ingesting gluten-containing foods in genetically susceptible individuals. It is influenced by HLA-DQ2 or HLA-DQ8. Pathogenesis Clinical features Adults: Commonly between the ages of 30 and 60. More frequent in females Silent celiac disease (positive serology and villous atrophy without symptoms) Latent celiac disease (positive serology is not accompanied by villous atrophy) It may be associated with chronic diarrhoea, bloating, chronic fatigue, or asymptomatic. Anaemia (iron and vitamin malabsorption). Dermatitis herpetiformis (itchy, blistering skin lesion) might be present. (Option C) Pediatric cases: Both sexes were affected equally. It may present with malabsorption. Begins after the introduction of gluten to the diet (6-24 months of age) Manifestations include irritability, abdominal distention, anorexia, chronic diarrhoea, failure to thrive, weight loss, or muscle wasting. It may also present as abdominal pain, nausea, vomiting, bloating, or constipation. Extraintestinal complaints include arthritis or joint pain, aphthous stomatitis, iron deficiency anaemia, delayed puberty, and short stature. Serum markers IgA antibodies against tissue transglutaminase (tTG): Most sensitive. Anti-endomysial antibodies (EMA): Most specific. IgG antibodies against gliadin (a component of gluten). Histology Biopsy of the second part of the duodenum or proximal jejunum: Increased intraepithelial CD8+ T lymphocytes (intraepithelial lymphocytosis). Crypt hyperplasia (Increased mitosis). Villous atrophy (Reduced mucosal surface area, causing malabsorption). Inflammatory cell infiltration. {{caption_text}} Ulcerative colitis (Option A) is a chronic inflammatory bowel disease (IBD) that affects the colon and rectum. It causes ulceration and inflammation of the inner lining of the colon, leading to symptoms like bloody diarrhoea, abdominal pain, cramping, and weight loss. The condition is characterised by periods of flare-ups and remissions and is believed to have an autoimmune origin. Whipple’s disease (Option B) is a rare bacterial infection caused by Tropheryma whipplei . It primarily affects the small intestine, causing malabsorption, diarrhoea, and weight loss, and can also involve the joints, heart, nervous system, and lungs. It is characterised by PAS-positive macrophages in tissue samples. Crohn’s disease (Option D) is a chronic inflammatory bowel disease that can affect any part of the GI tract, causing symptoms like abdominal pain, diarrhoea, and weight loss. It involves transmural inflammation and skip lesions. The exact cause is unknown, but it’s linked to an autoimmune response.

@Neet_pg_bot

Q18: In contrast with Ulcerative colitis, which of the following is Crohn's disease is likely to show? (Q840077)

A. Seldom presents with daily hematochezia

B. Increased frequency of perianal fistula

C. Continuous lesion

D. Increased risk of colon cancer

Correct Answer: B. Increased frequency of perianal fistula

Explanation: Correct Option B - Increased frequency of perianal fistula: Perianal fistulas are seen only in Crohn's disease and not in ulcerative colitis. Fissures frequently develops and may extend deeply to become fistula tracts or sites of perforation. Incorrect Options: Options A, C & D: These are features of ulcerative colitis.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: Which of the following is not associated with GIST? (Q840010)

A. PDGFR Beta

B. SDH

C. c- KIT

D. NRG-1

Correct Answer: D. NRG-1

Explanation: Neuregulin/NRG-1 is not a marker for GIST diagnosis. It is seen in non-TRU type lung adenocarcinoma, including mucinous adenocarcinoma(most common subtype - 38.1%), followed by TRU type lung adenocarcinoma (23.8%) and GI and PB adenocarcinoma(23.8%). Gastrointestinal stromal tumors (GIST) Mutations: Most common: c-KIT (Option C) Others: PDGFRβ (Option A) Succinate dehydrogenase (SDH) (Option B) Markers: CD117 - Most sensitive DOG1 - Most specific CD34 - Miscellaneous

@Neet_pg_bot

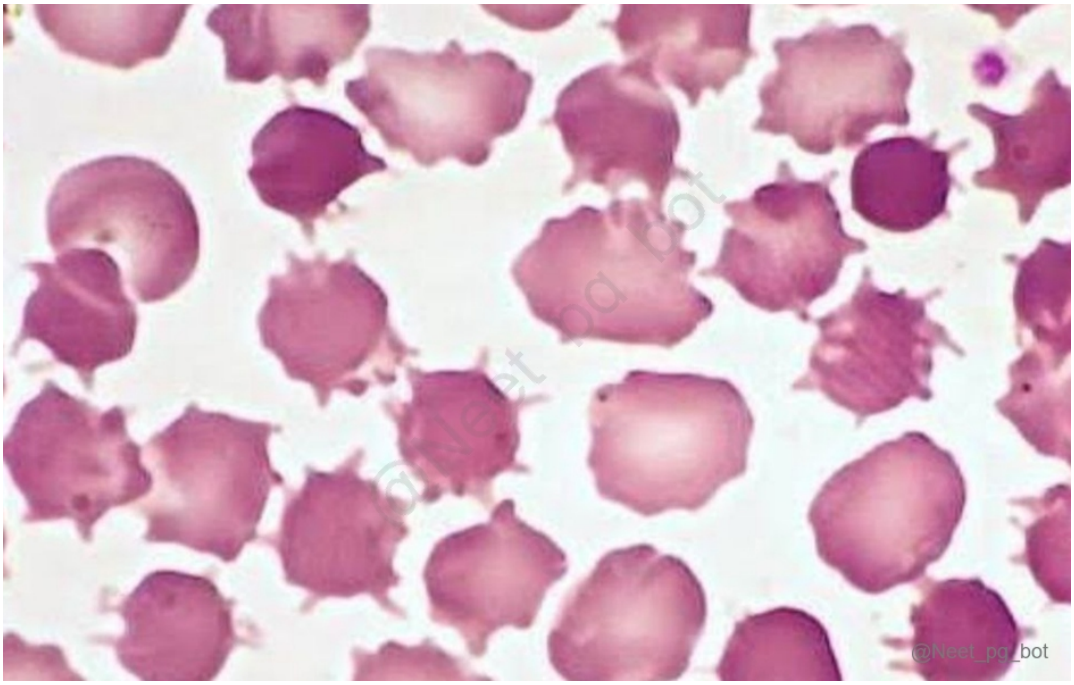
Q20: An adult man presents with a protruding abdomen, diarrhea, visual disturbances and neurological manifestations. Based on the given peripheral smear, what is the most likely diagnosis? (Q844190)

A. Abetalipoproteinemia

B. Whipple’s disease

C. Menetrier's Disease

D. Uremia



Correct Answer: A. Abetalipoproteinemia

Explanation: Correct Option A – Abetalipoproteinemia: Abetalipoproteinemia is characterized by the presence of acanthocytes (spur cells) on peripheral smear and results from mutations in the MTTP gene. Incorrect Options: Option B - Whipple’s disease: Whipple’s disease shows foamy macrophages in the intestinal biopsy. Option C - Menetrier's Disease: Menetrier's Disease shows foveolar cell hyperplasia. Option D – Uremia: Uremia does not show spur cells.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A child presents with itchy lesions and diarrhea and has been advised to follow a gluten-free diet. What is the most likely diagnosis? (Q844098)

A. Celiac disease

B. Whipple's disease

C. Crohn's disease

D. Ulcerative colitis

Correct Answer: A. Celiac disease

Explanation: The presence of an itchy lesion along with gluten sensitivity is suggestive of celiac disease. Itchy lesions → Suggestive of dermatitis herpetiformis , a skin manifestation of celiac disease. Diarrhea → Classic gastrointestinal symptom of malabsorption. Gluten-free diet advised → Strongly points toward gluten sensitivity, which is central to celiac disease. Celiac disease Cause: Autoimmune reaction to gluten (in wheat, barley, rye) Symptoms: Diarrhea, abdominal bloating, failure to thrive (in children), irritability, and skin lesions Dermatologic sign: Dermatitis herpetiformis – intensely itchy, blistering rash (usually elbows, knees, buttocks) Diagnosis: Positive anti-TTG or anti-endomysial antibodies; confirmed by duodenal biopsy Treatment: Strict lifelong gluten-free diet Incorrect Options: Whipple's disease, Crohn's disease and Ulcerative colitis (Options B, C, and D) do not show gluten sensitivity.

https://pubmed.ncbi.nlm.nih.gov/28722929/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q22: Which vitamin is to be supplemented in a patient following gastrectomy? (Q844083)

A. Vitamin A

B. Vitamin B1

C. Vitamin C

D. Vitamin B12

Correct Answer: D. Vitamin B12

Explanation: Correct Option D - Vitamin B12: Vitamin B12 deficiency can occur following gastrectomy due to intrinsic factor deficiency and hence can lead to pernicious anemia. Therefore, to prevent this, vitamin B12 supplementation is done following gastrectomy. Incorrect Options: Options A, B, and C are not usually supplemented in a patient following gastrectomy.

↑ *Back to this question in Part A*

@Neet_pg_bot

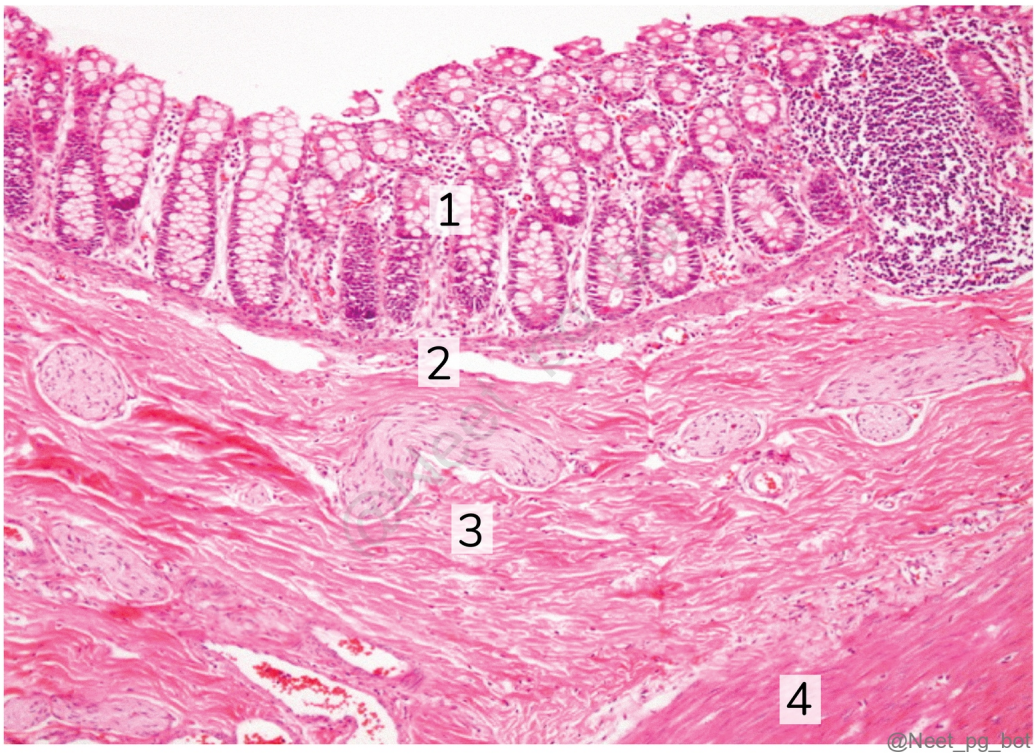
Q23: A child presents with failure to pass stools and is diagnosed with Hirschsprung disease. Which among the following layers of the colon will show congenital absence of neurons? (Q844079)

A. 1 & 2

B. 2 & 3

C. 3 & 4

D. 1 & 4



Correct Answer: B. 2 & 3

Explanation: Correct Option B - 2 & 3: In Hirschsprung disease, the congenital absence of neurons is seen in the submucosa (Meissner's plexus, Layer 2) and the muscularis propria (myenteric plexus, Layer 3). This absence leads to the failure of peristalsis and the subsequent inability to pass stools. Incorrect Options: Options A, C, and D: Layers 1 and 4 are not affected by Hirschsprung disease.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: Which of the following antibodies is associated with celiac disease? (Q843987)

A. Anti-TTG

B. ANCA

C. ASCA

D. AMA

Correct Answer: A. Anti-TTG

Explanation: Correct Option A - Anti-TTG: Anti-tissue transglutaminase is associated with celiac disease. Incorrect Options: Options B, C, and D: Anti-neutrophil cytoplasmic antibodies (ANCA), Anti-Saccharomyces cerevisiae antibodies (ASCA) and Anti-mitochondrial antibody (AMA) are not associated with celiac disease.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q25: Match the following diseases with their respective gene mutation: 1. Familial adenomatous polyposis i. SMAD4 2. Juvenile polyposis ii. STK11 3. Tuberous sclerosis iii. APC gene 4. Peutz-Jeghers syndrome iv. TSC1 (Q853371)

A. A-i, B-ii, C-iii, D-iv

B. A-ii, B-iii, C-i, D-iv

C. A-iii, B-i, C-iv, D-ii

D. A-iv, B-ii, C-iii, D-i

Correct Answer: C. A-iii, B-i, C-iv, D-ii

Explanation: Below are some gene mutations and their associated manifestations: Genes mutation Manifestations MLH1, MSH2 Results in microsatellite instability Causes cluster of cancer: Colorectal, Endometrial, Ovarian, Pancreatic cancers Colon cancer develops at a young age, and it usually occurs on the right side. SMAD4 and BMPR1 Juvenile polyposis syndrome STK11 Peutz-Jeghers syndrome APC gene Familial Adenomatous Polyposis(FAP), sporadic colon cancer, Gardner syndrome and Turcot syndrome MUTYH MUTYH-associated polyposis. TSC1 (hamartin) or TSC2 (tuberin) Tuberous sclerosis

Robbins & Cotran Pathological Basis of Diseases, 10th Edition, Page 809, 813.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q26: What is the eye manifestation seen in HLA B27-positive patients with ulcerative colitis? (Q866755)

A. Uveitis

B. Conjunctivitis

C. Scleritis

D. Iridocyclitis

Correct Answer: A. Uveitis

Explanation: Uveitis Ulcerative colitis is an inflammatory bowel disease (IBD) with possible extraintestinal manifestations. HLA-B27–positive patients have a higher risk of certain autoimmune complications, particularly in the eye. The most classic ocular manifestation is acute anterior uveitis . Features of uveitis in HLA-B27–associated IBD: Usually unilateral , sudden onset. Symptoms: eye pain, redness, photophobia, blurred vision. Exam: ciliary flush, cells & flare in anterior chamber. Can be recurrent. Conjunctivitis (Option B): It is more common in reactive arthritis (Reiter's syndrome), not as strong an association with ulcerative colitis. Conjunctivitis involves superficial eye redness without the deep inflammation of uveitis. Scleritis (Option C): Deep, boring eye pain; associated with systemic autoimmune diseases like rheumatoid arthritis. It is less commonly seen in ulcerative colitis. Iridocyclitis (Option D): refers to inflammation of the iris and ciliary body (a subset of anterior uveitis).

↑ *Back to this question in Part A*

@Neet_pg_bot

Q27: Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, is caused by mutations in which type of genes? (Q866735)

A. APC

B. MMR

C. MYC

D. TERT1

Correct Answer: B. MMR

Explanation: HNPCC / Lynch syndrome is caused by germline mutations in DNA mismatch repair (MMR) genes. The most commonly affected genes are: MLH1 MSH2 MSH6 PMS2 Loss of these MMR proteins → failure to correct base-pairing errors → microsatellite instability (MSI) → increased risk of colorectal cancer (esp. right-sided) and extra-colonic cancers (endometrial, ovarian, gastric, urinary tract). Lynch syndrome is associated with germline mutations in DNA mismatch repair (MMR) genes, leading to microsatellite instability (MSI). MSI is a hallmark of Lynch syndrome-associated tumours, including colorectal adenocarcinoma. APC (Option A): tumor suppressor gene mutated in Familial Adenomatous Polyposis (FAP) , not Lynch syndrome. MYC (Option C): proto-oncogene involved in Burkitt lymphoma (t(8;14)), not colorectal cancer syndromes. TERT1 (Option D): encodes telomerase reverse transcriptase; mutations linked to certain familial cancers but not HNPCC.

Q1: Which of the following conditions is not typically associated with Mallory-Denk bodies? (Q845632)

A. Wilson’s Disease

B. Hemochromatosis

C. Indian childhood cirrhosis

D. Alpha-1 antitrypsin deficiency

Correct Answer: B. Hemochromatosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Among the given options, Hemochromatosis is not associated with Mallory-Denk bodies. Mallory-Denk bodies are seen in: Alcoholic liver disease (ALD) Non-alcoholic fatty liver disease (NAFLD) Indian childhood cirrhosis (ICC) (Option C) Wilson's disease (Option A) Alpha-1 antitrypsin deficiency (Option D) Hepatocellular carcinoma Cholestasis Hepatic or primary biliary diseases. Mallory-Denk bodies are not seen in: Hemochromatosis (Option B) Secondary biliary diseases.

@Neet_pg_bot

Q2: Which of the following combinations represents the organs involved in hereditary hemochromatosis? Liver Pancreas Myocardium Basal ganglia (Q890275)

A. 1, 2, and 3 only

B. 1 and 4 only

C. 2 and 4 only

D. 1, 2, 3, and 4

Correct Answer: A. 1, 2, and 3 only

Explanation: Hereditary hemochromatosis mainly causes parenchymal iron deposition in liver, pancreas, heart, and endocrine organs , not the basal ganglia. Organs involved in Hemochromatosis: Organ Effect Pancreas Fibrosis → Diabetes Heart Cardiomyopathy, arrhythmia Skin Slate-gray pigmentation Joints Pseudogout (CPPD deposition) Pituitary/Testes Hypogonadism Liver: Early: Golden-yellow hemosiderin in periportal hepatocytes Prussian blue positive No significant inflammation Progression → micronodular cirrhosis Late: Small, shrunken, dark brown liver

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 773

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following statements regarding secondary hemochromatosis is not true? (Q890274)

A. Bantu siderosis is caused by decreased iron excretion

B. Neonatal hemochromatosis is not a hereditary disorder

C. It can occur after repeated blood transfusions

D. Disease manifests after approximately 20 g of iron accumulation

Correct Answer: A. Bantu siderosis is caused by decreased iron excretion

Explanation: Bantu siderosis results from increased oral iron intake and absorption, not decreased excretion (there is no regulated iron excretion). Secondary Hemochromatosis (Hemosiderosis): Transfusional / Parenteral iron overload: Repeated blood transfusions (Option C) Chronic hemolytic anaemias (e.g., sickle cell disease) Severe thalassemia, aplastic anaemia Increased iron absorption: β-thalassemia Myelodysplastic syndrome Increased oral intake of iron: African iron overload (Bantu siderosis) Chronic liver diseases: Alcoholic liver disease, porphyria

cutanea tarda Neonatal hemochromatosis: Develops in utero Not hereditary (Option B) Iron Burden: Normal Severe Hemochromatosis Total body iron: 2-6 g May exceed 50 g Liver stores: ~0.5 g >1/3 of total iron Disease manifests after ~20 g of iron accumulation. (Option D)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 771, 772

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following is the major life-threatening complication of hereditary hemochromatosis? (Q890273)

A. Hepatocellular carcinoma

B. Acute liver failure

C. Splenic rupture

D. Autoimmune hepatitis

Correct Answer: A. Hepatocellular carcinoma

Explanation: Hereditary hemochromatosis markedly increases the risk of HCC, especially in patients with cirrhosis. Iron-induced oxidative DNA damage predisposes to malignant transformation. Clinical Features: Triad: Cirrhosis Diabetes mellitus Skin pigmentation Hepatomegaly, abdominal pain, cardiac dysfunction Atypical arthritis, hypogonadism More common in males (5-7:1). Symptoms usually appear after 40 years (earlier in men; delayed in women due to menstruation). Major Complication: Hepatocellular carcinoma Risk is ~200-fold increased Risk persists even after iron reduction Acute liver failure (Option B): Hereditary hemochromatosis typically causes chronic progressive liver injury leading to fibrosis and cirrhosis , rather than acute liver failure. Liver damage develops gradually due to progressive iron accumulation and oxidative injury . Splenic rupture (Option C): Splenic rupture is not a recognised complication of hereditary hemochromatosis. Although mild splenomegaly may occur secondary to portal hypertension in advanced cirrhosis , spontaneous rupture is not associated with this condition. Autoimmune hepatitis (Option D): Autoimmune hepatitis is an immune-mediated inflammatory liver disease characterised by autoantibodies and interface hepatitis .

@Neet_pg_bot

Q5: A 42-year-old man presents with fatigue, skin hyperpigmentation, and newly diagnosed diabetes mellitus. Laboratory studies show elevated serum ferritin and transferrin saturation. The gene responsible for this condition is located on which chromosome? (Q890272)

A. Chromosome 6

B. Chromosome 7

C. Chromosome 18

D. Chromosome 21

Correct Answer: A. Chromosome 6

Explanation: The most likely diagnosis is Hereditary Hemochromatosis , and the gene responsible (HFE) is located on Chromosome 6 . Hereditary Hemochromatosis: Caused by mutations affecting hepcidin regulation: HFE gene (the most common cause) TFR2 (transferrin receptor 2) HAMP (hepcidin gene) HJV (hemojuvelin) → juvenile hemochromatosis Mutations in HFE, HJV, HAMP, or TFR2 → Reduced hepcidin synthesis → Increased ferroportin activity → Increased intestinal iron absorption → Systemic iron overload Most Common Genetic Cause: HFE mutation C282Y (cysteine → tyrosine at position 282) Present in ≥70% of cases Homozygosity frequency ≈ 1 in 220 Low penetrance H63D mutation → milder, worldwide distribution

https://pmc.ncbi.nlm.nih.gov/articles/PMC6660136/

↑ *Back to this question in Part A*

@Neet_pg_bot

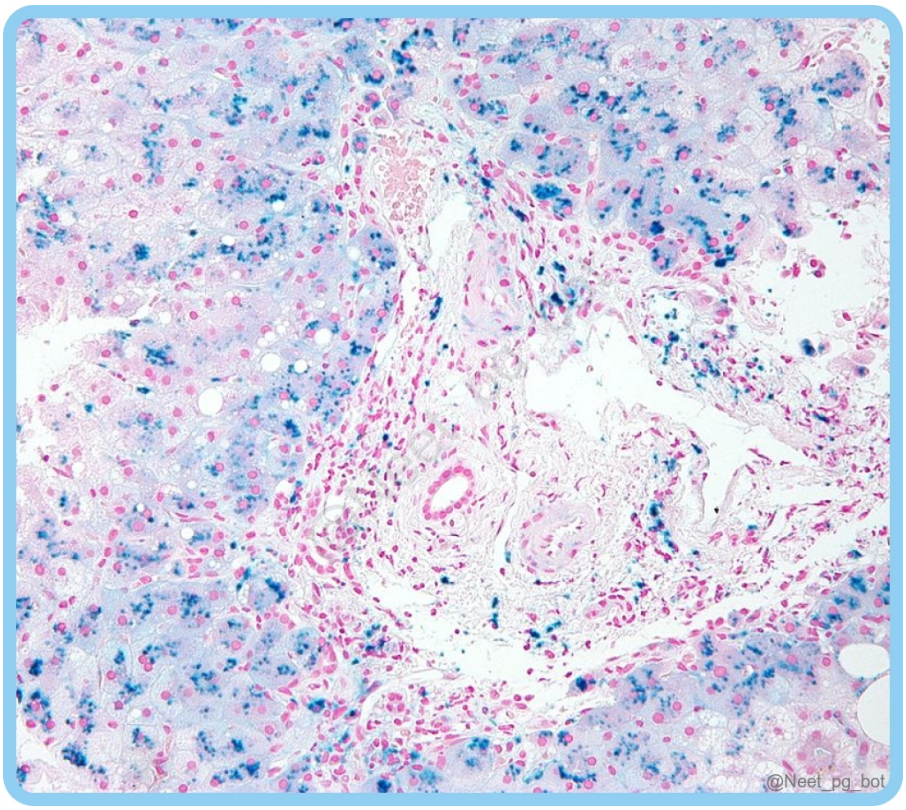
Q6: ■ A 45-year-old man presents with fatigue, diabetes mellitus, and skin hyperpigmentation. Liver biopsy shows findings as shown. Micronodular cirrhosis is present with minimal inflammation. What is the most likely diagnosis? (Q890271)

A. Wilson disease

B. Primary biliary cholangitis

C. Hereditary hemochromatosis

D. α1-antitrypsin deficiency



Correct Answer: C. Hereditary hemochromatosis

Explanation: The correct diagnosis is Hereditary hemochromatosis , because iron deposition begins in periportal hepatocytes, appears as Prussian blue-positive hemosiderin, and progresses to micronodular cirrhosis with minimal inflammation. Hemochromatosis - Morphology: Liver: Earliest deposition in periportal hepatocytes Golden-yellow hemosiderin granules Prussian blue positive Inflammation is typically minimal. Progression → micronodular cirrhosis Late stage → small, shrunken, dark brown liver Other organs: Pancreas → fibrosis → diabetes mellitus Heart → cardiomyopathy, arrhythmias Skin → slate-grey pigmentation Joints → pseudogout (calcium pyrophosphate deposition) Pituitary/testes → hypogonadism Wilson's disease (Option A) involves copper accumulation. Copper is stained with Rhodanine or Orcein stains, not Prussian blue. It also typically presents at a younger age. Primary Biliary Cholangitis (PBC) (Option B) is an autoimmune destruction of the bile ducts. It typically presents with itching (pruritus) and elevated alkaline phosphatase, mainly in women. α1-antitrypsin deficiency (Option D) shows PAS-positive, diastase-resistant pink globules in the hepatocytes, not iron-positive granules.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 771-773

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following findings is wrong regarding the diagnosis of Wilson's disease? (Q890270)

A. KF rings on slit lamp examination

B. Increased hepatic copper content on liver biopsy

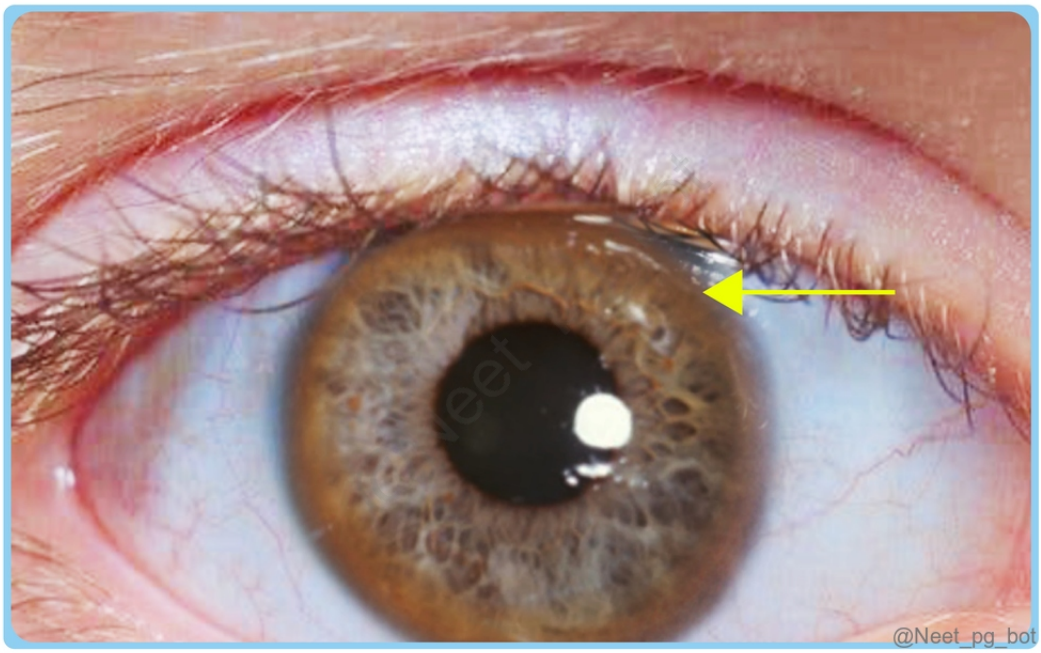
C. Increased urinary copper excretion

D. Elevated serum ceruloplasmin levels

Correct Answer: D. Elevated serum ceruloplasmin levels

Explanation: Wilson's disease is characterised by decreased serum ceruloplasmin due to impaired incorporation of copper into apoceruloplasmin from ATP7B dysfunction. Tests for diagnosis in Wilson’s disease: Test Finding

Utility Serum ceruloplasmin ↓ Screening Hepatic copper content (Option B) ↑ Most sensitive & accurate Urinary copper (Option C) ↑ Most specific Slit lamp exam KF rings (Option A) Supportive ATP7B sequencing Mutation Family screening & if biochemistry equivocal



References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 774

https://www.niddk.nih.gov/health-information/liver-disease/wilson-disease/diagnosis

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 14-year-old boy is diagnosed with Wilson's disease. Genetic testing in the patient identifies a pathogenic mutation in the ATP7B gene. His asymptomatic sibling is evaluated for family screening. Which of the following is the most appropriate test to screen this first-degree relative? (Q890269)

A. Serum ceruloplasmin measurement

B. 24-hour urinary copper excretion

C. Targeted genetic testing for the familial ATP7B mutation

D. Slit-lamp examination for Kayser-Fleischer rings

Correct Answer: C. Targeted genetic testing for the familial ATP7B mutation

Explanation: Wilson disease is an autosomal recessive disorder caused by mutations in the ATP7B gene , resulting in impaired biliary copper excretion and accumulation of copper in the liver, brain, and other tissues. When a specific pathogenic ATP7B mutation has already been identified in the affected patient (proband) , the most appropriate method for screening asymptomatic first-degree relatives is targeted genetic testing for the known familial mutation . This allows early identification of affected individuals before clinical manifestations develop and enables timely initiation of therapy. The diagnosis of Wilson's disease is usually based on biochemical findings such as: Decreased serum ceruloplasmin levels Increased hepatic copper content (the most sensitive and accurate test) Increased urinary copper excretion (the most specific test) Demonstration of Kayser-Fleischer rings on slit-lamp examination However, ATP7B mutation analysis is useful for confirming the diagnosis and for screening family members , particularly when the familial mutation is already known . Serum ceruloplasmin measurement (Option A): Often decreased in Wilson disease and used in biochemical screening, but levels may be normal in some patients or altered by liver injury. 24-hour urinary copper excretion (Option B): A highly specific diagnostic test, commonly used in the evaluation of suspected Wilson disease, but less definitive for screening when the familial mutation is known. Slit-lamp examination for Kayser-Fleischer rings (Option D): Helpful supportive finding, especially in patients with neurologic disease, but rings may be absent in early or asymptomatic cases.

@Neet_pg_bot

Q9: Which of the following is not typically associated with developing fatty liver disease? (Q845639)

A. Hepatitis B

B. Hepatitis C

C. Type 2 diabetes

D. Alcoholism

Correct Answer: A. Hepatitis B

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hepatitis B primarily affects the liver by causing inflammation and can lead to chronic liver disease, cirrhosis, and liver cancer, but it does not directly cause fatty liver disease. Fatty liver disease is often associated

with several factors, such as alcoholism (Option D) , obesity, insulin resistance, metabolic syndrome, and type 2 diabetes (Option C). Chronic Hepatitis C (Option B) can cause liver inflammation and damage, potentially resulting in fat accumulation in the liver cells and leading to fatty liver disease.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 837, 842

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following is typically observed in liver biopsy findings of acute hepatitis A infection? (Q845638)

A. Interface hepatitis

B. Councilman bodies

C. Ground glass hepatocytes

D. Bridging fibrosis

Correct Answer: B. Councilman bodies

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Councilman bodies, also known as acidophilic or apoptotic bodies, are eosinophilic structures representing apoptotic hepatocytes. These are characteristic findings of acute viral hepatitis. Biopsy findings of acute viral hepatitis Ballooning degeneration of hepatocytes Councilman bodies Spotty necrosis Dropout necrosis and Kupffer cell hyperplasia (Empty space lined by Kupffer cells) Absent or mild portal inflammation Interface hepatitis (Option A) is characterised by inflammatory cell infiltrates at the interface between the portal tracts and hepatic lobules and is prominent in Chronic viral hepatitis rather than acute. Ground glass hepatocytes (Option C) (aka Shikata cells) are densely eosinophilic cells with glassy cytoplasm due to HBsAg. They are seen in chronic Hepatitis B infection but not acute hepatitis. Bridging fibrosis (Option D) refers to fibrous septa or thick collagenous bands connecting adjacent portal tracts and central veins. It is typically observed in Chronic hepatitis and is indicative of advanced liver fibrosis.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page831

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: What is the most likely autoantibody detected in Type I autoimmune hepatitis (AIH)? (Q845636)

A. Anti-LKM 1

B. Anti-smooth muscle antibodies (ASMA)

C. Anti-Liver Cytosol 1 (ACL-1)

D. Anti-cyclic citrullinated peptide (anti-CCP)

Correct Answer: B. Anti-smooth muscle antibodies (ASMA)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Autoimmune hepatitis (AIH) is characterised by the presence of autoantibodies targeting various liver antigens. In Type 1 AIH, the most commonly detected autoantibody is anti-smooth muscle antibodies

(ASMA), which target actin filaments in the smooth muscle cells of blood vessels and the liver. Features Type I AIH Type II AIH More common in Young female Children Auto-antibodies Anti SMA (Anti smooth muscle antibody) (Option B) ANA (Anti-nuclear antibody) Anti-soluble liver antigen Anti LKM- 1 (Hepatitis C) (Option A) Anti–liver cytosol-1 (ACL-1) (Option C) Anti LKM- 3 (Hepatitis D) Microscopic Examination of AIH: Interphase Hepatitis: 1 st change, present at interphase (between portal triad and hepatocytes): Max conc of antibodies Piecemeal Necrosis Emperipolesis/Entosis (Hepatocyte Eating Lymphocyte): Cell within cell appearance Hepatic Rosette: Hepatocytes arranged in round alignment

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Pages 839-840

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 45-year-old male with diabetes mellitus presents with fatigue and abdominal discomfort. He denies any history of alcohol consumption. Laboratory tests show elevated serum AST and ALT levels. Imaging reveals hepatic steatosis. Which of the following is consistent with the patient's presentation? (Q845635)

A. AST/ALT > 2 with obesity

B. AST/ALT > 2 without alcohol intake

C. AST/ALT < 1 with diabetes mellitus

D. AST/ALT < 1 without dyslipidemia

Correct Answer: C. AST/ALT < 1 with diabetes mellitus

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation is consistent with Non-alcoholic steatohepatitis, characterised by AST/ALT < 1. Features NASH (Non-alcoholic steatohepatitis) Alcoholic steatohepatitis Risk factors Obesity Diabetes mellitus (Option C) Dyslipidemia (Option D ruled out) Alcohol intake AST/ALT Ratio AST/ALT < 1 (Option A and B ruled out) AST/ALT > 2 GGT levels Normal Increased

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 842- 846

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following changes is reversible with alcohol abstinence? (Q845633)

A. Perivenular fibrosis

B. Periportal fibrosis

C. Bridging fibrosis

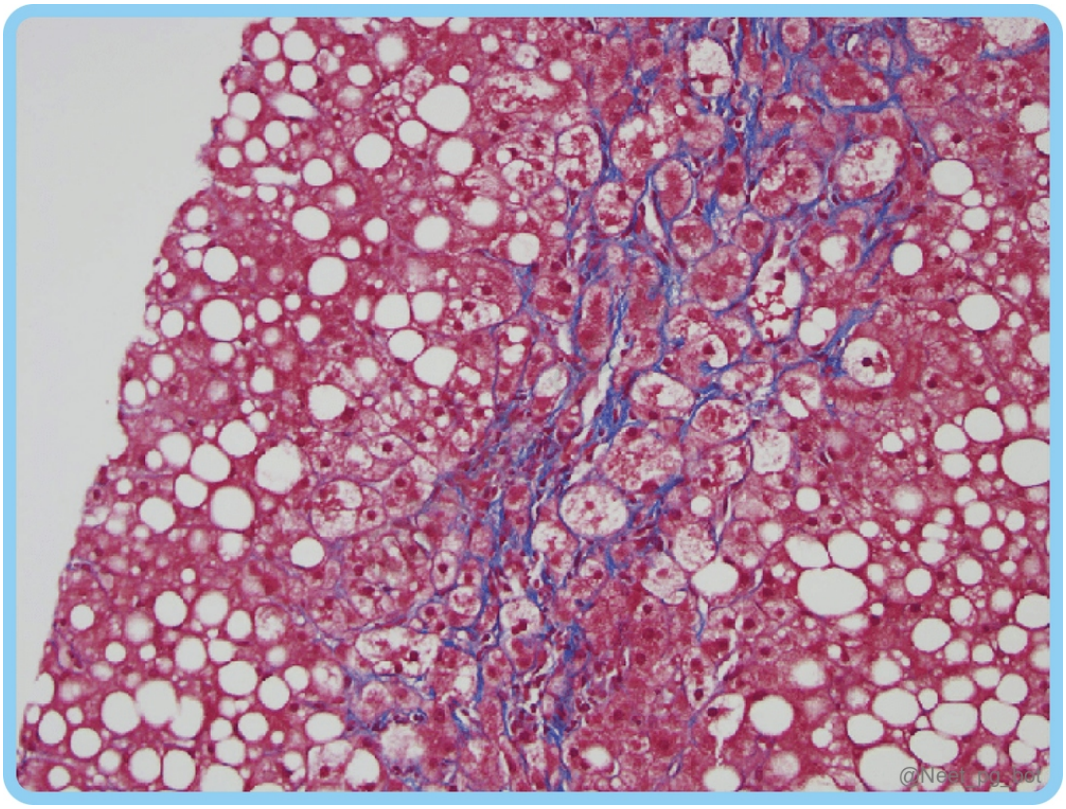
D. Micronodular cirrhosis

Correct Answer: A. Perivenular fibrosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: In the early stages of alcoholic liver disease, fibrosis typically begins around the central veins (central venules) in the liver lobules (perivenular or centrilobular zone) with a characteristic "chicken wire" appearance. With cessation of alcohol intake and appropriate treatment, this perivenular or pericellular fibrosis can regress, leading to improvement in liver function and histology.



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 844

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which cells are primarily involved in the fibrosis in liver cirrhosis? (Q845617)

A. Kupffer cells

B. Pit cells

C. Stellate cells

D. Hepatocytes

Correct Answer: C. Stellate cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hepatic stellate cells (or Ito cells) are pericytes located in the space of Disse, between hepatocytes and sinusoidal endothelial cells in the liver. In the healthy liver, these cells store vitamin A in lipid droplets and regulate sinusoidal blood flow. Upon liver injury, they activate and transform into myofibroblast-like cells, release TGFβ, and lead to fibrosis by producing excessive extracellular matrix, such as collagen. Pathogenesis of Fibrosis: Upon activation by TGF-β (the most potent fibrogenic cytokine) and PDGF (which drives cell proliferation), Stellate cells transform into myofibroblasts. This leads to: Collagen Shift: The normal Type IV collagen in the Space of Disse is replaced by heavy Type I and Type III collagen (fibrillar collagen). Fibrogenic Interleukins: Pro-inflammatory cytokines like IL-13, IL-1, and TNF-α further stimulate the production of extracellular matrix (ECM). Matrix Imbalance: Stellate cells release TIMPs (Tissue Inhibitors of Metalloproteinases). These inhibit the enzymes (MMPs) that normally break down scar tissue, leading to unchecked collagen accumulation. Capillarization: The dense collagen buildup causes sinusoidal endothelial cells to lose their fenestrations (pores), blocking nutrient exchange between blood and hepatocytes. Kupffer cells (Option A) are macrophages found in sinusoids of the liver, involved in phagocytosis. Pit cells (Option B) are liver-associated lymphocytes, primarily NK (Natural Killer) cells. They contribute to liver immune surveillance but are not directly implicated in liver fibrosis. Hepatocytes (Option D) are vital liver cells.

@Neet_pg_bot

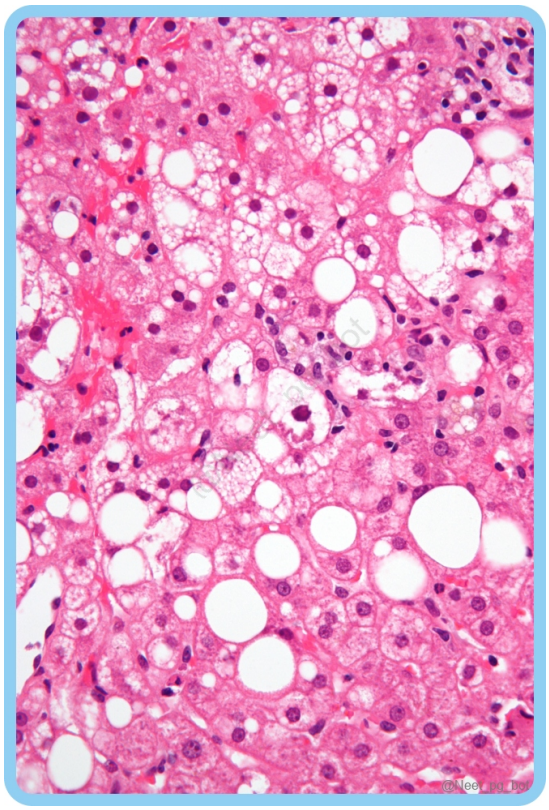
Q15: A 51-year-old male with a history of chronic alcohol use presents with fatigue, abdominal discomfort, and unintentional weight loss. A biopsy of the liver was done. Which of the following histopathological features is characteristic of the condition depicted in the biopsy image? (Q845631)

A. Mallory-Denk bodies

B. Ground-glass hepatocytes

C. Councilman bodies

D. Glycogenated hepatocytes



Correct Answer: A. Mallory-Denk bodies

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The histopathological feature characteristic of the condition depicted in the biopsy image is Mallory-Denk bodies , a hallmark of both alcohol-induced and nonalcoholic steatohepatitis. These are eosinophilic cytoplasmic inclusions seen in hepatocytes. They comprise intermediate filaments, primarily cytokeratin 8 and 18, and other proteins like ubiquitin. They indicate cellular injury and are often associated with hepatocyte ballooning and inflammation. Mallory - Denk bodies are also seen in (New Indian WATCH) N on alcoholic fatty liver disease Indian childhood cirrhosis W ilson’s disease A lcoholic liver disease T umors like hepatocellular carcinoma C hronic cholestasis Focal nodular H yperplasia Ground-glass hepatocytes (Option B): This morphological change is seen in chronic hepatitis B infection, where hepatocytes display a granular, homogenous eosinophilic cytoplasm due to the accumulation of HBsAg in the swollen smooth endoplasmic reticulum. Councilman bodies (Option C): Councilman bodies (or acidophilic bodies) are eosinophilic, round structures representing hepatocyte apoptosis. They are typically seen in acute viral hepatitis and indicate severe hepatocellular injury. Glycogenated hepatocytes (Option D): Glycogenated hepatocytes are hepatocytes with increased intracytoplasmic glycogen content. This finding is often seen in conditions associated with metabolic disturbances, such as glycogen storage diseases or acute fatty liver of pregnancy.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 343-345

↑ *Back to this question in Part A*

Q16: A 60-year-old male presents with abdominal distension and jaundice. Examination reveals hepatosplenomegaly. Lab tests show elevated liver enzymes and decreased albumin levels. Imaging shows nodules <3mm throughout the liver. Which of the following conditions can present with these findings? (Q845629)

A. Viral hepatitis

B. Drug-induced hepatitis

C. Hemochromatosis

D. Wilson disease

Correct Answer: C. Hemochromatosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation suggests micronodular liver cirrhosis with nodules <3mm. Hemochromatosis is one of the causes of micronodular cirrhosis. Causes of micronodular cirrhosis (Granule size <3mm) Causes of macronodular cirrhosis (Granule size >3mm) Early stage of Alcoholic Liver Disease (ALD) Indian Childhood Cirrhosis (ICC) Primary Biliary Cirrhosis (PBC) Hemochromatosis (Option C) Hepatic venous outflow obstruction (Budd-Chiari syndrome) Late stage of alcoholic liver disease (ALD) Viral hepatitis (Option A) Wilson disease (Option D) Drug-induced hepatitis (Option B) Alpha-1 antitrypsin deficiency

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 844

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: Which of the following is the manifestation of increased estrogen levels in Cirrhosis? (Q845628)

A. Increased PT and aPTT

B. Flapping tremors

C. Palmar erythema

D. Jaundice

Correct Answer: C. Palmar erythema

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Increased estrogen levels in chronic liver failure lead to vascular changes, resulting in palmar erythema and spider angiomas. This condition can also cause hypogonadism and gynecomastia in males. Increased PT and aPTT (Option A) are primarily due to impaired synthesis of clotting factors by the damaged liver rather than the effects of hyperestrogenemia. Flapping tremors (aka asterixis) (Option B) are commonly associated with hepatic encephalopathy in cirrhosis, primarily due to elevated ammonia levels rather than estrogen. Jaundice (Option D) seen in cirrhosis is a result of impaired bilirubin metabolism due to liver dysfunction rather than being directly influenced by estrogen levels.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page. 828

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: Which of the following stains would be most useful for highlighting collagen deposition in the fibrotic areas of the liver? (Q845626)

A. Periodic acid-Schiff (PAS) stain

B. Masson's trichrome stain

C. Masson's fontana stain

D. Congo red stain

Correct Answer: B. Masson's trichrome stain

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Masson's trichrome stain is commonly used to visualize collagen fibers, making it suitable for highlighting fibrotic areas in liver tissue. Periodic acid-Schiff (PAS) stain (Option A): It stains carbohydrates (glycogen), basement membranes, and fungal walls. In the Liver, it is primarily used to identify Alpha-1 antitrypsin deficiency . In this condition, "globules" of misfolded protein in the hepatocytes stain a deep magenta/purple . Why it's wrong for fibrosis: While it can show basement membranes, it does not provide the color contrast needed to distinguish the thick bundles of Type I and III collagen from the surrounding liver tissue. Masson's Fontana stain (Option C): It stains Melanin and argentaffin granules (substances that reduce silver). In the Liver, it is rarely used but can help identify certain pigments or neuroendocrine cells. Why it's wrong for fibrosis: It has no affinity for collagen. Despite the similar name ("Masson's"), it is a silver-based stain used for completely different diagnostic purposes. Congo Red stain (Option D): This is the definitive diagnostic tool for Amyloidosis , a condition where insoluble, misfolded proteins (amyloid) deposit in the extracellular space. While amyloid can cause liver enlargement and firmness that mimics fibrosis, it is structurally a protein deposit, not a collagen scar. The hallmark of this stain is its unique apple-green birefringence when viewed under polarized light .

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 826

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: Which type of collagen is predominantly involved in the fibrotic process of cirrhosis? (Q845625)

A. Collagen Type I and III

B. Collagen Type I and IV

C. Collagen Type II and III

D. Collagen Type II and IV

Correct Answer: A. Collagen Type I and III

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The fibrotic process in cirrhosis primarily involves activating hepatic stellate cells, leading to collagen deposition by myofibroblasts. These cells predominantly produce Collagen Types I and III. Pathogenesis of Liver Fibrosis: 1. Primary Insult (The Trigger): Chronic Injury (Alcohol, HBV/HCV, NASH/NAFLD) → Hepatocyte death. Release of Reactive Oxygen Species (ROS) and damage-associated molecular patterns (DAMPs). Kupffer cells (macrophages) become activated and release pro-inflammatory cytokines. 2. Activation of Hepatic Stellate Cells (HSCs): Paracrine Signaling: Cytokines from damaged hepatocytes and Kupffer cells reach the Space of Disse. Phenotypic Switch: Quiescent HSCs (Vitamin A-storing) → Myofibroblasts (Contractile and Fibrogenic). Key Growth Factors: PDGF: Stimulates HSC proliferation . TGF-β: The most potent stimulus for collagen synthesis . 3. The "Cytokine Symphony" (Fibrogenic Interleukins): IL-1 and TNF-α: Initial inflammatory "wake-up" call for HSCs. IL-13: Directly promotes TGF-β production and enhances the fibrogenic phenotype. IL-6: Contributes to the acute phase response and sustains the survival of activated myofibroblasts. Chemokines (MCP-1): Recruit more inflammatory cells, creating a self-perpetuating loop. 4. ECM Remodeling & Collagen Deposition The Shift: Normal Type IV collagen (basement membrane-like) is replaced by fibrillar Type I and Type III collagen . Matrix Imbalance: Activated HSCs secrete TIMPs (Tissue Inhibitors of Metalloproteinases). Inhibition: TIMPs bind to and neutralize MMPs (Matrix Metalloproteinases), preventing the degradation of the newly formed scar tissue. 5. Structural Consequences (Cirrhosis) Capillarization of Sinusoids: The dense collagen "seals" the pores (fenestrae) in endothelial cells, blocking nutrient/oxygen exchange. Increased Vascular Resistance: Myofibroblast contraction and structural scarring lead to Portal Hypertension . Regenerative Nodules: Surviving hepatocytes proliferate within the fibrous "cages," forming the classic nodules seen in cirrhosis.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 857-859

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A 35-year-old male presents with chronic jaundice and mild abdominal discomfort. Examination revealed hepatomegaly. Lab tests indicate elevated levels of direct bilirubin. Upon liver biopsy, a pigmented liver is observed. What is the most likely underlying mechanism for these clinical and pathological findings? (Q845623)

A. Deficiency of UDP glucuronosyl transferase (UGT)

B. OATP transporter defect

C. MRP2 (Multidrug resistance-associated protein 2) defect

D. Deficiency of biliverdin reductase

Correct Answer: C. MRP2 (Multidrug resistance-associated protein 2) defect

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical and pathological findings are consistent with Dubin-Johnson syndrome, which is characterised by impaired excretion of conjugated bilirubin into bile due to a defect in the MRP2 transporter leading to conjugated hyperbilirubinemia. The characteristic pigmented liver is due to the accumulation of epinephrine metabolite (not bilirubin). Type of hyperbilirubinemia Disorder Defect Unconjugated hyperbilirubinemia Crigler-Najjar syndrome type 1 Complete deficiency of UGT. (Option A) Crigler-Najjar syndrome type 2 Partial deficiency of UGT. Gilbert syndrome Very mild deficiency of UGT. Conjugated hyperbilirubinemia Dubin Johnson syndrome Defect in canalicular MRP2 protein. (Option C) Pigmented liver (due to epinephrine metabolite) Rotor syndrome Defect in ATPs (decreased biliary excretion) Non-pigmented liver

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 852-854

↑ *Back to this question in Part A*

@Neet_pg_bot

Q22: A 2-week-old infant presents with persistent jaundice since birth and markedly elevated unconjugated bilirubin levels (>20 mg/dL) despite exposure to sunlight. Genetic testing confirms homozygosity for a specific mutation. What is the likely

diagnosis? (Q845622)

A. Criggler-Najjar syndrome type 1

B. Criggler-Najjar syndrome type 2

C. Gilbert syndrome

D. Rotor syndrome

Correct Answer: A. Criggler-Najjar syndrome type 1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the provided scenario, the likely diagnosis is Crigler-Najjar syndrome type 1, a rare autosomal recessive disorder characterised by the complete deficiency of the enzyme UDP-glucuronosyltransferase 1A1 (UGT1A1), leading to severe unconjugated hyperbilirubinemia. Without treatment, this condition can progress to kernicterus, a potentially fatal neurologic complication due to bilirubin deposition in the brain. It is 100% fatal if left untreated. Syndromes of Unconjugated hyperbilirubinemia Disorder Defect Severity of Unconjugated hyperbilirubinemia Crigler-Najjar syndrome type 1 (Option A) Complete deficiency of UGT Severe Crigler-Najjar syndrome type 2 (Option B) Partial deficiency of UGT Mild to moderate Gilbert syndrome (Option C) Very mild deficiency of UGT Mild, asymptomatic Syndromes of Conjugated hyperbilirubinemia Disorder Defect Gross Feature of liver Dubin Johnson syndrome Defect in canalicular MRP2 protein. Pigmented liver (due to epinephrine metabolite) Rotor syndrome (Option D) Defect in ATPs (decreased biliary excretion) Non pigmented liver

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 856

↑ *Back to this question in Part A*

@Neet_pg_bot

Q23: Which change can be seen in a structure that connects hepatocytes with cholangiocytes? (Q845620)

A. Liver regeneration

B. Amyloid deposition

C. Bile synthesis

D. Fibrosis

Correct Answer: A. Liver regeneration

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The structure connecting hepatocytes with cholangiocytes is the Canals of Hering. It contains oval cells (aka liver stem cells), which play a pivotal role in liver regeneration. Therefore, changes observed in this structure are related to liver regeneration.

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 824

@Neet_pg_bot

Q24: Which zone of the liver lobule is primarily affected by toxins and drug metabolism? (Q845619)

A. Zone 1 (periportal zone)

B. Zone 2 (midzonal zone)

C. Zone 3 (centrilobular zone)

D. Entire lobule uniformly

Correct Answer: C. Zone 3 (centrilobular zone)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Zone 3 (centrilobular) is primarily affected by toxins and drug metabolism because Zone 3 hepatocytes are close to the central vein and have the highest levels of cytochrome P450 activity and lowest oxygen tension. Zone Location Hepatocyte characteristics Sensitivity to Injury Zone 1 (periportal zone) (Option A) Around the portal tracts High oxygenation, reduced metabolic activity, Rich blood supply Least susceptibile to toxin-mediated and ischemic injury Zone 2 (mid zonal zone) (Option B) Between zone 1 and zone 3 Intermediate oxygenation, metabolic activity and blood supply Moderate susceptibility to toxin-mediated and ischemic injury Zone 3 (pericentral zone) (Option C) Around the central vein Low oxygenation, active metabolism, Poor blood supply Susceptible to drugs/toxin-mediated damage and ischemic injury during hypoperfusion of the liver

Q7 (p. 2055) *Q8 (p. 2057)* *Q9 (p. 2059)* *Q10 (p. 2061)* *Q11 (p. 2062)* *Q12 (p. 2063)*
Q13 (p. 2065)

Q1: Which of the following mutations is responsible for hereditary haemochromatosis? (Q845720)

A. ATP7B mutation

B. HFE mutation

C. SERPINA 1 mutation

D. UGT1A1 mutation

Correct Answer: B. HFE mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hereditary hemochromatosis is due to an HFE gene mutation on chromosome 6p that causes excess iron absorption, leading to increased iron deposition. This results in the classic triad of cirrhosis , secondary diabetes mellitus , and bronze skin . Hereditary Hemochromatosis: Key laboratory findings: High ferritin, high serum iron and low TIBC. Liver biopsy: Golden-yellow hemosiderin granules in periportal hepatocytes that appear blue with a Prussian blue stain followed by a micronodular pattern of cirrhosis. Other findings: Dilated cardiomyopathy (m/c cardiac manifestation). Increased risk of hepatocellular carcinoma HJV (Hemojuvelin gene) causes juvenile hemochromatosis. Wilson disease is an autosomal recessive disorder involving the ATP7B gene mutation (Option A) Gilbert syndrome , a harmless autosomal recessive disease, results from UGT1A1 gene mutation (Option B) α1-Antitrypsin deficiency is an autosomal recessive disorder occurring due to mutation in SERPINA1 gene leading to pulmonary emphysema and cirrhosis. Liver biopsy shows positive periodic acid-schiff stain and diastase resistance, highlighting the characteristic magenta cytoplasmic granules (Option C)

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 848-850

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 48-year-old man comes to the OPD with complaints of excessive thirst, excessive micturition, and increased hunger. He also states that his skin colour has changed in the past six months. He is icteric on examination, and his skin examination reveals findings similar to those in the image below. What is the most likely cause of the change in his skin colour? (Q845722)

A. Excessive melanin production due to adrenal insufficiency

B. Excessive deposition of melanin and iron in the skin

C. Insulin resistance

D. Excessive deposition of bilirubin in the skin

Correct Answer: B. Excessive deposition of melanin and iron in the skin

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The above patient has features of “ Bronze diabetes ” and liver dysfunction, which are typically seen in hemochromatosis. In Hemochromatosis, skin colour changes due to the deposition of excessive melanin >> iron in the skin. It is also known as "bronze diabetes" due to skin discolouration and associated pancreatic disease. The disease typically manifests after 20 g of stored iron has accumulated in the body. Organs affected Clinical features Liver Hepatomegaly, elevated liver enzymes, risk of HCC Pancreas Iron induced damage of beta cells - diabetes mellitus Heart Cardiomyopathy , arrhythmias, congestive heart failure Skin Hyperpigmentation - bronze skin due to melanin and iron deposition Joints Arthropathy and joint pain CNS Rarely - memory issues, depression and fatigue Excessive melanin production due to adrenal insufficiency (Option A) is typically seen in Addison’s disease, where adrenal insufficiency leads to increased ACTH derived from Proopiomelanocortin, which also produces MSH and Endorphins, thus leading to melanogenesis, causing darkening of the skin and mucosal membranes Insulin resistance (Option C) gives rise to Acanthosis Nigricans, which are hyperpigmented, velvety plaques typically found in body folds such as the neck, axillae, and groin. It is also associated with gastric adenocarcinoma Bilirubin (Option D) deposition leads to jaundice, characterized by a yellowish discoloration of the skin, not the bronze pigmentation seen in hemochromatosis. Jaundice is related to liver dysfunction or hemolysis, not iron overload

↑ *Back to this question in Part A*

@Neet_pg_bot

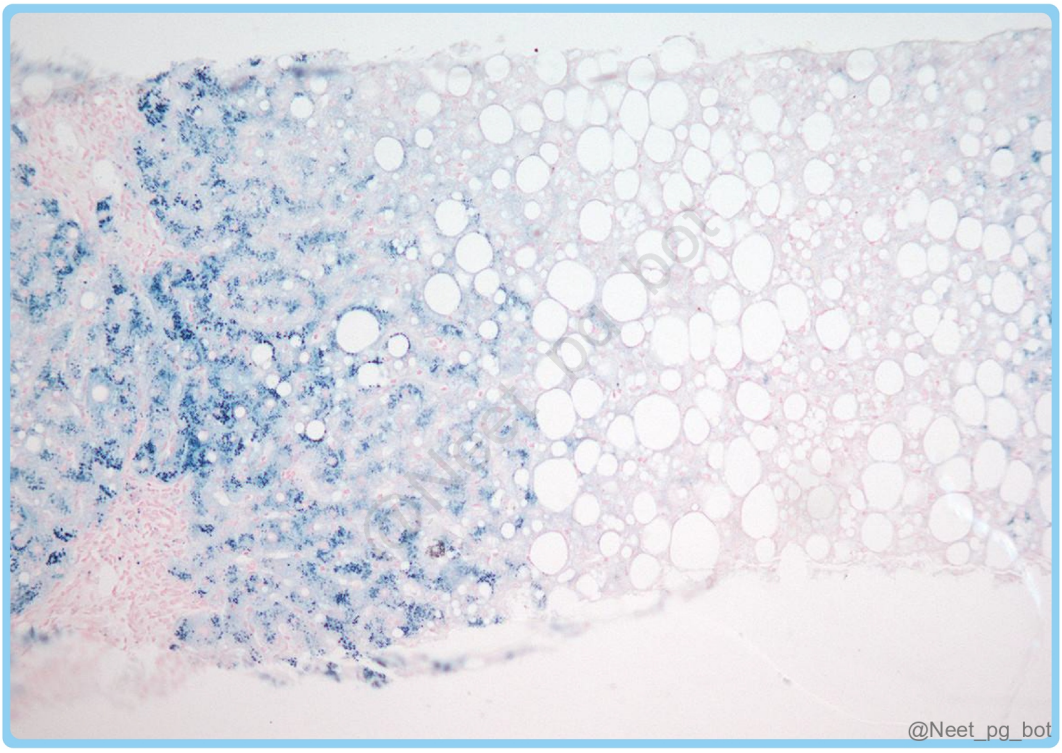
Q3: A 38-year-old female presents with fatigue, joint pain, and bronze skin pigmentation. Labs show a heterozygous mutation in the HFE gene. The histopathology image is shown below. Which of the following is the best screening test for this condition? (Q845725)

A. Serum ferritin level

B. Transferrin saturation

C. Liver function tests

D. Genetic testing for the HFE gene



Correct Answer: B. Transferrin saturation

Explanation: The diagnosis in this case is hemochromatosis . Transferrin saturation (TSAT) is the best screening test for hereditary hemochromatosis. Serum ferritin (Option A) is a protein that stores iron in the body. However, while serum ferritin levels can be a useful indicator, they are not as specific as transferrin saturation (TSAT) for diagnosing hemochromatosis. In hereditary hemochromatosis, LFTs (Option C) may show abnormalities in advanced stages of the disease when iron overload has caused liver damage (e.g., elevated alanine transaminase or AST levels). However, LFTs are not specific screening tests for hemochromatosis . Genetic testing (Option D) for mutations in the HFE gene is the definitive diagnostic test for hereditary hemochromatosis .

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 848

↑ *Back to this question in Part A*

@Neet_pg_bot

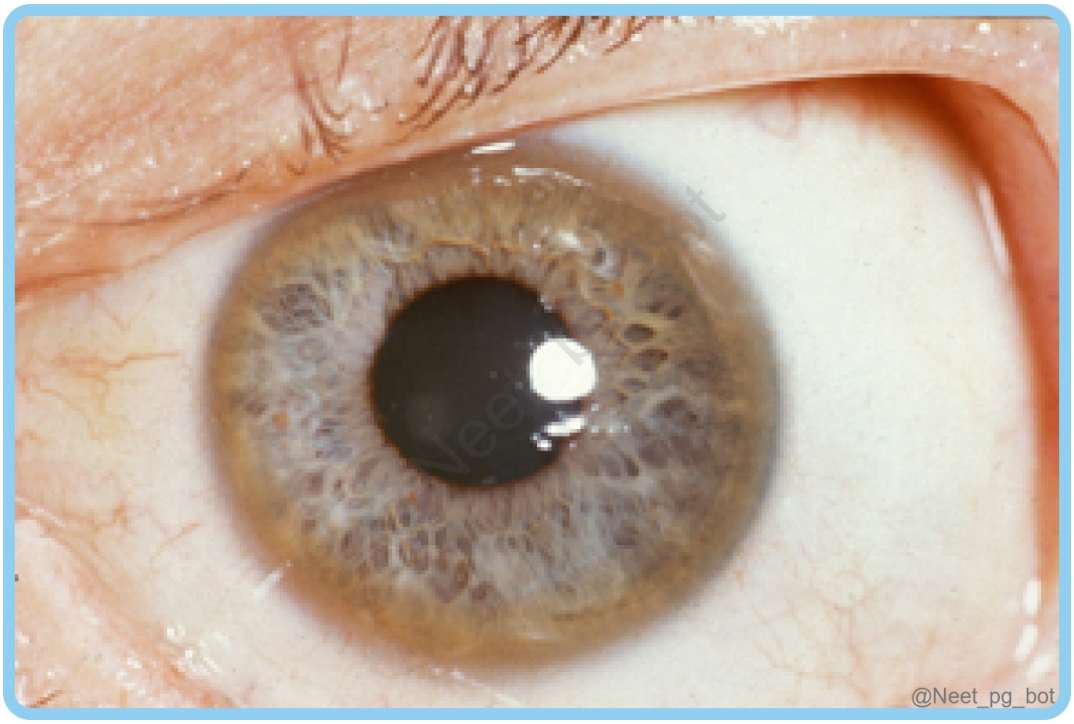
Q4: A 25-year-old patient presents with a history of tremors, dysarthria, and personality changes. Serum ceruloplasmin levels were found to be low. Based on the image below, what ocular finding is associated with the underlying condition? (Q845727)

A. Arcus senilis

B. Kayser-Fleischer rings

C. Roth spots

D. Horner's syndrome

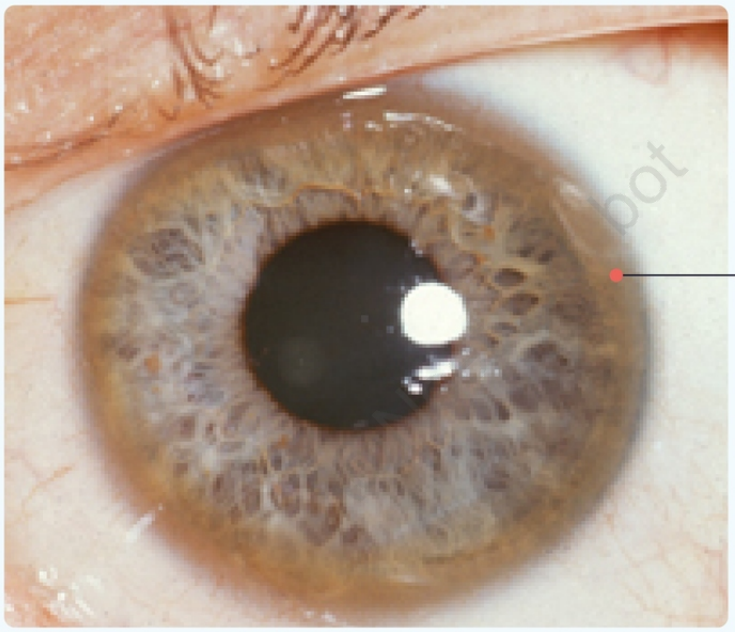


Correct Answer: B. Kayser-Fleischer rings

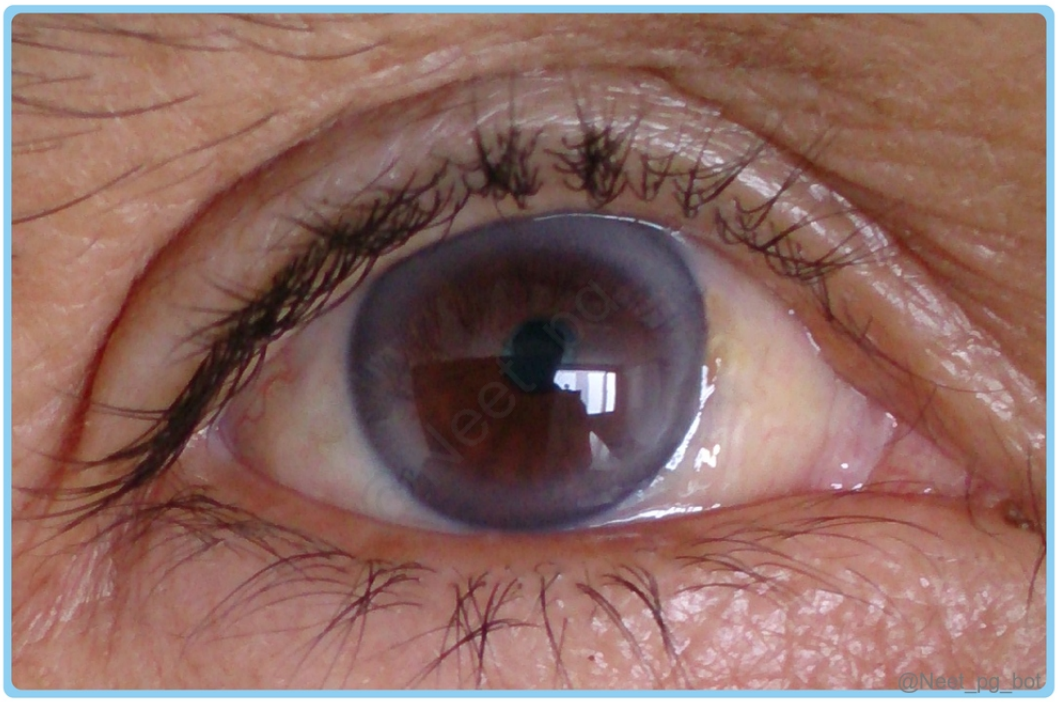
■ *Listen (English)*

■ *Listen (Hindi)*

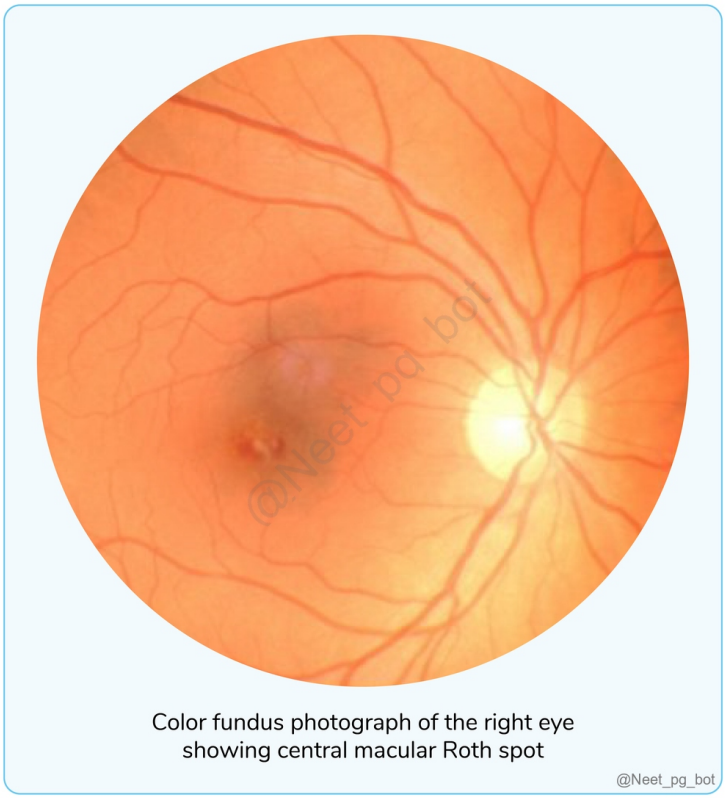
Explanation: The image shows characteristic Kayser-Fleischer rings, a brownish-green discolouration in the cornea. These rings are associated with Wilson's disease, a genetic disorder involving copper metabolism. Wilson's disease is a genetic disorder characterised by impaired copper metabolism. It leads to copper accumulation primarily in the liver, brain, and other organs. Molecular genetic testing can identify mutations in the ATP7B gene, which is responsible for Wilson's disease. Clinical Features: Kayser-Fleischer Rings: These are characteristic brownish-green rings seen in the cornea due to copper deposition and are a hallmark feature of Wilson's disease. Serum copper is raised, while ceruloplasmin levels (a copper-binding protein) are decreased in Wilson's disease. Increased urinary copper excretion is a characteristic finding in Wilson's disease. Arcus senilis refers to a white or greyish ring around the cornea that is commonly seen in elderly individuals. It is caused by lipid deposits in the peripheral cornea and is generally considered a normal age-related change. (Option A) Roth spots are retinal haemorrhages with a white or pale centre. Roth spots can be seen in various medical conditions, including bacterial endocarditis, leukemia, and diabetic retinopathy (Option C) Horner's syndrome is a clinical syndrome characterised by a triad of eye and face symptoms. It includes ptosis (drooping of the upper eyelid), miosis (constriction of the pupil), and anhidrosis (decreased sweating) on the affected side of the face (Option D)



@Neet_pg_bot



@Neet_pg_bot



Color fundus photograph of the right eye showing central macular Roth spot

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 850

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following tests is the most specific for confirming the diagnosis of Wilson's Disease? (Q845730)

A. Serum Ceruloplasmin

B. Urinary excretion of copper

C. LFT

D. Liver Biopsy

Correct Answer: D. Liver Biopsy

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Testing for Wilson's disease: Serum Ceruloplasmin (Option A) : Low levels are suggestive. 24-Hour Urinary Copper Excretion (Option B) : Increased in Wilson's disease Liver Function Tests (LFTs) (Option C): May show abnormalities. Kayser-Fleischer Rings Examination: Greenish-brown rings in the cornea. Genetic Testing: For ATP7B gene mutations, confirming diagnosis. Liver Biopsy (Option D) : Demonstrates hepatic copper accumulation (Most specific). Brain Imaging: MRI to assess neurological involvement.

References:

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 850

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which special stain is commonly used to aid in the diagnosis of Wilson's disease? (Q845731)

A. Oil Red O stain

B. Periodic acid-Schiff (PAS) stain

C. Rubeanic acid stain

D. Prussian blue stain

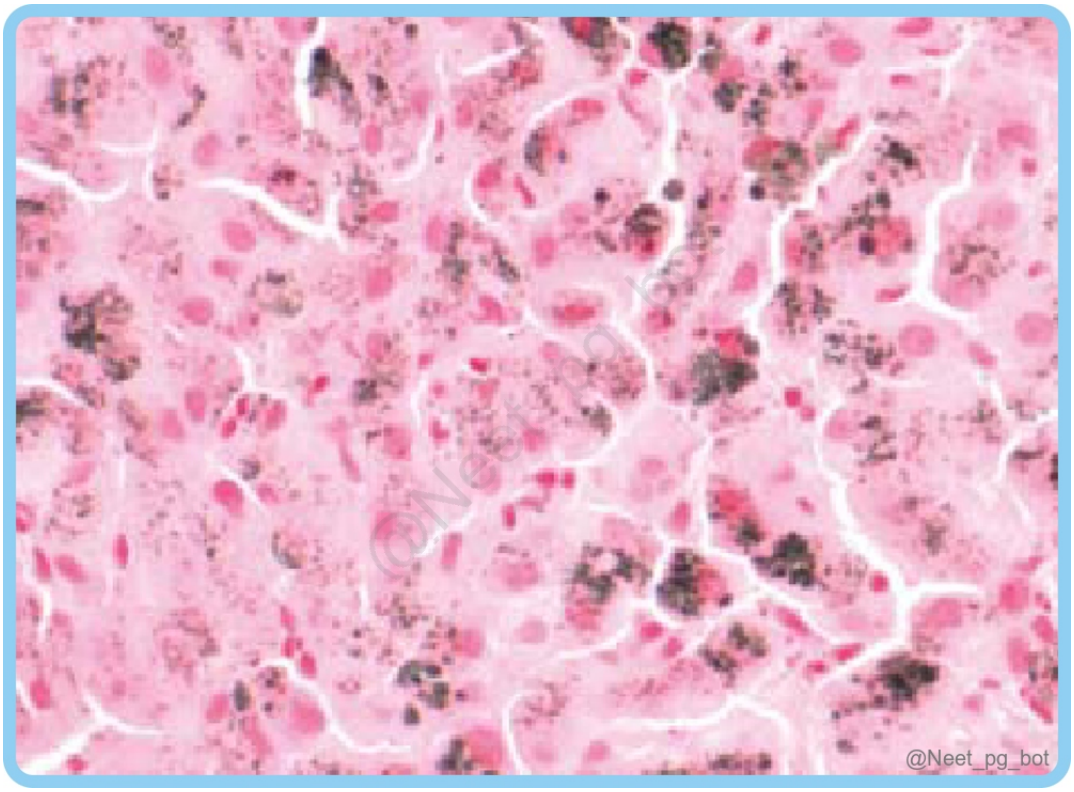
Correct Answer: C. Rubeanic acid stain

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The Rubeanic acid stain, also known as the Rhodanine stain, is commonly used to detect copper accumulation in liver tissue, particularly in the hepatocytes' cytoplasmic granules. This stain forms a distinctive brown-black color when it reacts with copper, aiding in the diagnosis of Wilson's disease. Rubeanic acid stain Stains the copper present within cytosolic granules of hepatocytes Oil red O stain Stains lipids (Option A) PAS

stain Stains cells with high glycogen storage and also stains basement membrane (Option B) Prussian stain Stains hemosiderin / stored iron (Option D)



References:

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 850

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 50-year-old male presents with a history of chronic alcohol abuse and complains of right upper quadrant abdominal pain. On examination, hepatomegaly is noted. Laboratory investigations show elevated liver enzymes. Gross feature of the liver has a characteristic mottled appearance. Based on these findings and the image below, what is the most likely diagnosis? (Q845733)

A. Cirrhosis

B. Hepatitis

C. Nutmeg Liver

D. Liver Abscess

Correct Answer: C. Nutmeg Liver

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The patient's history of chronic alcohol abuse and the characteristic mottled appearance of the liver on imaging studies point towards Nutmeg Liver as the most likely diagnosis. Nutmeg liver, also known as congestive hepatopathy or passive hepatic congestion, is a condition characterized by a mottled appearance of the liver on imaging studies, resembling the cross-section of a nutmeg seed. This appearance is due to centrilobular congestion and haemorrhage caused by chronic passive congestion of the liver , often secondary to right-sided heart failure , chronic venous congestion , or conditions leading to hepatic venous outflow obstruction. Acute passive congestion (“nutmeg liver”). (A) The cut surface of the liver has a variegated mottled red appearance, representing congestion and haemorrhage in the centrilobular regions of the parenchyma. (B) On microscopic examination, the centrilobular region is suffused with red blood cells, and atrophied hepatocytes are not easily seen. Portal tracts and the periportal parenchyma are intact.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 864

↑ *Back to this question in Part A*

@Neet_pg_bot

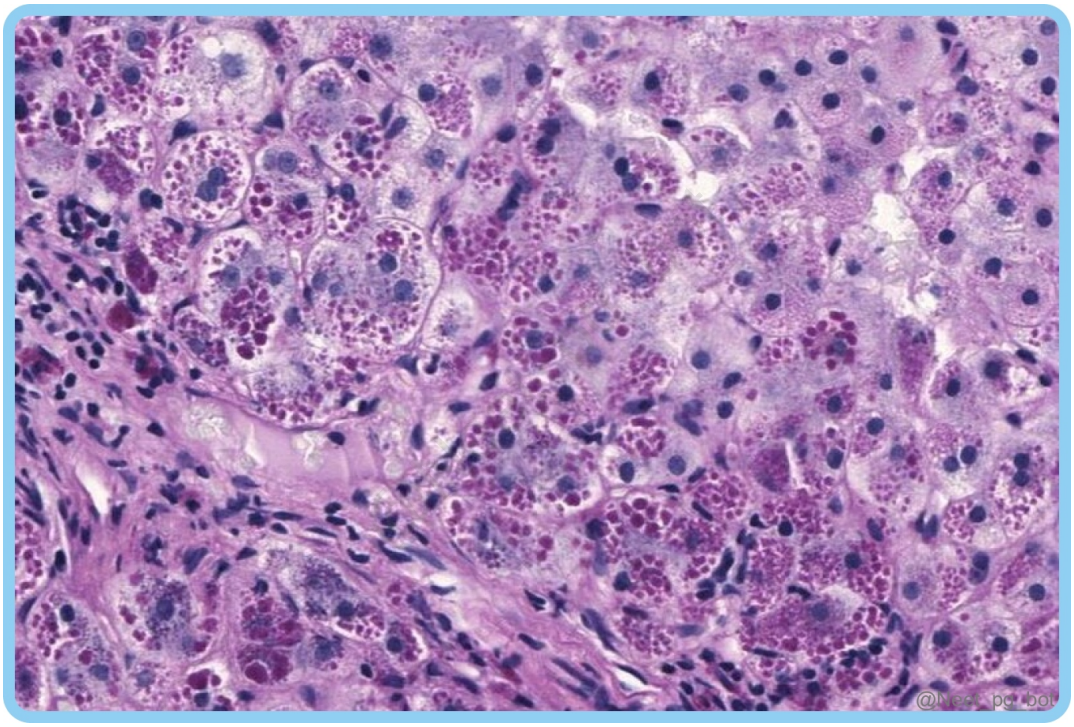
Q8: A 25-year-old female presents with fatigue, jaundice, and abdominal pain. On examination, hepatomegaly is noted. Hepatocytes show globular inclusions which are strongly periodic acid–Schiff (PAS)-positive. Her sibling died of the same liver condition a few years back. What is the primary function of the enzyme implicated in this condition ? (Q845735)

A. Inhibits neutrophil elastase

B. Stimulates neutrophil elastase

C. Stimulates matrix metalloproteinase activity

D. Regulates aminotransferase activity



Correct Answer: A. Inhibits neutrophil elastase

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Alpha-1 antitrypsin (α1AT) is a serine protease inhibitor that plays a crucial role in inhibiting proteases, particularly neutrophil elastase. Alpha-1 Antitrypsin (α1AT) deficiency is an autosomal recessive (AR) disorder with defective gene in Chromosome 14 - SERPINA1 gene In Alpha-1 Antitrypsin Deficiency (AATD), there is a deficiency or dysfunction of α1AT, leading to decreased inhibition of neutrophil elastase . This results in uncontrolled protease activity , particularly neutrophil elastase, which can cause tissue damage, especially in the lungs and liver leading to pan-acinar emphysema and liver cirrhosis respectively Genotype PiZZ: This is the most severe form of AATD. It results from a homozygous mutation in the SERPINA1 gene on Chromosome 14 . Individuals with the PiZZ genotype have the lowest serum levels of α1AT, leading to uncontrolled protease activity. This causes pan-acinar emphysema in the lungs and liver cirrhosis .
Histopathology: The deficiency is characterised by the presence of round-to-oval cytoplasmic globular inclusions in hepatocytes, which are strongly periodic acid–Schiff (PAS)-positive and diastase-resistant.

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 851

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 50-year-old patient with a history of recurrent biliary colic and cholangitis undergoes cholecystectomy. Multiple stones are retrieved intraoperatively, and an image of the stones is provided for reference. Which of the following is true about the type of pigmented stones likely seen in this patient? (Q845738)

A. Predominantly found in western populations

B. Associated with metabolic syndrome

C. Found in sterile bile

D. Seen in obesity

Correct Answer: C. Found in sterile bile

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The provided image and clinical scenario depicting black-pigmented stones retrieved during cholecystectomy. Feature Cholesterol Stones Pigment Stones Predisposing conditions Seen in Western populations (Option A) , related to metabolic syndrome (Option B) , obesity (Option D) and common in females Chronic hemolytic anaemia - Black stones Bacterial infections, parasitic infestations - Brown stones Composition >50% crystalline cholesterol monohydrate Calcium salts of unconjugated bilirubin and inorganic calcium salts Appearance Pale yellow, round to ovoid, granular, hard external surface Brown to black, soft, soap-like, spiculated or moulded contours Location Arise exclusively in the gallbladder Found in sterile gallbladder bile (black stones) or infected large bile ducts (brown stones) (Options C). Radiopacity Radiolucent (may become radiopaque with calcium carbonate) Black stones: 50-75% are radiopaque, Brown stones: Radiolucent

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 874

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: All the following infections are associated with an increased risk of pigmented gallstones, except? (Q845740)

A. Escherichia coli

B. Ascaris lumbricoides

C. Clonorchis sinensis

D. Aspergillus flavus

Correct Answer: D. Aspergillus flavus

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Aspergillus flavus is an acute branching septate fungi, that produces aflatoxins, which are potent carcinogens that can cause liver damage, oxidative stress, and DNA mutations and ultimately increase the risk of hepatocellular carcinoma. They are not associated with an increased risk of gallstones. It causes allergic bronchopulmonary aspergillosis (ABPA), aspergilloma, invasive aspergillosis, and otomycosis. Pigmented gallstones are linked to infections that cause increased unconjugated bilirubin in bile. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts, such as endoprostheses (stents) or parasites such as Clonorchis sinensis and Ascaris lumbricoides (Option B & C) . Gallstones are solid concretions in the gallbladder or biliary tree formed due to imbalance in bile components (cholesterol, bile salts, bilirubin). Type Composition Mechanism Key Associations Cholesterol stones Cholesterol (>70%) Supersaturation of bile with cholesterol Obesity, female, OCPs, pregnancy Pigment stones Calcium bilirubinate ↑ Unconjugated bilirubin Hemolysis, infection Pigment Stones – Subtypes: Type Color Cause Location Black pigment stones Black Sterile bile, hemolysis Gallbladder Brown pigment stones Brown Infection (bacteria/parasites) Bile ducts E. coli (option A) : Produces β-glucuronidase, leading to deconjugation of bilirubin.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Pages 873, 874

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following conditions is not a complication associated with gallstones? (Q845741)

A. Acute pancreatitis

B. Gall bladder carcinoma

C. Bouveret syndrome

D. Budd-Chiari syndrome

Correct Answer: D. Budd-Chiari syndrome

Explanation: Complications of gallstones: Empyema Perforation Fistula formation Inflammation of the biliary tree (cholangitis) Obstructive cholestasis Pancreatitis (Option A) Gallstone ileus (Bouveret syndrome) (Option C) Increased risk of gallbladder carcinoma (Option B)

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 875

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 45-year-old patient presents to the OPD with severe right upper quadrant pain radiating to the right shoulder, accompanied by nausea and vomiting. Clinical examination revealed a positive result for a clinical test shown in the image down below. An ultrasound of the abdomen shows an enlarged and tense gallbladder. Which of the following findings is most likely associated with this patient's condition? (Q845742)

A. Xanthogranulomatous cholecystitis

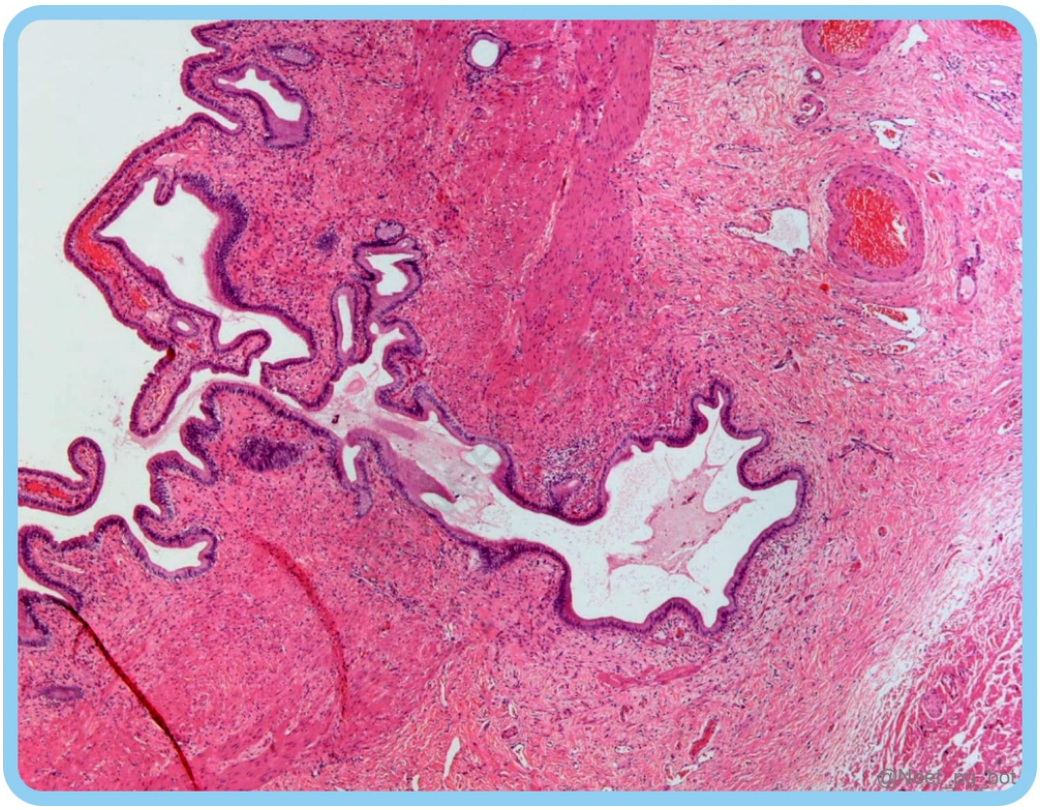
B. Rokitansky-Aschoff sinuses

C. Subserosal fibrosis

D. Subserosal haemorrhages

Correct Answer: D. Subserosal haemorrhages

Explanation: Based on the provided clinical vignette and positive murphy sign, the patient's presentation aligns with acute cholecystitis. The most likely finding associated with this condition is subserosal hemorrhages. Characteristics Acute cholecystitis Chronic cholecystitis Gall bladder appearance Thickened, tense, edematous, bright red or green-black Thickened, fibrotic, opaque grey-white Serosa Subserosal haemorrhages (Option D) , fibrinopurulent exudate Smooth serosa with Subserosal fibrosis (Option C) (subepithelial fibrosis also seen) Histology Erosion of mucosa, Edema, congestion, sparse neutrophils Scattered lymphocytes, plasma cells, macrophages, fibrosis, Rokitansky-Aschoff sinuses (Option B) Special forms Gallbladder empyema (pure pus), gangrenous cholecystitis, emphysematous cholecystitis Porcelain gallbladder, adenomyomatosis, Xanthogranulomatous cholecystitis (Option A) , IgG4-related sclerosing cholecystitis, hydrops of the gallbladder



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 875 - 876

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which condition is characterised by extensive dystrophic calcification of the gallbladder wall? (Q845743)

A. Porcelain gallbladder

B. Gangrenous cholecystitis

C. Acute cholecystitis

D. Hyalinizing cholecystitis

Correct Answer: A. Porcelain gallbladder

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Porcelain gallbladder is characterized by extensive dystrophic calcification of the gallbladder wall. This condition is associated with chronic cholecystitis and may lead to an increased risk of gallbladder carcinoma. Porcelain gallbladder (Option A) Hyalinizing cholecystitis (Option D) Characterized by extensive dystrophic calcification of the gallbladder wall. Characterized by complete replacement of the gallbladder wall and mucosa by dense fibrosis, with or without calcification. Associated with chronic cholecystitis and an increased risk of gallbladder carcinoma

[10_Liver_ Biliary System and Pancreas] 046 Hepatic Tumors And Pancreas — Quick Jump

Q1 (p. 2067) *Q2 (p. 2068)* *Q3 (p. 2069)* *Q4 (p. 2070)* *Q5 (p. 2071)* *Q6 (p. 2071)*
Q7 (p. 2073) *Q8 (p. 2074)* *Q9 (p. 2075)* *Q10 (p. 2076)* *Q11 (p. 2077)* *Q12 (p. 2079)*
Q13 (p. 2080)

Q1: Which of the following is the most common benign tumor of the liver? (Q845809)

A. Cavernous hemangioma

B. Hepatoblastoma

C. Klatskin tumor

D. Hepatic adenoma

Correct Answer: A. Cavernous hemangioma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Cavernous hemangioma is the most common benign tumor of the liver Benign hepatic tumors : Cavernous hemangioma (most common) > focal nodular hyperplasia (FNH) >hepatocellular adenoma (rare) M/C benign hepatic tumour Cavernous hemangioma M/C hepatic tumour in children Hepatoblastoma (Option B) M/C Primary liver malignancy Hepatocellular carcinoma M/C cancer, which metastasis to the liver Colon carcinoma M/C sarcoma Angiosarcoma Klatskin tumor (Option C): Occurs at the junction of the right and left hepatic ducts meet, primarily a duct tumor. Hepatic Adenoma (Option D): Benign tumor of the liver, commonly associated with prolonged OCP usage in females.

@Neet_pg_bot

Q2: A 30-year-old woman presents to the emergency department with severe abdominal pain and signs of hypovolemic shock. She has a history of long-term contraceptive pill use. Imaging studies reveal a large hepatic mass with evidence of haemorrhage. Laboratory tests show elevated liver enzymes. What is the likely diagnosis based on her clinical presentation and medical history? (Q845810)

A. Angiosarcoma

B. Hepatic adenoma

C. Hepatoblastoma

D. Cholangiocarcinoma

Correct Answer: B. Hepatic adenoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the patients gender, history of use of OCP and clinical presentation, she most likely has a hepatic adenoma Hepatocellular adenoma is a benign neoplasm that typically occurs in young women. Strong association with the use of oral contraceptives Estrogen is known to promote the growth of hepatic adenomas by stimulating hepatocyte proliferation. On imaging - well-circumscribed and encapsulated discrete mass, sometimes with associated hemorrhage - giving heterogenous appearance (fat+ hemorrhage) . The molecular subtypes of hepatic adenoma based on bordeaux classification are Hepatocyte nuclear factor 1-alpha (HNF1α) -inactivated hepatocellular adenoma which are multiple and presents in young patients Inflammatory hepatocellular adenoma - Most common to present with hemorrhage β-Catenin –activated hepatocellular adenoma

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 867-872 https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3125451/ https://www.ncbi.nlm.nih.gov/books/NBK513264/ https://www.aasld.org/liver-fellow-network/core-series/pathology-pearls/pathology-pearls-hepatocellular-adenoma

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 25-year-old sexually active woman who has been on OCP for the past 4 years comes to the ER with severe abdominal pain and features of hypovolemic shock. Ultrasound reveals a large hemorrhagic hepatic mass and fluid in the peritoneum. What is the most probable diagnosis? (Q845811)

A. Hepatocyte nuclear factor 1-alpha (HNF1α)-inactivated hepatocellular adenoma

B. β-Catenin–activated hepatocellular adenoma

C. Nodular regenerative hyperplasia (NRH).

D. Focal Nodular Hyperplasia

Correct Answer: B. β-Catenin–activated hepatocellular adenoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The risk of malignant depends on the molecular subtypes : (HNF1α)-inactivated hepatocellular adenoma- minimal risk Inflammatory hepatocellular adenoma(most common) - moderate risk β-Catenin–activated hepatocellular adenoma - high risk unclassfied β-Catenin-–activated hepatocellular adenoma is strongly associated with OCP and anabolic steroid use. Resection is recommended for β-catenin–activated tumours and tumours that are 5 cm or larger due to the risk of malignant transformation and haemorrhage. Incorrect options:

HNF1α-inactivated Hepatocellular Adenoma (option A) Subtype of hepatic adenoma, often steatotic, usually smaller, asymptomatic, and rarely ruptures. Patient has acute hemorrhage, which is more typical of classic OCP-associated hepatic adenoma. Nodular Regenerative Hyperplasia (NRH) (option C) Diffuse hepatic nodularity without true fibrosis; usually asymptomatic or causes portal hypertension. Does not present as a large hemorrhagic mass or cause acute hemoperitoneum. Focal Nodular Hyperplasia (FNH) (option D) Benign liver lesion, often in young women, usually asymptomatic. Rarely bleeds or ruptures, and hemorrhagic presentation is unusual.

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 865-866

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following conditions presents with a central stellate scar? (Q845812)

A. Metastatic liver lesion

B. Focal Nodular Hyperplasia

C. Liver abscess

D. Liver Cirrhosis

Correct Answer: B. Focal Nodular Hyperplasia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Focal Nodular Hyperplasia is a benign, non-neoplastic lesion which presents with a central stellate scar and is most common in women. It occurs due to altered blood flow , which causes hyperplastic changes in hepatocytes. It is usually asymptomatic and is incidentally seen on imaging. Hallmark: Central Stellate Scar Appearance: On imaging (CT or MRI), it appears as a star-shaped fibrous area in the center of the lesion. Contents: Unlike a true scar, it contains large anomalous arteries that show intense enhancement during the arterial phase of imaging. Histology: The scar contains bile duct proliferation and inflammatory cells, but lacks the normal organized venous drainage of the liver. Conditions showing Central Stellate Scar: Liver: Focal Nodular Hyperplasia (FNH) : benign Fibrolamellar Hepatocellular Carcinoma (HCC): malignant Kidney: Oncocytoma: benign . Chromophobe Renal Cell Carcinoma (RCC): malignant Pancreas: Serous Cystadenoma (microcystic adenoma): benign Breast: Radial Scar (Complex Sclerosing Lesion): benign , mimics carcinoma Metastatic liver lesion (Option A): These usually present as multiple "umbilicated" nodules (central necrosis) rather than a stellate scar. They are typically poorly circumscribed and lack the organized hyperplastic growth seen in FNH. Liver abscess (Option C): This is a localized collection of pus caused by bacterial, parasitic, or fungal infection. Imaging shows a fluid-filled cavity with "rim enhancement" and surrounding edema, not a solid fibrous scar. Liver Cirrhosis (Option D): While cirrhosis involves extensive scarring, it is diffuse throughout the entire organ. It is characterized by regenerative nodules surrounded by bands of collagen, rather than a single localized lesion with a central star-shaped scar.

@Neet_pg_bot

Q5: All of the following increases the risk of Hepatocellular carcinoma, except? (Q845813)

A. Alcohol

B. NASH (Non-Alcoholic Steatohepatitis)

C. Hemochromatosis

D. Gilbert's syndrome

Correct Answer: D. Gilbert's syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Gilbert's Syndrome is a benign condition associated with mild unconjugated hyperbilirubinemia and does not cause liver damage or increase the risk of HCC. The most common risk factors are Viral infections (chronic hepatitis B and hepatitis C) Toxic (Alcohol (Option A) and Aflatoxins) Metabolic (Diabetes and NASH (Option B) , Hemochromatosis (Option C) , Wilson's syndrome) Immune-related (Primary biliary cirrhosis and autoimmune hepatitis)

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 868-870

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 2-year-old child presented with progressive jaundice for the past 2 months. Initial investigations were done, and subsequent histopathological examination of liver biopsy showed changes consistent with hepatoblastoma. Which of the following additional biomarkers will be elevated in this child? (Q845817)

A. CA 19-9

B. AFP

C. Neurotensin

D. CEA

Correct Answer: B. AFP

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Alpha-fetoprotein will be elevated in a patient with hepatoblastoma. Hepatoblastoma is the most common liver tumour of childhood. Activation of the Wnt signalling pathway is characteristic of hepatoblastoma, leading to nuclear β-catenin and increased expression of Wnt target genes such as glutamine synthetase in nearly all cases Hepatoblastoma: M/c primary malignant tumor seen in children (< 3 yrs of age) WNT pathway activation (APC pathway defect) FAP - Gardners syndrome → Hepatoblastoma Beckwith-Wiedemann syndrome (Wilms Tumor)- WT-2 gene mutation ↑ AFP , also seen in: YST (Yolk Sac Tumor), HCC classical T/t: Surgery, Chemotherapy Prognosis is better than HCC Due to Pure fetal histology (Blastemal Cells - Blue). CA 19-9 and Neurotensin markers are elevated in Heptatocellular carcinoma. (Options A and C) CEA is a tumor marker for colorectal carcinoma. (Option D)

@Neet_pg_bot

Q9: Which of the following is not a genetic mutation associated with hereditary pancreatitis? (Q845818)

A. PRSS1

B. SPINK1

C. CFTR

D. BRCA1

Correct Answer: D. BRCA1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: BRCA 1 mutation is most commonly associated with hereditary breast and ovarian cancer in women, whereas PRSS1, SPINK1, and CFTR are linked to hereditary pancreatitis. Hereditary Pancreatitis: Recurrent

severe acute pancreatitis attacks, often beginning in childhood due to a defect that increases trypsin activity in the gut. Gene Features PRSS1 (trypsinogen 1 gene) (Option B) Most common cause for hereditary pancreatitis. Autosomal dominant inheritance Gain-of-function mutation make trypsin resistant to self-inactivation Increased risk of developing chronic pancreatitis and pancreatic cancer. SPINK1 (Option C) Autosomal recessive inheritance Loss of function mutation encoding a trypsin inhibitor CFTR (cystic fibrosis transmembrane conductance regulator) (Option D) Loss of CFTR leads to abnormal secretions Promote plugging and duct obstruction Associated conditions: recurrent sinopulmonary infections, intestinal obstruction, diabetes, and male infertility. CASR (Calcium-sensing receptor): Mutation alters calcium concentrations and activates trypsin. CTRC (Chymotrypsin C): Responsible for protecting pancreas from trypsin-related injury. CPA1 (Carboxypeptidase A1): Acts as exopeptidase, regulating zymogen activation.

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 884

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following factors is most strongly associated with the development of acute pancreatitis in adult males? (Q845819)

A. Gallstone disease

B. Alcohol

C. Trauma

D. HIV infection

Correct Answer: B. Alcohol

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Acute pancreatitis is characterized by abdominal pain, associated with excessive alcohol intake, pancreatic duct obstruction, genetic factors, trauma, medications, infections, hypercalcemia, and ischemia. While gallstones are the leading cause of acute pancreatitis in the general population (especially in women), alcohol consumption is the most strongly associated factor and the most common cause in adult males . Most Common Cause (General Population): Gallstones (Option A). They account for about 40% of cases. Gallstones block the common bile duct, causing a backup of digestive enzymes. Most Common Cause (Adult Males): Alcohol (Option B). In many demographic studies, chronic heavy alcohol use is the primary driver for pancreatitis in men, accounting for roughly 30% of cases and often leading to recurrent or chronic issues. The "Strongest Association": In the context of male patients, the correlation between high-volume alcohol intake and pancreatic inflammation is the most consistent clinical finding. Trauma (Option C): A known cause (often blunt force, like a steering wheel injury), but far less common than alcohol or stones. HIV Infection (Option D): Not a primary cause of pancreatitis itself, though medications used to treat HIV (like didanosine) or opportunistic infections can sometimes trigger it.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 882

↑ *Back to this question in Part A*

@Neet_pg_bot

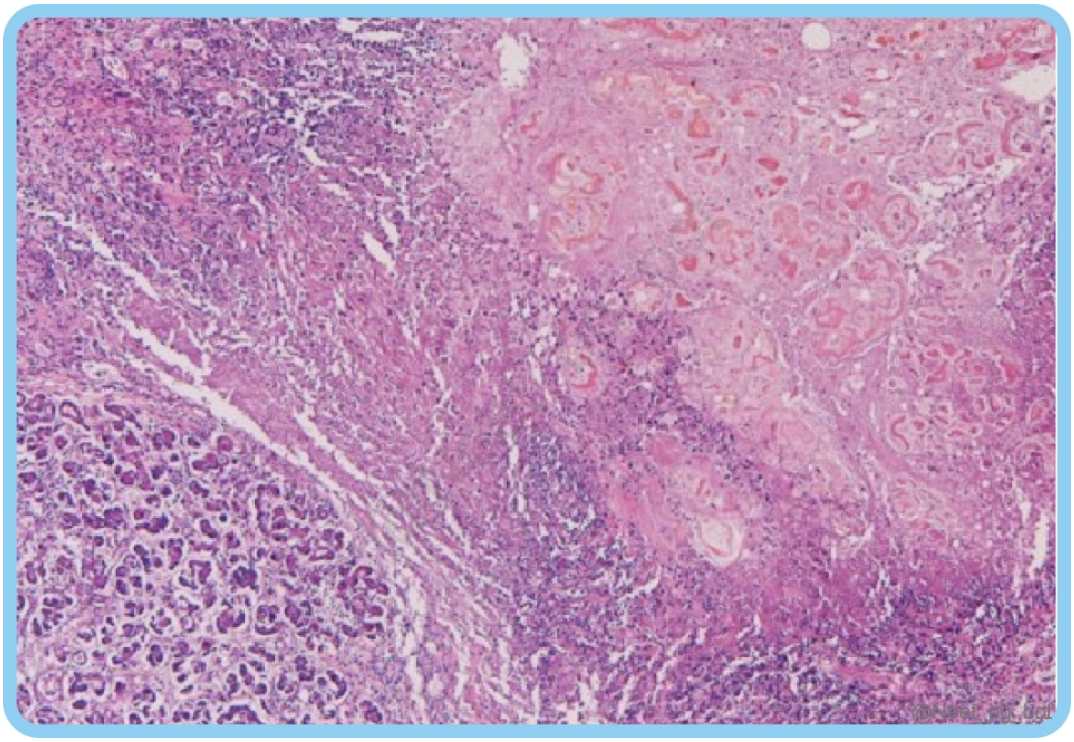
Q11: A 45-year-old female presented with a history of type-2 diabetes and hypertension presented to hospital with a 3 day history of generalized weakness, diffuse abdominal pain and altered mental status. Upon examination, her GCS was 10 with diffuse abdominal tenderness. Investigations showed elevated glucose, creatinine, lipase, and calcium levels. Histopathological examination suggests which of the following associated findings in this patient? (Q845820)

A. Pancreatic hyperplasia

B. Destruction of pancreatic beta cells

C. Intracellular activation of enzymes

D. Fibrosis of pancreatic ducts



Correct Answer: C. Intracellular activation of enzymes

Explanation: The patient's clinical findings, including abdominal pain, elevated lipase, and calcium, with microscopic image findings, suggest hypercalcemia-induced acute pancreatitis due to intracellular enzyme activation, a morphological hallmark of pancreatitis. Gross : Fat and parenchymal necrosis with saponification. Microscopic : interstitial inflammation, edema, fat necrosis, vessel wall damage, and hemorrhage. (image). Hypercalcemia Induced Acute Pancreatitis: Increased calcium influx causes inappropriate activation of digestive enzymes with intracellular trypsin autoactivation causing acinar cell injury. Elevated calcium levels are linked to encephalopathy and acute kidney failure. Possible causes of hypercalcemia: malignancy, hyperparathyroidism, hypervitaminosis D, granulomatous diseases. Acute Pancreatitis: Feature Details Common Causes G allstones, E thanol (Alcohol), T rauma, S teroids, M umps, A utoimmune, S corpion sting, H ypertriglyceridemia/Hypercalcemia, E RCP, D rugs. Pathophysiology Inappropriate activation of trypsinogen to trypsin within the pancreas, leading to inflammation and necrosis. Clinical Presentation Sudden, severe epigastric pain radiating to the back ; nausea and vomiting; pain partially relieved by leaning forward. Physical Exam Signs Cullen’s sign (periumbilical ecchymosis) or Grey Turner’s sign (flank ecchymosis) indicating hemorrhagic pancreatitis. Diagnosis Requires 2 of 3: Typical abdominal pain, Serum lipase or amylase >3 × upper limit of normal, Characteristic findings on CT/MRI. Management Aggressive fluid resuscitation (isotonic crystalloids), pain control, and nutritional support.

https://pathology.jhu.edu/type1-diabetes/under-the-microscope

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A female patient presents with progressive jaundice and weight loss for the past six months. She also complains of low grade upper abdominal pain. Lab investigation revealed a random blood sugar of 320mg/dL and a raised serum Ig-G4 levels and a USG scan showed a mass like lesion over the head of pancreas. Based on these findings which of the following is the most likely finding in the histopathological examination ? (Q846627)

A. Pleomorphic cuboidal to columnar epithelial cells

B. Necrotic changes in the acini and ducts

C. Honeycombing appearance with cuboidal epithelium

D. Swirling fibrosis with inflammation of veins

Correct Answer: D. Swirling fibrosis with inflammation of veins

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the clinical presentation, history, raised blood glucose and serum Ig-G4, along with a mass-like lesion in the pancreas points towards Autoimmune pancreatitis and histopathological examination of the pancreatic specimen will show characteristic swirling/storiform fibrosis with inflammation of veins Treatment Excellent response to steroids Azathioprine for relapsing disease Raised Ig-G4 and the characteristic histological appearance help differentiate autoimmune pancreatitis from carcinoma pancreas since they both present with almost similar clinical features, and a mass-like lesion can be seen while imaging both. Pleomorphic cuboidal to columnar epithelial cells (Option A) are seen in carcinoma pancreas Necrotic changes in the acini and ducts (Option B) are seen in acute necrotising pancreatitis Honeycombing appearance with cuboidal epithelium (Option C) is seen in serous cystadenoma of the pancreas.

References:

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Pages 886, 887

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following statements about pancreatic cystic neoplasms is true? (Q846628)

A. Serous cystadenomas are commonly malignant.

B. Mucinous cystic neoplasms (MCNs) occur predominantly in males.

C. Intraductal papillary mucinous neoplasms (IPMNs) have a risk of malignant transformation.

D. Mucinous cystic neoplasms typically have a central scar on imaging.

Correct Answer: C. Intraductal papillary mucinous neoplasms (IPMNs) have a risk of malignant transformation.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Intraductal papillary mucinous neoplasms (IPMNs), especially those involving the main duct or mixed type, have a risk of malignant transformation. Features Serous cystadenoma (Option A) Mucinous cystic neoplasm Intraductal Papillary Mucinous Neoplasm (IPMN) (Option C) Demographics Females > males Females > males (Option B ruled out) Males = females Location Head of pancreas Body or tail of pancreas Anywhere in pancreas Morphology Microcystic , honeycombing appearance with central scar Macrocystic, multilocular, no central scar (Option D ruled out) Dilated ducts with papillary projections Malignancy risk Low High High (main

duct> mixed> branch duct) Histology Glycogen rich cuboidal cells Ovarian like stroma with mucin secreting epithelium Papillary architecture with mucin secreting epithelium Serum markers N/A CEA and CA 19-9 CEA Symptoms Usually asymptomatic Abdominal pain due to mass effect Weight loss Recurrent pancreatitis or jaundice Imaging Microcystic with central scar and stellate calcification Thin septation Unilocular or multilocular Dilated pancreatic duct or cystic lesion

Q1: A 58-year-old male with history of multiple sexual partners presented with anorexia and jaundice. The biopsy shows ground-glass opacity in the cells. What is the most probable diagnosis? (Q866753)

A. Hepatitis A

B. Hepatitis B

C. Hepatitis C

D. Hepatitis D

Correct Answer: B. Hepatitis B

Explanation: Hepatitis B This clinical scenario of a male with a promiscuous sexual history and ground-glass opacities on biopsy points to Hepatitis B infection. In chronic Hepatitis B infection , hepatocytes can appear pale and finely granular on histology, called ground-glass hepatocytes . This appearance is due to the accumulation of Hepatitis B surface antigen (HBsAg) within the endoplasmic reticulum of infected hepatocytes. Common in chronic carriers and chronic hepatitis B patients. Risk factor- Multiple sexual partners, high risk of sexually transmitted infections, including HBV. Hepatitis A (Option A): Feco–oral transmission (contaminated food/water), not sexually transmitted in most cases. Does not produce ground-glass hepatocytes. Histology: hepatocyte ballooning degeneration, Councilman bodies in acute hepatitis. Hepatitis C (Option C): Transmitted mainly via blood (IV drug use, transfusions). Histology shows lymphoid aggregates in portal tracts, steatosis, and no ground-glass appearance. Hepatitis D (Option D: Histology changes depend on concurrent HBV changes; ground-glass cells still come from the HBV component.)

↑ *Back to this question in Part A*

@Neet_pg_bot

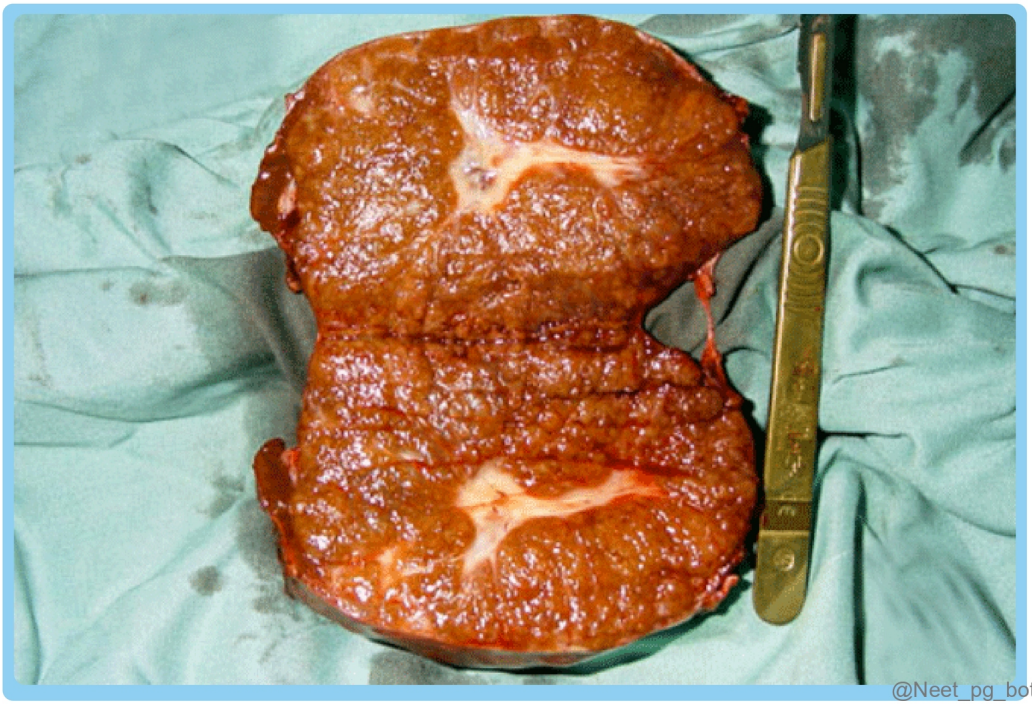
Q2: A cut section of liver is shown below. What is the likely diagnosis? (Q866392)

A. Hepatic adenoma

B. Hepatocellular carcinoma

C. Focal nodular hyperplasia

D. Hemangioma



Correct Answer: C. Focal nodular hyperplasia

Explanation: A well-demarcated liver lesion with a central stellate scar on gross examination is characteristic of Focal Nodular Hyperplasia (FNH) . It is a benign, non-neoplastic lesion that is most common in women. It occurs due to altered blood flow, which causes hyperplastic changes in hepatocytes. Multifocal FNH can occur in Hepatic or extrahepatic hemangioma Vascular malformations Brain tumours (meningioma, astrocytoma) Histopathology It is less than 5 cm in diameter, well-circumscribed, lacks a capsule, and has a central stellate scar. Microscopically, fibrous septa radiating from the central scar divide the hepatic parenchyma into nodules. A large central artery is usually present. The image shows fibrous septae dividing the parenchyma. USG: It is incidentally seen on imaging. A USG of the liver indicating a mass with a central stellate scar Incorrect Options: Hepatic adenoma (Option A): Usually solitary, lacks central scar, associated with oral contraceptives. Hepatocellular carcinoma (HCC) (Option B): Malignant tumor; often shows hemorrhage, necrosis, no central scar. Hemangioma (Option D): Cavernous vascular lesion, red-blue on cut section, no central scar.

@Neet_pg_bot

Q3: An alcoholic patient presents with lower back pain and fever. During history-taking, he mentions experiencing similar episodes in the past with elevated amylase levels. Which type of necrosis is likely to be present in the peri-pancreatic fat? (Q860168)

A. Fibrinoid necrosis

B. Fat necrosis

C. Coagulative necrosis

D. Liquefactive necrosis

Correct Answer: B. Fat necrosis

Explanation: History of alcoholism and recurrent pancreatitis (elevated amylase) indicates pancreatic inflammation. In acute pancreatitis, pancreatic enzymes (especially lipase) leak into surrounding fat. These enzymes digest the peri-pancreatic fat, leading to saponification-calcium binds free fatty acids forming chalky deposits. This is called fat necrosis, a type of enzymatic necrosis. Most commonly affects peri-pancreatic fat, but can also occur in breast or subcutaneous tissue. Microscopically, ghost outlines of fat cells with basophilic calcium deposits are seen. Clinically associated with epigastric/back pain, fever, and elevated pancreatic enzymes. Incorrect Options: Option A) Fibrinoid necrosis: Seen in immune-mediated vascular injury, not pancreatitis. Option C) Coagulative necrosis: Typical of ischemic solid organs like heart or kidney. Option D) Liquefactive necrosis: Occurs in brain infarcts or abscesses, not in peri-pancreatic fat.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following is associated with conjugated hyperbilirubinemia? (Q860186)

A. Crigler Najar -1 syndrome

B. Crigler Najar -2 syndrome

C. Gilbert syndrome

D. Dubin-Johnson syndrome

Correct Answer: D. Dubin-Johnson syndrome

Explanation: Dubin-Johnson Syndrome is associated with conjugated hyperbilirubinemia. It is an autosomal recessive disorder. It is characterised by impaired excretion of conjugated bilirubin into bile due to a defect in the MRP2 transporter, leading to conjugated hyperbilirubinemia. Darkly pigmented liver (accumulation of epinephrine metabolite). Syndromes of Unconjugated hyperbilirubinemia Disorder Defect Severity of Unconjugated hyperbilirubinemia Crigler-Najjar syndrome type 1 (Option A ruled out) Complete deficiency of UGT Severe Crigler-Najjar syndrome type 2 (Option B ruled out) Partial deficiency of UGT Mild to moderate Gilbert syndrome (Option C ruled out) Very mild deficiency of UGT Mild, asymptomatic Syndromes of Conjugated hyperbilirubinemia Disorder Defect Gross Feature of liver Dubin Johnson syndrome (Option D) Defect in canalicular MRP2 protein. Pigmented liver (due to epinephrine metabolite). Rotor syndrome Defective ATP-dependent biliary excretion. Non-pigmented liver.

@Neet_pg_bot

Q5: A 45-year-old patient with a history of chronic liver disease presents with symptoms of nausea, vomiting, edema, and ascites. On examination, his liver function tests are severely deranged. Further investigation reveals a diagnosis of hepatocellular carcinoma. The pathogenesis of this condition is most likely related to: (Q820599)

A. Benzol

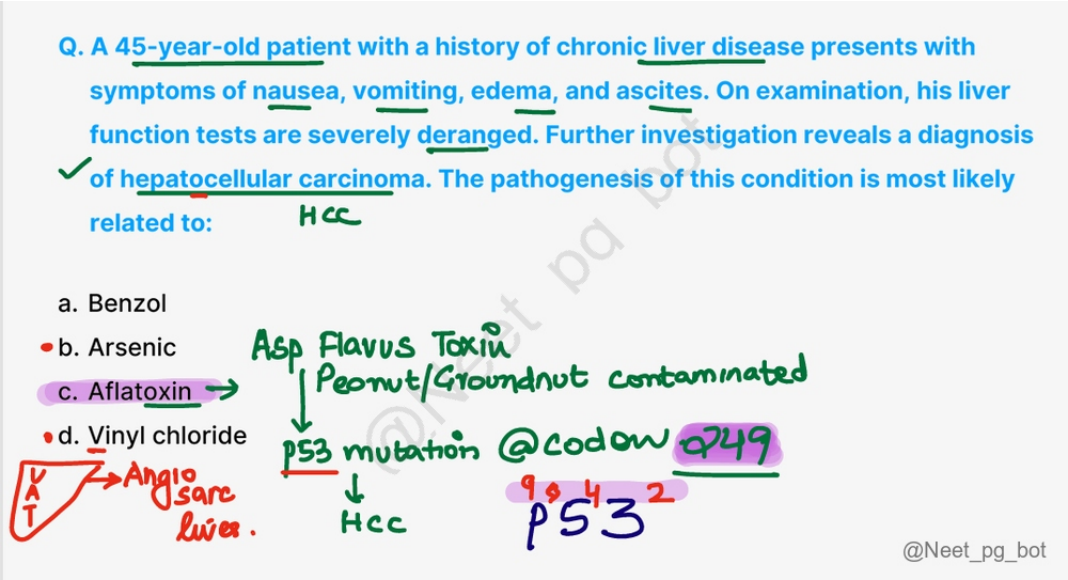
B. Arsenic

C. Aflatoxin

D. Vinyl chloride

Correct Answer: C. Aflatoxin

Explanation:



↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: What is the most likely diagnosis for a 25-year-old male who presented with fever and has the following viral marker results: HBsAg: Positive and IgM anti-HBc antibody: Positive (Q830720)

A. Acute hepatitis

B. Chronic hepatitis

C. Window period

D. Persistent infection

Correct Answer: A. Acute hepatitis

Explanation: Correct Option A - Acute hepatitis: HBsAg is the surface antigen of the Hepatitis B virus and indicates current infection. IgM anti-HBc antibodies are specific to acute infection and indicate recent exposure to the virus. Incorrect Options: Option B - Chronic hepatitis : Chronic hepatitis B is characterized by the persistence of HBsAg for more than six months. The presence of IgM anti-HBc antibody indicates an acute or recent infection, making chronic hepatitis less likely. Option C - Window period: The window period refers to the time between infection and the appearance of detectable markers. In this context, the presence of both HBsAg and IgM anti-HBc antibody suggests an active infection rather than a window period. Option D - Persistent infection: Persistent infection could be considered for cases with prolonged presence of HBsAg, but the presence of IgM anti-HBc antibody indicates an ongoing immune response, which is more consistent with acute infection.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following is the best serum marker for alcoholic liver disease? (Q854711)

A. SGPT

B. SGOT

C. Carbohydrate-deficient transferrin (CDT)

D. Serum Bilirubin

Correct Answer: C. Carbohydrate-deficient transferrin (CDT)

Explanation: Best serum marker for alcoholic liver disease Elevated in people consuming ≥ 40–60 g alcohol/day for 1–2 weeks More reliable than AST, ALT, or bilirubin Not heavily influenced by liver disease severity Alcoholic liver disease LFT AST/ SGOT (Option B ruled out) Non-specific ; ↑ (<300-400) This is a liver enzyme that rises in conditions causing liver damage, including alcohol-induced liver injury, but it is also elevated in a variety of non-liver conditions, like muscle injury or cardiac events. ALT/ SGPT (Option A ruled out) Specific for liver injury ; ↑ (<300-400) This is another liver enzyme that primarily indicates liver cell injury , but it is less specific for alcohol-related liver disease compared to GGT. AST/ALT ratio: ≥ 2: 1 Specific for ALD ALP (Alkaline phosphatase) Elevated in bile duct pathologies GGT (γ-glutamyl transferase) Non-specific marker of ALD 5'-Nucleotidase Specific marker for bile duct pathologies S.Bilirubin (Option D ruled out) Usually normal/mildly ↑ S.Albumin ↓ in chronic liver disease (cirrhosis) Carbohydrate-deficient transferrin (CDT) Best serum marker for alcoholic liver disease.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 842- 846

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following cells plays a key role in phagocytosis and chronic inflammation in the liver? (Q858141)

A. Hepatocytes

B. Ito cells

C. Sinusoidal endothelial cells

D. Kupffer cells

Correct Answer: D. Kupffer cells

Explanation: Kupffer cells are specialised macrophages found in sinusoids of the liver and play a key role in phagocytosis and chronic inflammation . They are responsible for clearing pathogens, debris, and old red blood cells from the blood as it passes through the liver. Incorrect Options: Hepatocyte s (Option A) are vital liver cells responsible for various metabolic functions but are not directly responsible for phagocytosis. Ito cells (Option B), also called Hepatic stellate cells, are pericytes located in the space of Disse , between hepatocytes and sinusoidal endothelial cells in the liver that store vitamin A and regulate sinusoidal blood flow. Upon liver injury, they activate into myofibroblast-like cells, releasing TGFβ and promoting fibrosis through excessive collagen production. Sinusoidal endothelial cells (Option C) line the liver's sinusoids and facilitate material exchange between blood and liver cells. While they are not primarily involved in phagocytosis, their unique fenestrated structure enables them to filter blood and regulate molecule movement.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 824 NIH Link

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A patient suffering from cholelithiasis underwent cholecystectomy. The image of the specimen is shown below. Which of the following is the correct diagnosis? (Q855934)

A. Chronic cholecystitis

B. Gallbladder cholesterol polyp

C. Carcinoma gallbladder

D. Strawberry gallbladder

@Neet_pg_bot

Correct Answer: B. Gallbladder cholesterol polyp

Explanation: The image shows a characteristic finding of a gallbladder cholesterol polyp , which typically presents as a raised, pedunculated lesion on the gallbladder mucosa. They are often benign and can be composed of cholesterol, adenomas, or inflammatory tissue. Gall bladder polyp is a pre-malignant condition presenting with cholecystitis & biliary colic. Types Cholesterol polyp (More common) Adenomatous polyp (Has malignant potential) Risk factors for malignancy in adenomatous polyp: Coexistence of gallstones Age > 60 years Increase in size Size > 10 mm Chronic cholecystitis (Option A) :– Thickened wall, stones, fibrotic mucosa, inflammation Strawberry gallbladder" (Option C), it occurs when cholesterol deposits accumulate in the gallbladder wall, giving it a speckled, yellowish appearance. {{caption_text}} Adenocarcinoma of the gallbladder (Option C) is the most common form of gallbladder cancer, arising from glandular cells and often associated with chronic cholecystitis, gallstones, and older age. It is more common in women. Early stages are usually asymptomatic, but as the tumour progresses, symptoms like right upper quadrant pain, jaundice, and weight loss may occur. HER2/neu overexpression and elevated CA 19-9 levels can aid in diagnosis and prognosis.

@Neet_pg_bot

Q10: What is the gene mutation seen in hemochromatosis? (Q857113)

A. HFE

B. PTEN

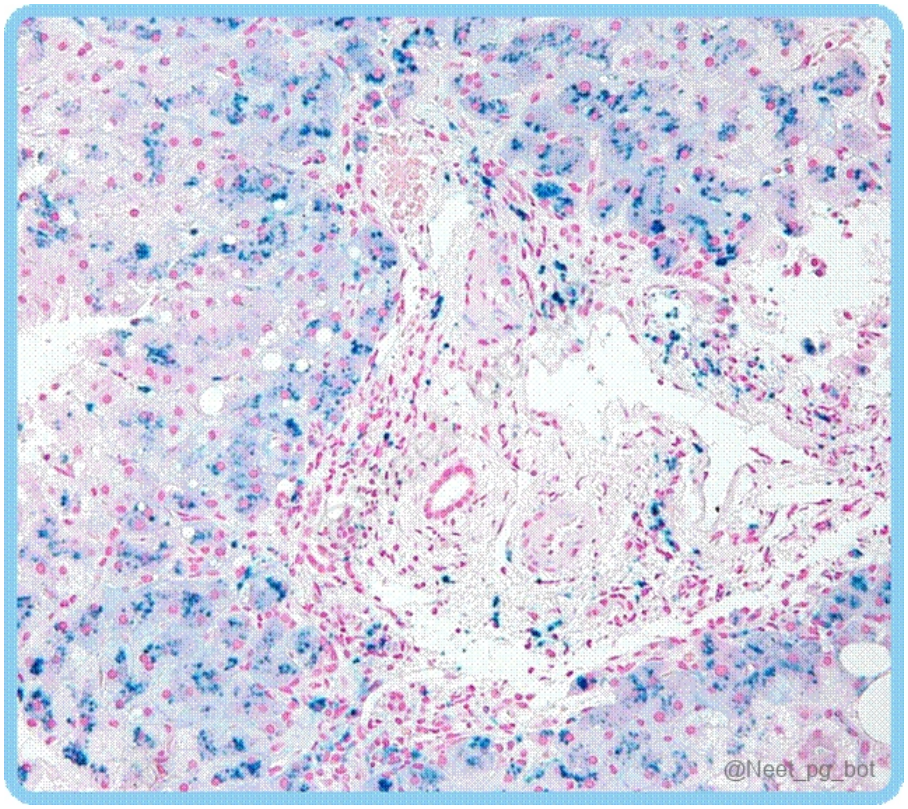
C. ATP7B gene

D. MRP2 protein

Correct Answer: A. HFE

Explanation: Hereditary hemochromatosis is due to an HFE gene mutation on chromosome 6p that causes excess iron absorption, leading to increased iron deposition. This results in the classic triad of cirrhosis , secondary

diabetes mellitus , and bronze skin. Hereditary Hemochromatosis: Laboratory findings: High ferritin, high serum iron and low TIBC. Liver biopsy: Golden-yellow hemosiderin granules in periportal hepatocytes that appear blue with a Prussian blue stain followed by a micronodular pattern of cirrhosis. Other findings: dilated cardiomyopathy (M/C cardiac manifestation). Increased risk of hepatocellular carcinoma {{caption_text}} In Hemochromatosis, skin colour changes due to the deposition of excessive melanin >> iron in the skin. It is also known as "bronze diabetes" due to skin discolouration and associated pancreatic disease & typically manifests after 20 g of stored iron has accumulated in the body. Organs affected Clinical features Liver Hepatomegaly, elevated liver enzymes, risk of HCC Pancreas Iron-induced damage of beta cells - diabetes mellitus Heart Cardiomyopathy, arrhythmias, congestive heart failure Skin Hyperpigmentation (bronze skin due to melanin and iron deposition) Joints Arthropathy and joint pain CNS Rarely - Memory issues, depression and fatigue Hemochromatosis is of two types: Types of hemochromatosis Features Hereditary hemochromatosis HFE -related: It is the classic form of hereditary hemochromatosis that is inherited in an autosomal recessive (chromosome 6p) HAMP gene mutation-related HJV gene mutation (juvenile hemochromatosis Acquired/secondary hemochromatosis Repeated blood transfusion Excessive oral intake or iron PTEN (Option B) is a tumour suppressor gene linked to certain cancers and is not associated with hemochromatosis. ATP7B gene (Option C) mutations cause Wilson's disease , which involves copper accumulation, not iron overload, as in hemochromatosis. MRP2 protein (Option D) is involved in bile excretion and is related to Dubin-Johnson syndrome , not hemochromatosis.



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 848-850

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 30-year-old female presenting with an unsteady gait, forgetfulness, labile moods, and Kayser-Fleischer rings was diagnosed with Wilson’s disease. Which of the following options correctly indicates the gene mutated in this condition and its location? (Q857558)

A. ATP7B gene on chromosome 13

B. ATP7A gene on chromosome X (Xq21.1)

C. ATP7B gene on chromosome 17

D. ATP7A gene on chromosome 17

Correct Answer: A. ATP7B gene on chromosome 13

Explanation: Wilson’s disease is caused by mutations in the ATP7B gene located on chromosome 13 . The ATP7A gene on chromosome X (Xq21.1) is associated with Menkes disease . Wilson’s disease It is a genetic disorder caused by ATP7B gene mutations, leading to impaired copper transport and accumulation in the liver, brain, and other organs. Clinical Features: Kayser-Fleischer Rings: These are characteristic brownish-green rings seen in the cornea due to copper deposition and are a hallmark feature of Wilson's disease. Serum copper is raised, while ceruloplasmin levels (a copper-binding protein) are decreased in Wilson's disease. Increased urinary copper excretion is a characteristic finding. {{caption_text}} Findings: Low levels of Serum Ceruloplasmin. Increased 24-hour Urinary Copper Excretion (Most specific) . Liver Function Tests (LFTs) may show abnormalities. Kayser-Fleischer Rings Examination: Greenish-brown rings in the cornea. Genetic Testing: For ATP7B gene mutations, confirming diagnosis. Liver Biopsy (Gold standard): Demonstrates hepatic copper accumulation. Brain Imaging: MRI to assess neurological involvement.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 850

↑ *Back to this question in Part A*

@Neet_pg_bot

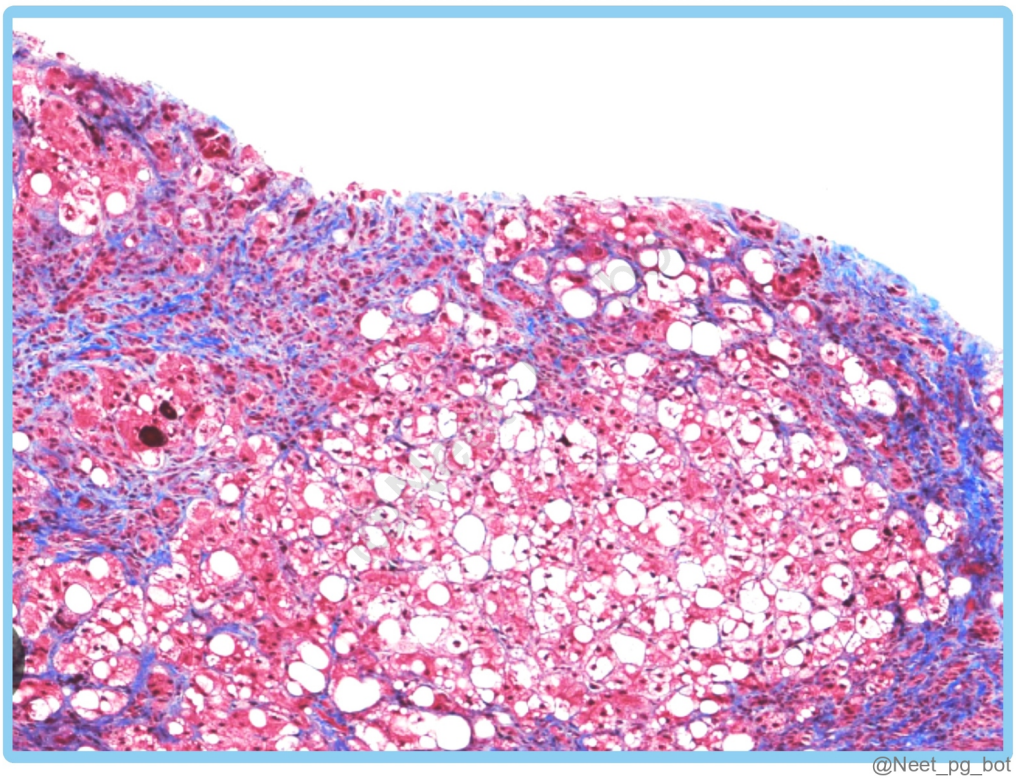
Q12: A patient with cirrhosis and ascites presented to you. The gross appearance of his liver is shown below. Which of the following is true about it? (Q855403)

A. Dark areas represent necrosis, white areas represent viable liver

B. Dark areas represent viable liver tissue, white areas represent necrosis

C. White areas represent central hepatocytes

D. Dark areas represent peri-portal hepatocytes



Correct Answer: A. Dark areas represent necrosis, white areas represent viable liver

Explanation: The scenario of Cirrhosis and ascites, along with the image, shows dark areas indicating necrosis and white areas representing viable liver tissue. It is a chronic liver disease characterized by fibrosis and nodular regeneration of the liver parenchyma. Causes: Chronic alcohol abuse, viral hepatitis, or metabolic disorders. The liver undergoes significant remodelling, destroying its normal architecture and the formation of fibrous bands. The dark areas indicate necrosis (cellular damage and blood congestion), while the white areas represent viable liver tissue with functional hepatocytes. (Option B, C, and D ruled out) {{caption_text}} {{caption_text}} Microscopy: Thick bands of collagen separate rounded cirrhotic nodules (Masson's trichrome stain is commonly used to visualise collagen fibres). {{caption_text}}

@Neet_pg_bot

Q13: Which of the following is associated with hepatic angiosarcoma? (Q859271)

A. Iron

B. Copper

C. Zinc

D. Arsenic

Correct Answer: D. Arsenic

Explanation: Arsenic is a well-established carcinogen for hepatic angiosarcoma. Chronic arsenic exposure leads to DNA damage and promotes endothelial cell malignancy. It also notes that vinyl chloride , Thorotrast , and arsenic are the most frequently implicated agents in hepatic angiosarcoma development. Incorrect Options: Iron (Option A) overload (e.g., in hereditary hemochromatosis) is primarily associated with an increased risk of hepatocellular carcinoma (HCC) , not hepatic angiosarcoma. Copper (Option B) accumulation in Wilson's disease is linked to hepatocyte damage and cirrhosis but is not associated with angiosarcoma development. Zinc (Option C) is

essential for normal cellular function and is not carcinogenic.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 872

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Macrophages play an important role in phagocytosis and chronic inflammation. Which of the following cells perform the same function in the liver? (Q859301)

A. Hepatocytes

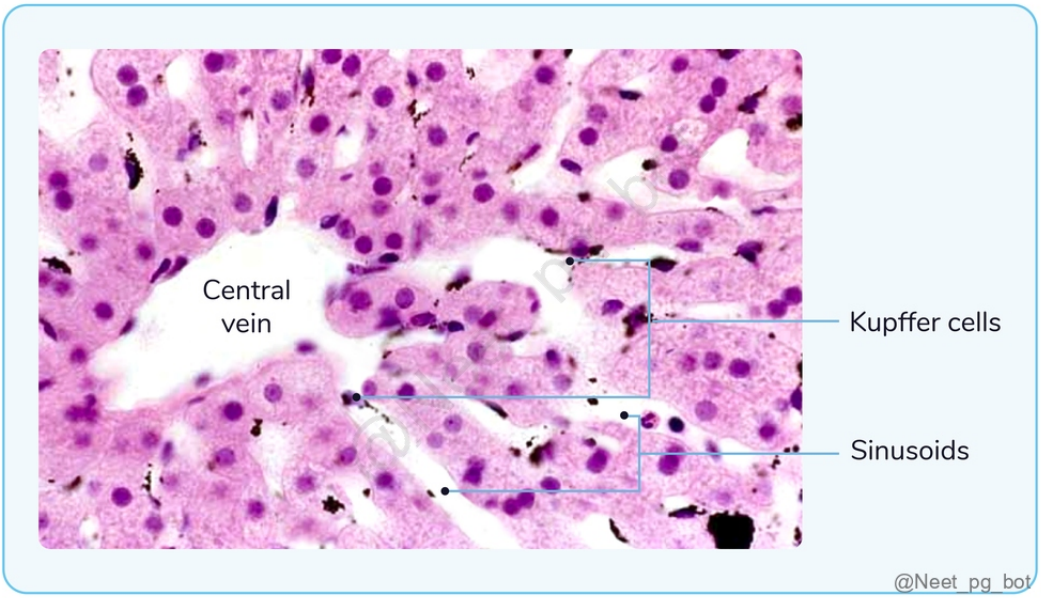
B. Merkel cells

C. Sinusoid all cells

D. Kupffer cells

Correct Answer: D. Kupffer cells

Explanation: Kupffer cells are specialised macrophages located within the liver sinusoids. They play a crucial role in phagocytosis, removing pathogens, damaged cells, and cellular debris from the bloodstream. They are also involved in the regulation of immune responses and the promotion of chronic inflammation when necessary. Therefore, Kupffer cells in the liver perform similar functions to macrophages, including phagocytosis and participation in chronic inflammation. {{caption_text}} Incorrect Options: Hepatocytes (Option A) are the main functional cells of the liver responsible for various metabolic functions, such as detoxification, synthesis of proteins, and storage of nutrients. While hepatocytes are involved in many liver functions, they do not primarily perform phagocytosis and chronic inflammation. Merkel cells (Option B) are specialised cells found in the skin and are involved in the sensation of touch and tactile discrimination. They are not present in the liver or involved in phagocytosis or chronic inflammation. Sinusoidal cells (Option C) refer to the cells lining the sinusoids in the liver, which are specialised blood vessels.



References:

Robbins and Cotrans Pathological Basis of Diseases, 10th Edition, Pages 97, 98

↑ *Back to this question in Part A*

@Neet_pg_bot

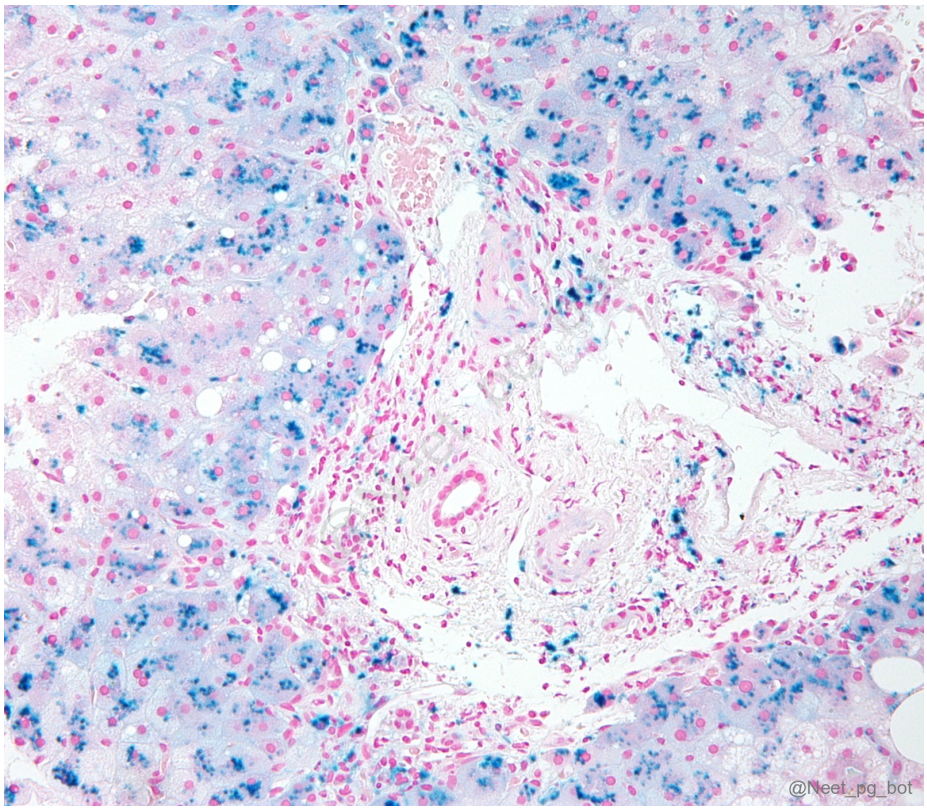
Q15: A 55-year-old man is found to have hepatomegaly on physical examination. He also complains of having dark tan skin despite avoiding sun exposure . His liver microscopy is given on the slide below. What is this patient most likely suffering from? (Q793776)

A. Wilson’s disease

B. Autoimmune hepatitis

C. α-1 antitrypsin deficiency

D. Hemochromatosis



Correct Answer: D. Hemochromatosis

Explanation: Correct Option D - Hemochromatosis: The patient's presentation with dark tan skin and histopathological findings showing iron deposition in liver cells is suggestive of hemochromatosis. Hemochromatosis is a hereditary disorder characterized by the accumulation of iron in the body, which can lead to damage to various organs, including the liver, heart, and pancreas. Incorrect Options: Option A - Wilson's disease: Wilson's disease is an inherited disorder that causes copper to accumulate in various organs, including the liver, brain, and eyes. The symptoms of Wilson's disease usually begin in childhood or early adulthood and can include neurological symptoms such as tremors, dystonia, and difficulty with coordination. The liver damage associated with Wilson's disease can lead to hepatomegaly, as well as signs of liver disease such as jaundice, ascites, and elevated liver enzymes. Option B - Autoimmune hepatitis: Autoimmune hepatitis is a chronic autoimmune disorder that causes inflammation and damage to the liver. The symptoms of autoimmune hepatitis can include fatigue, joint pain, skin rashes, and abdominal pain. Liver damage can lead to hepatomegaly, as well as signs of liver disease such as jaundice, ascites, and elevated liver enzymes. Option C - α-1 antitrypsin deficiency: α-1 antitrypsin deficiency is a genetic disorder that affects the production of a protein called α-1 antitrypsin, which plays a role in protecting the lungs and liver from damage. The symptoms of α-1 antitrypsin deficiency can include respiratory symptoms such as shortness of breath and coughing, as well as liver diseases such as hepatomegaly and elevated liver enzymes.

@Neet_pg_bot

Q16: A health care worker has been found to be seropositive for HBsAg, HBeAg, and anti-HBc IgM, indicating an acute HBV infection with high infectivity. A liver biopsy in such cases is likely to show all the following except: (Q793793)

A. Ballooning change of hepatocytes

B. Ground glass hepatocytes

C. Focal or spotty necrosis

D. Confluent necrosis of hepatocytes

Correct Answer: B. Ground glass hepatocytes

Explanation: Correct Option B - Ground glass hepatocytes: Ground glass hepatocytes are hepatocytes with a granular, eosinophilic cytoplasm. This appearance is due to the accumulation of hepatitis B surface antigen (HBsAg) within the endoplasmic reticulum of hepatocytes. This feature is more characteristic of chronic HBV infection rather than acute infection. It reflects ongoing viral replication and chronicity. Incorrect Options: Options A, C, and D A. Ballooning change of hepatocytes : Common in acute hepatitis. C. Focal or spotty necrosis : Common in acute hepatitis. D. Confluent necrosis of hepatocytes : Seen in severe acute hepatitis.

[11_Renal System] 048 Basics Of Renal Pathology — Quick Jump

Q1 (p. 2102)	*Q2 (p. 2104)*	*Q3 (p. 2107)*	*Q4 (p. 2111)*	*Q5 (p. 2114)*	*Q6 (p. 2117)*
Q7 (p. 2119)	*Q8 (p. 2124)*	*Q9 (p. 2126)*	*Q10 (p. 2127)*	*Q11 (p. 2128)*	*Q12 (p. 2129)*
Q13 (p. 2129)	*Q14 (p. 2130)*	*Q15 (p. 2131)*	*Q16 (p. 2132)*		

Q1: Which of the following statements regarding the glomerular basement membrane (GBM) is true? (Q845679)

A. The GBM is primarily composed of collagen type I and elastin.

B. The GBM is a selective barrier between the glomerular capillaries and Bowman's capsule.

C. Thickening of the GBM is a characteristic feature of minimal change disease.

D. The GBM is impermeable to large molecules such as albumin.

Correct Answer: B. The GBM is a selective barrier between the glomerular capillaries and Bowman's capsule.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: GBM forms the semipermeable barrier between the glomerular capillaries (inside) and the Bowman’s capsule (outside). The Glomerular filtration barrier GFB acts as a highly specialized "sieve" that allows water and small solutes to pass into the Bowman's space while retaining blood cells and large proteins. Filtration membrane: 3-layered structure: 1. Fenestrated Capillary Endothelium Structure: The innermost layer, containing pores (fenestrae) roughly 70–100 nm in diameter. Function: It prevents the passage of blood cells (RBCs, WBCs, platelets) but is too "leaky" to stop most plasma proteins. 2. Glomerular Basement Membrane (GBM): Composition: Primarily Type IV collagen , laminin, nidogen, and heparan sulfate proteoglycans. Function: It acts as a physical meshwork and a charge barrier . The heparan sulfate molecules provide a strong negative charge , which electrostatically repels negatively charged proteins like albumin. 3. Podocytes (visceral epithelial cells of Bowman’s capsule): Structure: Specialized cells with "foot processes" (pedicels) that wrap around the capillaries. Slit Diaphragm: Between these foot processes are narrow gaps called filtration slits , bridged by a protein zipper known as the slit diaphragm (composed of proteins like nephrin and podocin). Function: This is the final and finest physical filter. Selectivity: The barrier filters based on two main criteria: Feature Description Size Selectivity Molecules with a radius < 1.8 nm are filtered freely; those > 4 nm (like albumin) are restricted by the physical "pore" size. Charge Selectivity All three layers (especially the GBM and podocyte coat) are coated with polyanions (negative charges). Since most plasma proteins are negatively charged, they are repelled even if they are small enough to fit through the physical gaps. The GBM is primarily composed of collagen type I and elastin (Option A): GBM primarily comprises collagen type IV, laminins, proteoglycans, and other glycoproteins.

Thickening of the GBM is a characteristic feature of minimal change disease (Option C): The hallmark of Minimal Change Disease (MCD) is effacement of podocyte foot processes (visceral epithelium of the Bowman's capsule). The GBM is impermeable to large molecules such as albumin (Option D): GBM is permeable to small molecules but is a selective barrier to larger molecules such as albumin. {{caption_text}}

Q2: Which of the following kidney findings will be seen in malignant hypertension? (Q845680)

A. Putty kidney

B. Leather grain kidney

C. Flea-bitten kidney

D. Waxy kidney

Correct Answer: C. Flea-bitten kidney

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Flea-bitten kidney is defined as pinpoint petechial hemorrhages on the renal surface, caused by rupture of small glomerular or arteriolar vessels due to severe vascular damage. Mnemonic for differential diagnosis of flea-bitten kidney: We HaTe PSM We - We gener's granulomatosis. H a T e - H enoch Schonlein purpura, H US, T TP. P - P oststreptococcal glomerulonephritis, P olyarteritis nodosa. S - S ubacute bacterial endocarditis, S LE. M - M alignant hypertension. {{caption_text}} Putty kidney is seen in renal tuberculosis. (Option A) {{caption_text}} A leather-grain kidney appearance is seen in benign hypertension . (Option B) {{caption_text}} A Waxy kidney is seen in amyloidosis ..(Option D) {{caption_text}}

@Neet_pg_bot

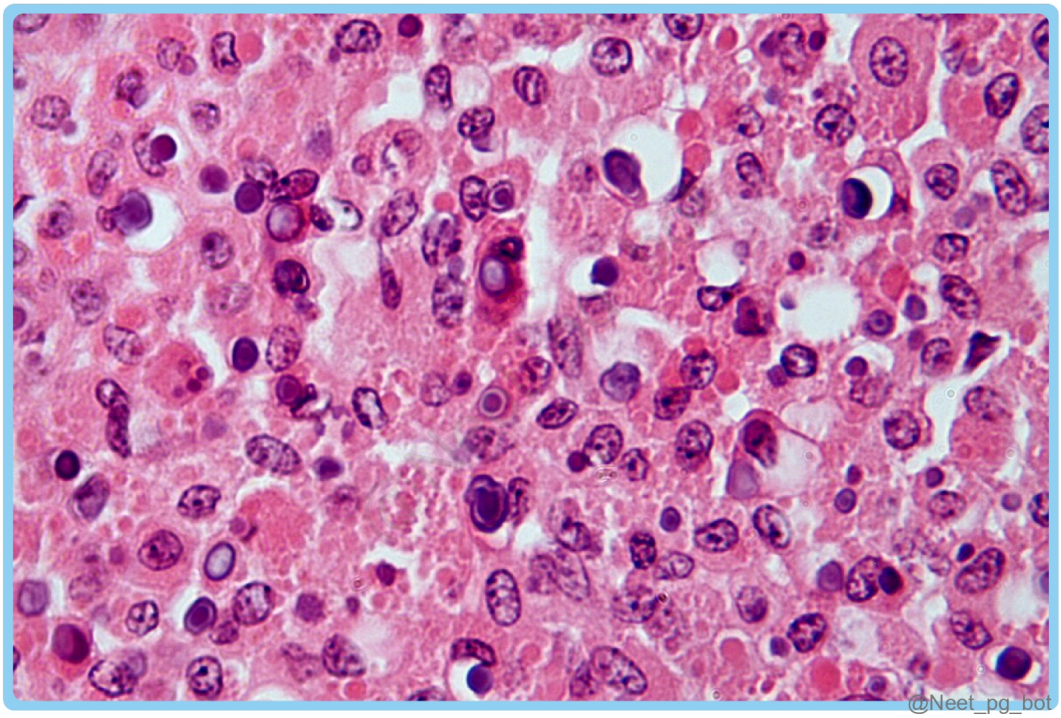
Q3: A 60-year-old female presents with a history of recurrent urinary tract infections and lower abdominal pain. Upon physical examination, palpable masses are noted in the pelvis. Urinalysis reveals persistent pyuria. A biopsy was done on the bladder lesions, which is shown below. Which of the following conditions is most likely responsible for the patient's presentation? (Q845681)

A. Bladder carcinoma

B. Malakoplakia

C. Schistosomiasis

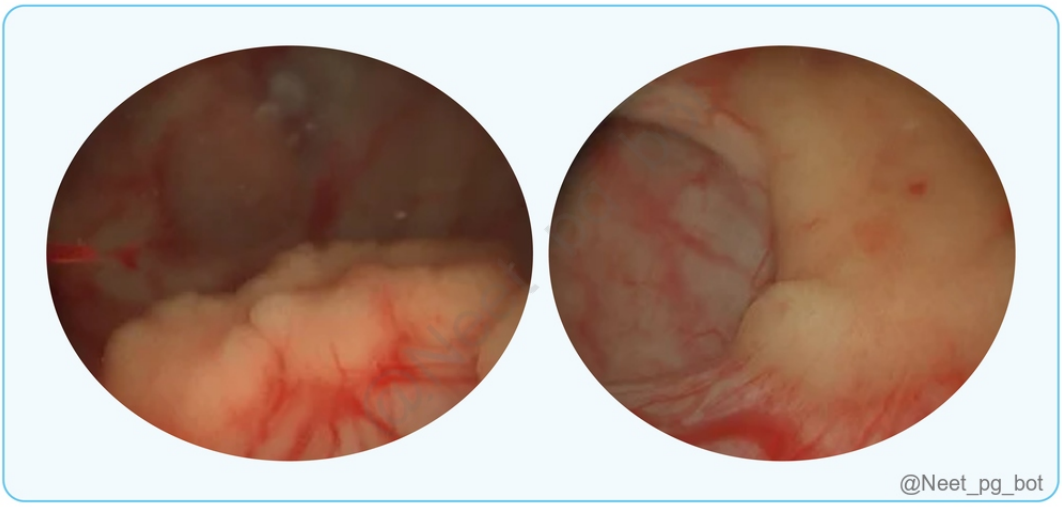
D. Tuberculous cystitis



Correct Answer: B. Malakoplakia

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Malakoplakia : Presentation: Patients may present with recurrent urinary tract infections and a bladder or pelvic mass, which can strongly mimic cancer. However, histopathology does not reveal malignant pleomorphic mitotic cells. Histology: The characteristic finding is bluish (basophilic) concretions known as Michaelis–Gutmann bodies, which are calcium deposits over bacterial remnants. These bodies are found within macrophages called Von Hansemann cells. Pathogenesis: Due to defective phagocytosis, macrophages engulf bacteria but fail to kill them. The most common causative organism is E. coli. Because the bacteria are not destroyed, calcium and iron gradually deposit over them, forming Michaelis–Gutmann bodies . Michaelis–Gutmann bodies : Basophilic calcium deposits within macrophages. {{caption_text}} Bladder carcinoma (Option A): Mass and UTI-like symptoms, but biopsy would show pleomorphic, atypical, mitotically active malignant cells Schistosomiasis (Option C): can cause chronic granulomatous inflammation in the bladder wall, leading to fibrosis and calcification. {{caption_text}} Tubercular cystitis reveals caseating granulomas with Langhans giant cells and epithelioid cells.(Option D)



@Neet_pg_bot

Q5: Match the following types of renal crystals with their characteristics Types of Renal Crystals Characteristics 1. Calcium Oxalate Monohydrate A. Coffin lid-shaped crystals, commonly found in alkaline urine 2.. Uric Acid B. Rhomboid-shaped crystals, typically seen in acidic urine. 3. Cystine C. Dumbbell or ovoid-shaped crystals are often colourless in acidic urine. 4. . Struvite (Magnesium Ammonium Phosphate) D. Hexagonal plates, often associated with acidic urine (Q845683)

A. 1-D, 2-B, 3-C, 4-A

B. 1-A, 2-B, 3-D, 4-C

C. 1-C, 2-B, 3-D, 4-A

D. 1-C, 2-D, 3-B, 4-A

Correct Answer: C. 1-C, 2-B, 3-D, 4-A

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The microscopic appearance of various types of crystals and their descriptions are given below: Struvite/ Staghorn stones: Triple phosphate crystal (Magnesium Ammonium Phosphate) Radioopaque. Seen in alkaline urine. Rectangular/coffin lid appearance. Associated with urea-splitting organisms. Cystine Stones Radiopaque. Seen in acidic urine. Hexagonal Shaped. Very hard stones. Calcium Oxalate Monohydrate stones Radiopaque/colourless. Seen in acidic urine. Dumbbell or ovoid-shaped. Most common type of renal calculi. Uric Acid crystals Radiolucent. Seen in acidic urine. Rhomboids or parallelograms. Ammonium Urate crystals Radiolucent. Associated with laxative abuse.

@Neet_pg_bot

Q6: A 45-year-old woman presents with complaints of severe lower abdominal pain, dysuria, and hematuria. She has a history of recurrent urinary tract infections (UTIs). Urinalysis reveals a high pH of 8.5 and the presence of white blood cells. Microscopic examination of the urine sediment shows the following finding. Which of the following is the most likely underlying cause of the patient's current presentation? (Q845684)

A. Hypercalcemia

B. Hyperuricemia

C. Infection with urease-producing bacteria

D. Cystinuria

Correct Answer: C. Infection with urease-producing bacteria

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Triple phosphate stones, also known as struvite stones, are composed of magnesium ammonium phosphate (Triple phosphate crystal). They typically form in alkaline urine due to urinary tract infections caused by urease-producing bacteria- Protease . Struvite stones are characterised by their "coffin lid" appearance under a microscope. They can grow rapidly and fill the renal pelvis, leading to complications like infection and obstruction. Hypercalcemia, Hyperuricemia and Cystinuria are seen with acidic urine.

@Neet_pg_bot

Q7: Match the following renal casts with the conditions they are associated with: Renal Cast Type Condition Associated 1. Hyaline casts A. Nephrotic syndrome 2. Muddy Granular casts B. Chronic Renal Failure 3. Waxy casts C. Acute tubular necrosis 4. Fatty casts D. Fever (Q845685)

A. 1-C, 2-A, 3-B, 4-D

B. 1-B, 2-D, 3-C, 4-A

C. 1-D, 2-C, 3-B, 4-A

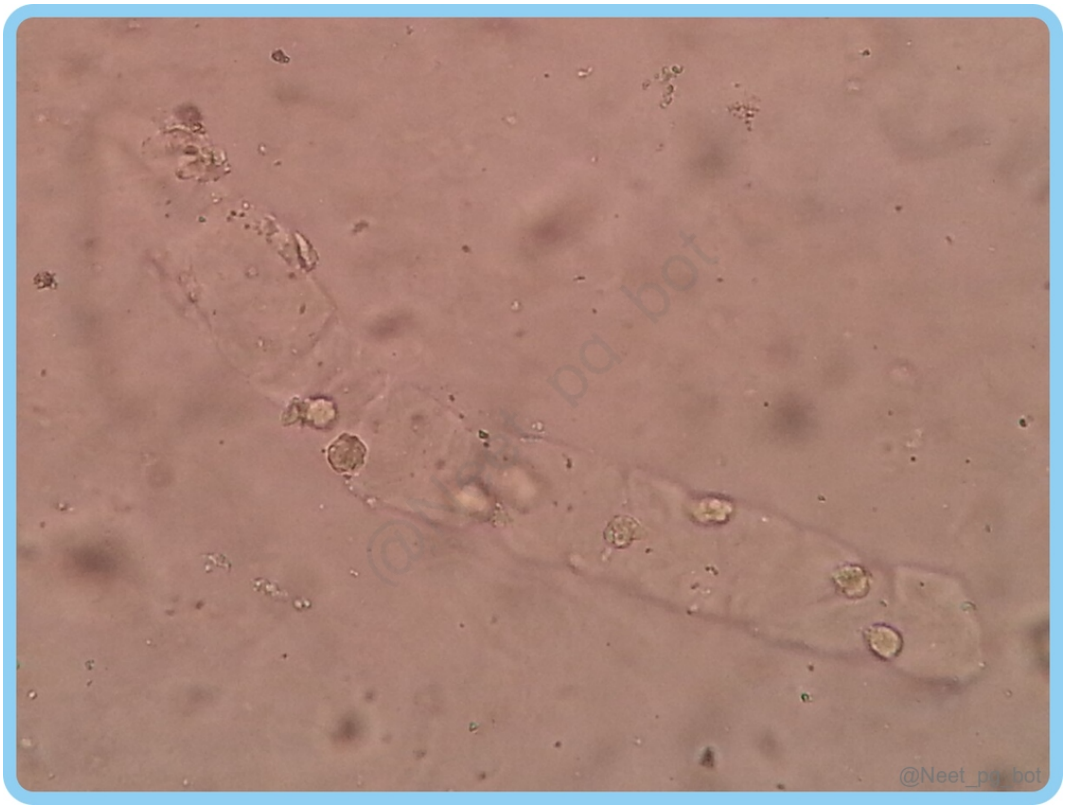
D. 1-D, 2-A,3-C, 4-B

Correct Answer: C. 1-D, 2-C, 3-B, 4-A

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: All casts are composed of Tamm-Horsfall protein produced in the thick ascending limb of loop of Henle . Various casts seen on urine examination are as follows. Renal Cast Type Condition Associated Images Hyaline casts Normal conditions, Fever, Pregnancy. Composed of Tamm-Horsfall protein which is normally produced by loop of Henle. Increase in number of these cast can cause Fever or dehydration Muddy Brown/ granular casts Acute tubular necrosis, It is suggestive of cell death following which occurs following poisoning, like ethylene glycol or mercury poisoning. Waxy casts Chronic renal failure Fatty casts Nephrotic syndrome, associated with lipidurea RBC casts Glomerulonephritis WBC casts Pyelonephritis, interstitial nephritis Epithelial casts Renal epithelial injury {{caption_text}} Broad casts Chronic renal disease



@Neet_pg_bot

Q8: A 45-year-old male presents with confusion, nausea, and abdominal pain after consuming antifreeze due to stress. Urinalysis reveals elevated BUN and creatinine. Microscopic examination is shown below. Identify the type of cast. (Q845687)

A. Hyaline casts

B. Granular casts

C. Waxy casts

D. Muddy brown casts

Correct Answer: D. Muddy brown casts

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical vignette of a patient with a history of anti-freeze consumption presenting with confusion, nausea, abdominal pain, elevated BUN and creatinine is suggestive of ethylene glycol poisoning . Muddy brown casts will be seen in this condition. Muddy brown casts: They are often seen in patients with ethylene glycol poisoning, leading to acute tubular necrosis (ATN). Ethylene glycol metabolites can damage renal tubules, resulting in the formation of muddy brown casts in urine sediment. Hyaline casts (Option A): Seen normally and are also increased during fever and dehydration. Granular casts (Option B): Seen due to degenerated cells. Waxy casts (Option C): Seen in chronic renal failure

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 947

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: All of the following are true about medullary sponge kidney except: (Q845692)

A. It is more common in adults.

B. It is characterised by dilated collecting ducts in the renal medulla.

C. It is caused by an autoimmune destruction of renal tubules.

D. Cysts are lined by cuboidal epithelium.

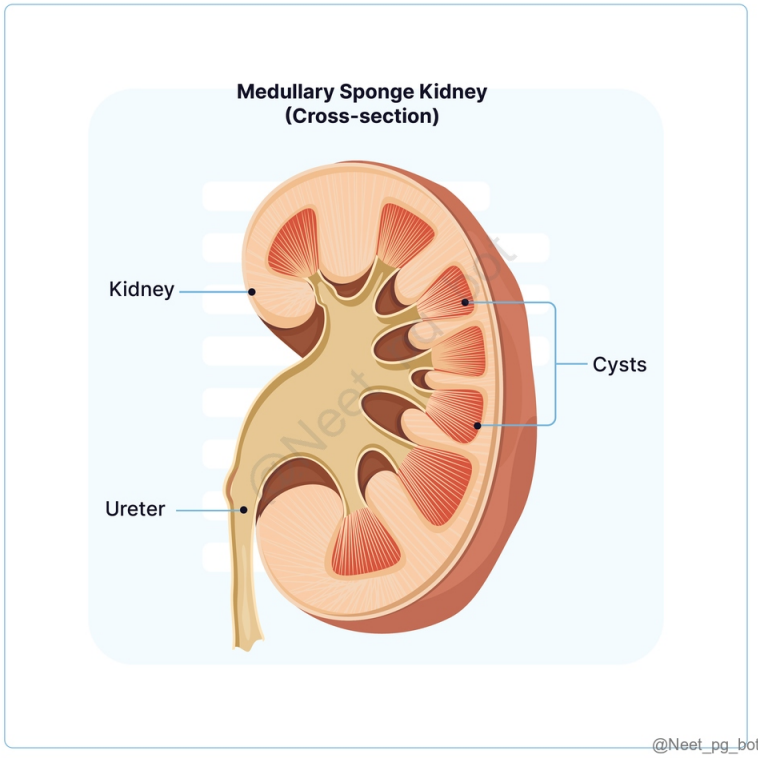
Correct Answer: C. It is caused by an autoimmune destruction of renal tubules.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Medullary Sponge Kidney (MSK) is a congenital developmental anomaly. There is no immune mediated tubule destruction involved. Medullary Sponge Kidney: The term medullary sponge kidney is restricted to multiple cystic dilations of the collecting ducts in the medulla. The condition occurs in adults. (Option A) .

Renal function is usually normal. On gross inspection, the papillary ducts in the medulla are dilated (Option B) and small cysts may be present. The cysts are lined by cuboidal epithelium or occasionally by transitional epithelium. (Option D).



MEDULLARY CYSTIC KIDNEY	MEDULLARY SPONGE KIDNEY

• Cysts are present at the corticomedullary junction
• Types
  ○ Autosomal dominant
  ○ Autosomal recessive / Familial juvenile nephronophthisis
  → Salt wasting
  → Polyuria
	• Medullary cysts
	• Cortex is normal
	• Renal stones +

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 45-year-old man presents with generalised oedema and frothy urine. Laboratory evaluation shows hypoalbuminemia and hyperlipidemia. Urinalysis

reveals heavy proteinuria. What is the minimum daily urinary protein loss required to define nephrotic syndrome in adults? (Q889840)

A. 2.5 g/day

B. 3 g/day

C. 3.5 g/day

D. 4 g/day

Correct Answer: C. 3.5 g/day

Explanation: Nephrotic syndrome in adults is defined by proteinuria ≥3.5 g/day. Nephrotic syndrome: Increased permeability of the glomerular capillary wall Leads to excessive loss of plasma proteins in urine Core features: Massive proteinuria: ≥ 3.5 g/day (less in children) Hypoalbuminemia: Serum albumin < 3 g/dL Generalized edema Hyperlipidemia Lipiduria

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 827

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following mutations are associated with nephrotic syndrome? Nephrin Podocin ACTN4 INF2 TRPC6 (Q889842)

A. 1 and 2 only

B. 1, 2 and 5 only

C. 1, 2, 3 and 4 only

D. 1, 2, 3, 4 and 5

Correct Answer: D. 1, 2, 3, 4 and 5

Explanation: All listed mutations are associated with nephrotic syndrome , primarily through disruption of podocyte structure and slit diaphragm integrity . NPHS1 (Nephrin) : Encodes nephrin , a vital component of the slit diaphragm. Mutations lead to congenital nephrotic syndrome of the Finnish type . Characterised by minimal change disease-like glomerulopathy and extensive foot process effacement. NPHS2 (Podocin) : Encodes podocin , an intracellular protein associated with the slit diaphragm. Mutations cause autosomal recessive FSGS , typically presenting as steroid-resistant nephrotic syndrome in children. ACTN4 & INF2 : Encode actin-binding proteins α-actinin-4 and inverted formin-2 . Associated with autosomal dominant FSGS . Features an insidious onset with a

high risk of progression to renal insufficiency. TRPC6 : Found in families with adult-onset FSGS . Mutations are thought to disrupt podocyte function by increasing calcium flux in the cells.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 831

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 42-year-old man with nephrotic syndrome presents with generalised oedema and frothy urine. Laboratory tests reveal hypoalbuminemia and marked hyperlipidemia. He is noted to have an increased risk of thrombosis. Which of the following plasma proteins is increased in nephrotic syndrome? (Q889844)

A. Antithrombin III

B. Albumin

C. Fibrinogen

D. Immunoglobulin G

Correct Answer: C. Fibrinogen

Explanation: The liver increases the synthesis of fibrinogen and other coagulation factors to compensate for the low plasma oncotic pressure. Nephrotic syndrom e is characterized by massive urinary loss of plasma proteins due to increased glomerular permeability. In response to reduced plasma oncotic pressure, the liver increases synthesis of several proteins, including: Fibrinogen Other coagulation factors Lipoproteins Elevated fibrinogen levels contribute to the hypercoagulable state seen in nephrotic syndrome, increasing the risk of venous thrombosis (e.g., renal vein thrombosis). Antithrombin III (Option A): Lost in the urine and decreased in plasma, contributing to thrombosis risk. Albumin (Option B): Lost in large amounts in urine. Although hepatic synthesis increases, plasma albumin levels remain low (hypoalbuminemia). Immunoglobulin G (Option D): Lost in urine, leading to decreased plasma levels and increased susceptibility to infections.

References:

https://pubmed.ncbi.nlm.nih.gov/9453016/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 40-year-old man presents with nephrotic-range proteinuria. Renal biopsy shows focal and segmental glomerulosclerosis. You are reviewing conditions associated with secondary FSGS. Which of the following is not associated with FSGS? (Q889847)

A. Reflux nephropathy

B. Sickle cell disease

C. ACTN4 mutation

D. Minimal change disease

Correct Answer: D. Minimal change disease

Explanation: Minimal change disease is a distinct primary podocytopathy characterised by diffuse foot process effacement without segmental sclerosis. It is not classified under FSGS. Focal Segmental Glomerulosclerosis (FSGS): Classification: Primary: Idiopathic Secondary: Viral & Toxic Injury: Caused by infections (HIV, SARS-CoV-2), heroin addiction, sickle cell disease (Option B) , or other direct toxicities. Adaptive Changes: Reduced renal mass (nephrectomy, reflux nephropathy (Option A) , agenesis) Obesity, advanced CKD Mechanism: glomerular hypertension → podocyte loss → sclerosis Inherited Forms: Uncommon mutations in slit diaphragm- and actin cytoskeleton-associated proteins. NPHS1 (nephrin) → congenital nephrotic syndrome (Finnish type) NPHS2 (podocin) → steroid-resistant childhood nephrotic syndrome ACTN4 (Option C) → autosomal dominant FSGS INF2 → autosomal dominant FSGS TRPC6 → adult-onset FSGS APOL1 Risk Alleles Secondary Scarring: IgA nephropathy ANCA-associated vasculitis

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 831

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following FSGS variants is associated with the best prognosis, and which is associated with the worst prognosis? (Q889849)

A. Hilar variant - Best; Cellular variant - Worst

B. Tip lesion variant - Best; Collapsing variant - Worst

C. Collapsing variant - Best; Tip lesion variant - Worst

D. Cellular variant - Best; Hilar variant - Worst

Correct Answer: B. Tip lesion variant - Best; Collapsing variant - Worst

Explanation: Tip lesion variant is associated with the best prognosis. It often responds well to corticosteroid therapy and has more favorable renal outcomes. Collapsing variant has the worst prognosis. It is characterized by collapse of glomerular capillary loops with podocyte proliferation and is associated with rapid progression to renal failure. Focal Segmental Glomerulosclerosis (FSGS): Focal : some glomeruli Segmental : part of tuft Primary podocytopathy → podocyte loss → sclerosis Clinical features: Nephrotic syndrome (often nonselective proteinuria) Hematuria, hypertension, ↓ GFR are common Poor steroid response ~50% → ESKD in 10 years 25–50% recurrence post-transplant Variants: Collapsing glomerulopathy (poor prognosis) Cellular variant Hilar lesion Tip lesion (better prognosis) Not otherwise specified (NOS)

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 831

Harrison’s Principles of Internal Medicine, 21st Edition, Page 2342

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which of the following conditions is characterised by the absence of mesangial immune complex deposits? (Q889850)

A. IgA nephropathy

B. Lupus nephritis (Class II)

C. Henoch-Schönlein Purpura

D. Anti-GBM disease

Correct Answer: D. Anti-GBM disease

Explanation: Anti-GBM disease is characterized by linear deposition of IgG along the glomerular basement membrane on immunofluorescence. It is a type II hypersensitivity reaction , in which antibodies bind directly to GBM antigens. It does not involve immune complex deposition in the mesangium. Conditions showing mesangial deposits: IgA Nephropathy (Berger's Disease) (Option A) : Granular mesangial IgA deposition. Membranoproliferative Glomerulonephritis (MPGN) (Types I and II) C3 Glomerulopathy (Dense Deposit Disease and C3 Glomerulonephritis) Lupus Nephritis (specifically Classes I and II) (Option B): Mesangial immune complex deposition with “full house” immunofluorescence. Henoch-Schönlein-Purpura (IgA-Vasculitis) (Option C) : IgA-mediated vasculitis with mesangial IgA deposits.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 821, 824, 826

↑ *Back to this question in Part A*

Q16: A child with nephrotic syndrome undergoes serum protein electrophoresis. Which protein is increased? (Q889852)

A. Albumin

B. α1-antitrypsin

C. α2-macroglobulin

D. IgG

Correct Answer: C. α2-macroglobulin

Explanation: α2-macroglobulin is increased in nephrotic syndrome. In nephrotic syndrome, there is massive urinary loss of low molecular weight proteins such as albumin and IgG. In response to decreased oncotic pressure, the liver increases the synthesis of various proteins. α2-macroglobulin is a very large molecule that: Is not filtered through the damaged glomerulus Is retained in plasma Increases in concentration Produces a rise in the α2-globulin fraction on serum electrophoresis Serum electrophoresis in nephrotic syndrome: Pattern: ↓ Albumin ↑ α2-globulin fraction ↓ γ-globulin (IgG) Albumin (Option A): Decreased due to heavy urinary loss. α1-antitrypsin (Option B): May be lost in urine and is not characteristically elevated. IgG (Option D): Lost in urine, leading to decreased levels and increased infection risk.

[11_Renal System] 049 Nephritic And Nephrotic Syndromes — Quick Jump

Q1 (p. 2134)	*Q2 (p. 2135)*	*Q3 (p. 2139)*	*Q4 (p. 2142)*	*Q5 (p. 2145)*	*Q6 (p. 2147)*
Q7 (p. 2149)	*Q8 (p. 2150)*	*Q9 (p. 2152)*	*Q10 (p. 2153)*	*Q11 (p. 2156)*	*Q12 (p. 2157)*
Q13 (p. 2158)	*Q14 (p. 2160)*	*Q15 (p. 2161)*	*Q16 (p. 2164)*	*Q17 (p. 2166)*	*Q18 (p. 2168)*

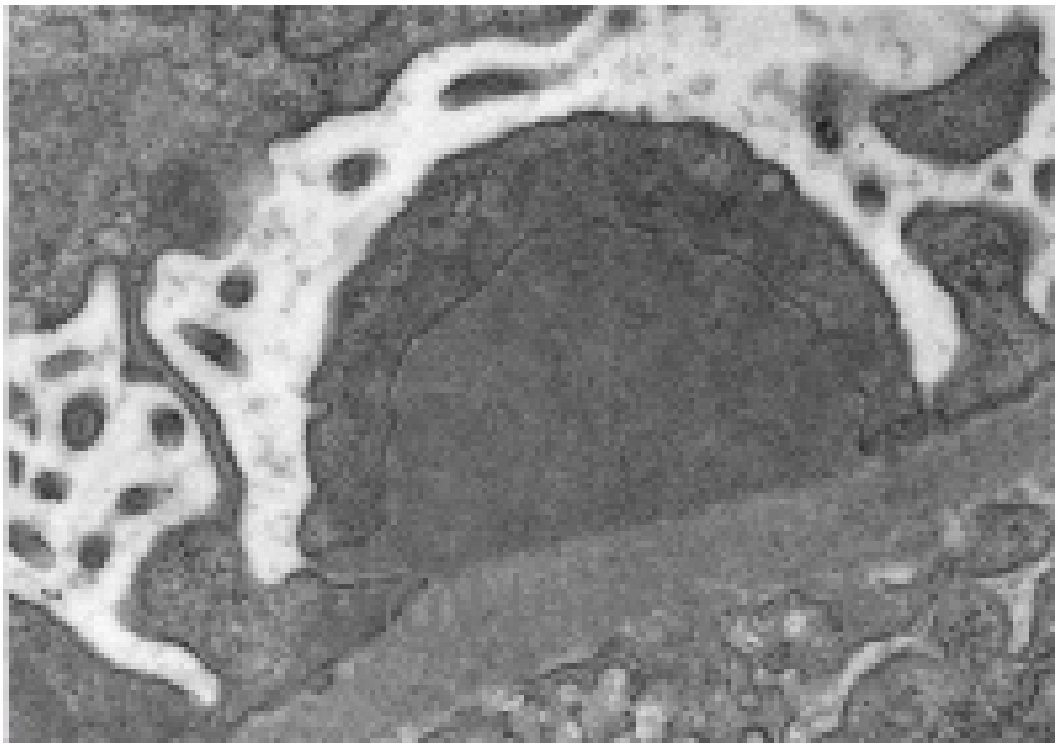
Q1: A 9-year-old boy is brought to the clinic with swelling around the eyes, dark "tea-colored" urine, and decreased urine output. His mother reports that he had a skin infection (impetigo) about 3 weeks ago. On examination, he has mild periorbital edema and elevated blood pressure. Urinalysis shows RBC casts and mild proteinuria. Serum studies reveal low C3 complement levels. A renal biopsy is performed, and electron microscopy reveals following changes. Which of the following is the most likely diagnosis? (Q845704)

A. IgA nephropathy

B. Post-streptococcal glomerulonephritis

C. Membranous nephropathy

D. Minimal change disease



Correct Answer: B. Post-streptococcal glomerulonephritis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This child has the classic triad of PSGN: 1. Recent Streptococcal Infection Occurs 1–3 weeks after pharyngitis or impetigo (as in this case). 2. Clinical Features Periorbital edema Cola/tea-colored urine Hypertension RBC casts (nephritic syndrome) 3. Lab Findings Low C3 complement Normal C4 Anti-streptolysin O (ASO) may be elevated (more after pharyngitis than impetigo) 4. Electron Microscopy Subepithelial “hump-shaped” electron-dense deposits → pathognomonic IgA nephropathy (Option A) Typically occurs 1–2 days after a URI (synpharyngitic). Complement levels are usually normal. Deposits are mesangial, not subepithelial "humps." Membranous nephropathy (Option C) Presents with nephrotic syndrome, not nephritic. EM shows subepithelial spikes (“spike and dome”), not humps. Minimal change disease (Option D) Presents with nephrotic syndrome (massive proteinuria, edema). EM: effacement of podocyte foot processes, no immune deposits.

@Neet_pg_bot

Q2: A 12-year-old male child presents to the clinic with a history of progressive hearing loss, blurred vision, and recurrent episodes of hematuria over the past few

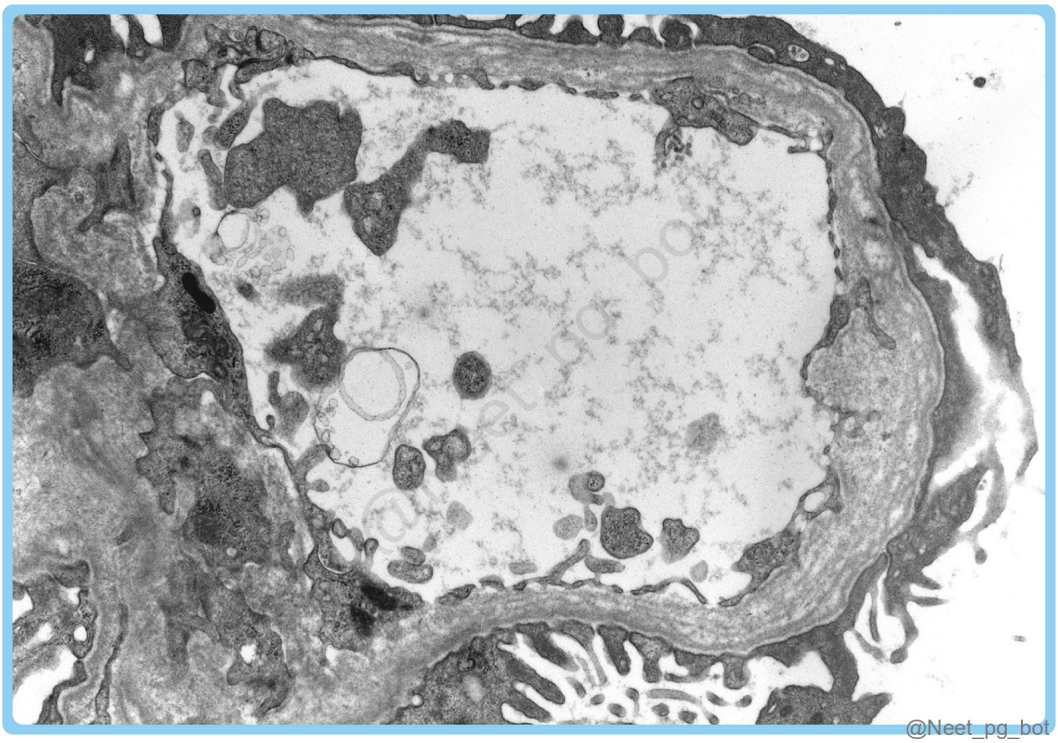
months.Electron microscopy reveals the ‘basketweave’ appearance of GBM. Which of the following morphological findings is responsible for this appearance? (Q846662)

A. Effacement of podocyte foot processes

B. Thickening of the glomerular basement membrane with subepithelial electron-dense deposits

C. Irregular thickening, thinning, and splitting of the glomerular basement membrane

D. Mesangial expansion with GBM thickening and eosinophilic nodular glomerulosclerosis



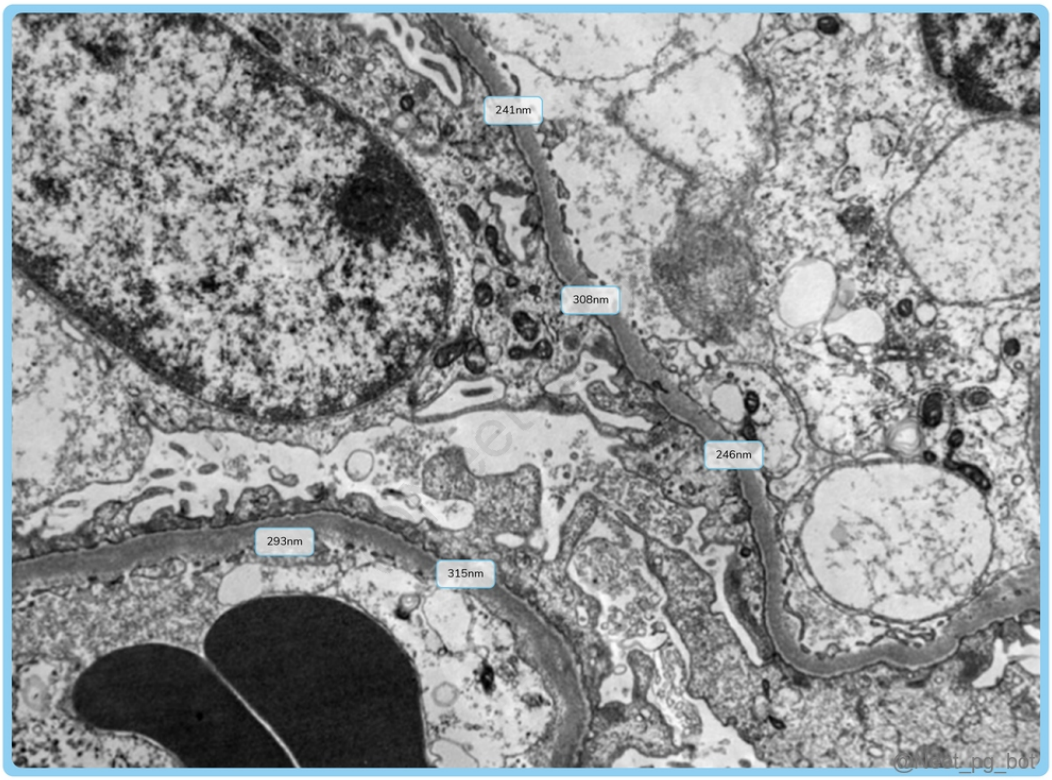
Correct Answer: C. Irregular thickening, thinning, and splitting of the glomerular basement membrane

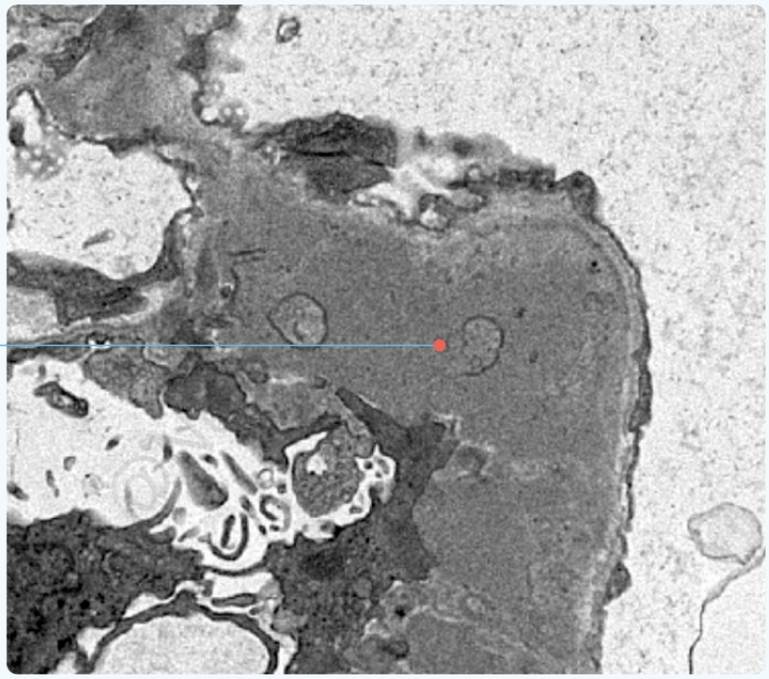
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and EM findings of the characteristic basket-weave appearance of GBM suggest Alport syndrome. Alport syndrome arises due to mutations affecting Type IV collagen , specifically the α 5 chain (in X-linked cases) or the α3 and α4$ chains. This results in hematuria progressing to chronic renal insufficiency. Inheritance: Most commonly X-linked dominant (COL4A5), but can also be Autosomal Recessive or Dominant (COL4A3/4). Clinical Presentation: It presents alongside sensorineural hearing impairment and various ocular manifestations, including lens subluxation, posterior subcapsular cataracts, and corneal dystrophy. Histologically , Alport syndrome shows distinct electron microscopic features: GBM exhibits irregular areas of thickening interspersed with thinning. Splitting and layering of the lamina densa (basket-weave appearance of GBM) Effacement of podocyte foot processes (Option A): Effacement of podocytes is characteristically seen in Minimal change disease, not the Alport syndrome. Thickening of the glomerular basement membrane with

subepithelial electron-dense deposits (Option B): Membranous nephropathy shows the thickening of the glomerular basement membrane without hypercellularity on light microscopy, while electron microscopy shows the ‘spike and dome’ appearance of subepithelial deposits. Mesangial expansion with GBM thickening and eosinophilic nodular glomerulosclerosis (Option D): Diabetic glomerulonephropathy shows mesangial expansion with GBM thickening and eosinophilic nodular glomerulosclerosis (Kimmelstiel-Wilson lesions)





@Neet_pg_bot

Q3: A 55-year-old patient with a history of poorly controlled diabetes presents with worsening kidney function. Upon examination, renal biopsy reveals glomerular changes consistent with diabetic nephropathy. Which histological findings would be least likely to be observed in the glomeruli of this patient's kidney biopsy? (Q846670)

A. Kimmelstiel-Wilson nodule

B. Diffuse glomerulosclerosis

C. Arteriolar hyalinosis

D. Armani-Ebstein lesion

Correct Answer: D. Armani-Ebstein lesion

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: In uncontrolled diabetes, glucosuria causes glycogen accumulation in the proximal tubular cells (not in the glomerulus), known as Armanni-Ebstein cells. This pathological finding is more commonly associated with diabetic ketoacidosis (DKA) than with diabetic nephropathy. Kimmelstiel-Wilson nodule (Option A) Kimmelstiel-Wilson nodules (aka Nodular glomerulosclerosis) are a hallmark of diabetic nephropathy. They are ovoid or spherical, PAS-positive nodules found in the mesangial core of glomeruli. They are often accompanied by mesangiolysis and sometimes surrounded by dilated capillary loops. Diffuse glomerulosclerosis (Option B) Diffuse glomerulosclerosis refers to a diffuse increase in the mesangial matrix and thickening of GBM. It correlates with deteriorating renal function and increasing proteinuria. This is the most common histopathological finding of diabetic nephropathy. Arteriolar hyalinosis (Option C) Arteriolar hyalinosis involves the accumulation of hyaline material in the walls of both afferent and efferent arterioles, contributing to ischemia and kidney damage in diabetes. Hyaline material accumulated in capillary loops is known as “fibrin caps” in Bowman’s capsule, it is called “capsular drops.”

Robbins and Cotran Pathologic Basis of Disease, 10th edition, page 1110, 1111

↑ *Back to this question in Part A*

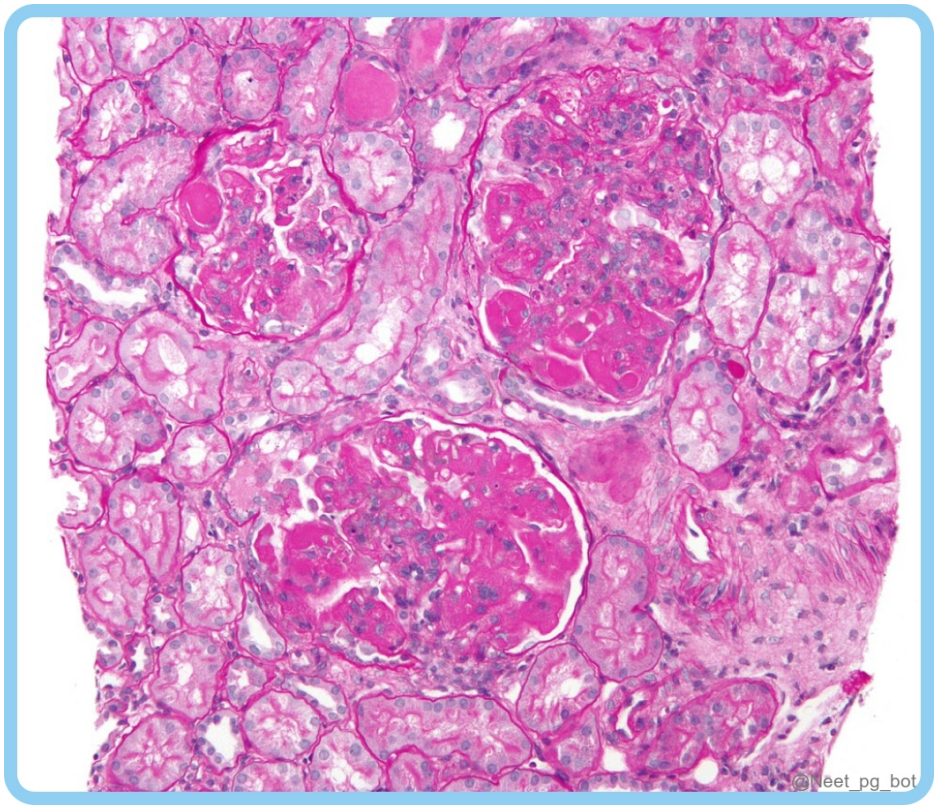
Q4: A 32-year-old female presents with a history of joint pain, skin rash, and recent onset of shortness of breath. Lab investigations reveal elevated anti-double-stranded DNA antibodies and low complement levels. A kidney biopsy shows >50% involvement of glomeruli with wire loop lesions on light microscopy. Which type of lupus nephritis is most likely observed in the biopsy findings? (Q846669)

A. Class III

B. Class IV

C. Class V

D. Class VI



Correct Answer: B. Class IV

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the clinical scenario and lab results, the patient likely has systemic lupus erythematosus (SLE) with renal involvement. The kidney biopsy revealing >50% glomerular involvement with wire loop lesions indicates class IV lupus nephritis, the most common and severe form. Classification of Lupus Nephritis (LN): Class I Minimal Mesangial LN Class II Mesangial proliferative LN Class III (Option A) Focal LN (<50% glomeruli) Class IV Diffuse LN (>50% glomeruli) Class V (Option C) Membranous LN Class VI (Option D) Advanced Sclerosing LN Light microscopy: Subendothelial immune complex deposits can result in the circumferential thickening of the capillary wall, leading to the formation of "wire loop" structures, which are observed in Class III, IV (maximum) and V. Electron microscopy: Thumbprint/ fingerprint sign (alternating areas of electron-dense deposits and lucent regions in GBM, indicating immune complex deposition) Immunofluorescence: Full House Effect (IgG, IgA, IgM, C1, C3 get deposited in the kidney)

@Neet_pg_bot

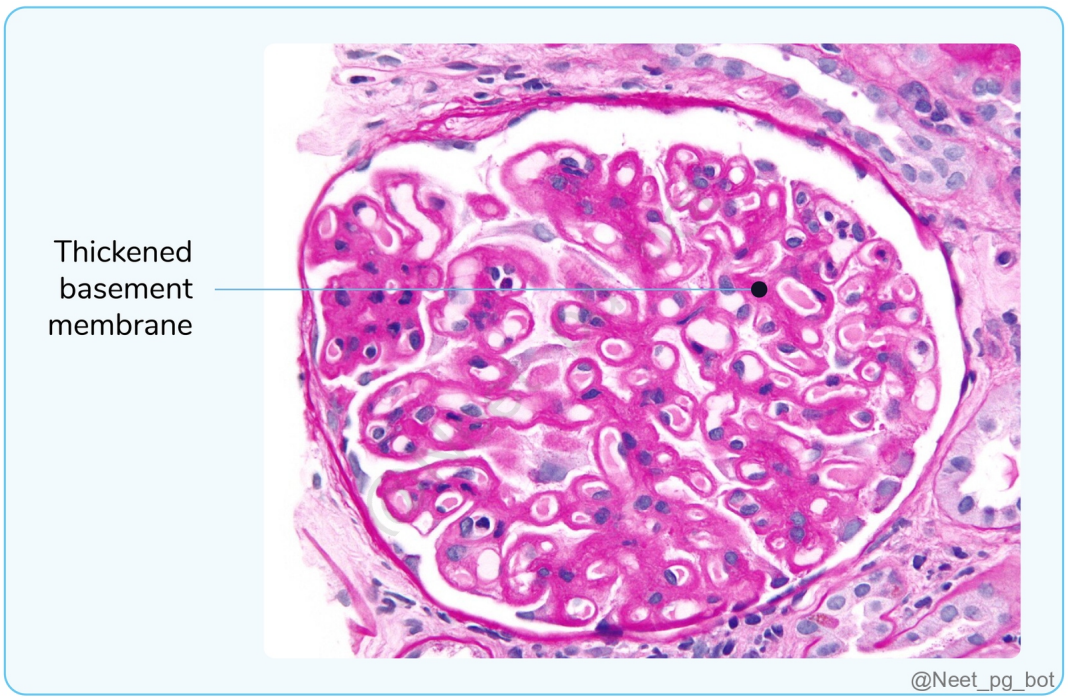
Q5: A 45-year-old male presents with generalised oedema and frothy urine. Laboratory investigations reveal significant proteinuria and hypoalbuminemia. A kidney biopsy reveals diffuse thickening of GBM, a spike and dome pattern on the silver stain and subepithelial deposits on electron microscopy. Which of the following genetic mutations is most likely associated with this condition? (Q846668)

A. Mutation in PLA2R

B. Mutation in LAMB2 gene

C. Mutations in APOL1 gene

D. Mutations in CFH gene



Correct Answer: A. Mutation in PLA2R

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation, along with the histological findings of diffuse thickening of GBM, a spike and dome pattern on the silver stain, and subepithelial deposits on electron microscopy, suggest Membranous nephropathy , the most common cause of nephrotic syndrome in elderly patients. In primary membranous nephropathy, antibodies primarily target the M-type phospholipase A2 receptor (PLA2R) located on the basal surface of podocytes. This triggers complement activation and subepithelial immune complex deposition, resembling Heymann nephritis lesions. Other less common target antigens include THSD7A and neutral endopeptidase (CD10). The presence of anti-PLA2R antibodies is crucial for diagnosing the disease. Secondary → drugs (gold, penicillamine, NSAIDs), infections (HBV, syphilis), lupus, solid tumor and diabetes mellitus

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 912-914

↑ *Back to this question in Part A*

@Neet_pg_bot

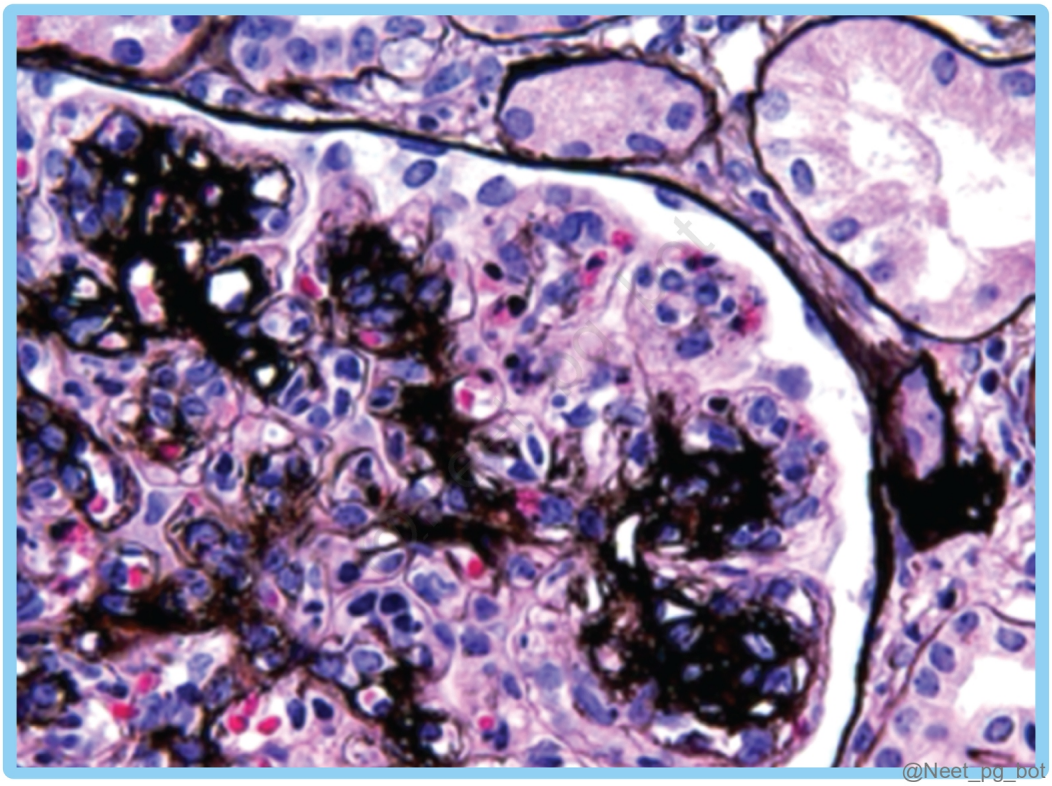
Q6: A 25-year-old female presents with edema, hypertension, significant proteinuria, and hematuria. Kidney biopsy reveals mesangial and endocapillary hypercellularity with mesangial and subendothelial electron-dense deposits, tram track appearance on silver stains and granular staining for IgG and C3 on Immunofluorescence. What is the most likely diagnosis? (Q846667)

A. Type I Membranoproliferative Glomerulonephritis

B. Type II Membranoproliferative Glomerulonephritis

C. Membranous Nephropathy

D. Focal Segmental Glomerulosclerosis



Correct Answer: A. Type I Membranoproliferative Glomerulonephritis

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Tram track or double contour appearance due to splitting of GBM Pathology Primary Causes / Associations Light Microscope Electron Microscope Immunofluorescence Type I MPGN (Option A) Hepatitis C , Hepatitis B, SLE, Cryoglobulinemia, or Chronic Infections Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening and Splitting. (Double-contour or tram track appearance) Subendothelial and mesangial deposits IgG ++ C3 (C1q ++ C4 may also present) Type II MPGN (Dense Deposit Disease) (Option B) C3 Nephritic Factor (C3NeF) ; Factor H deficiency; Alternative complement pathway dysregulation Dense intramembranous deposits C3; no C1q or C4 Membranous Nephropathy (Option C) Primary (anti-PLA2R); Secondary (NSAIDs, Malignancy, HBV, SLE) Diffuse capillary wall thickening Subepithelial deposits Granular IgG and C3; diffuse Focal Segmental Glomerulosclerosis (FSGS) (Option D) HIV, Heroin use, Obesity, Sickle Cell Disease, or Primary/Idiopathic Focal and segmental sclerosis and hyalinosis Effacement of foot processes; epithelial denudation Focal; IgM + C3 in many cases

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 917-920

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which genetic mutation is responsible for a syndrome of steroid-resistant nephrotic syndrome of childhood onset? (Q846666)

A. NPHS1

B. NPHS2

C. α-actinin 4

D. TRPC6

Correct Answer: B. NPHS2

Explanation: The above clinical scenario points towards the diagnosis of steroid-resistant nephrotic syndrome, which is defined as the absence of remission despite 4 weeks of therapy with daily prednisone at a dose of 2 mg/kg/d. Mutations in the NPHS2 gene lead to this syndrome, typically manifesting in childhood. The NPHS2 gene is located on chromosome 1q25–q31. The NPHS2 gene encodes the protein product known as podocin which is localised to the slit diaphragm within the kidney. Patients typically present from birth to 6 years of age have a steroid-resistant course and reach End-stage Renal Disease (ESRD) before the end of their first decade. NPHS1 (Option A): NPHS1 mutations are associated with congenital nephrotic syndrome of the Finnish type. α-actinin 4 (Option C): Mutations in the gene encoding the podocyte actin-binding protein α-actinin 4 (ACTN4) underlie some cases of autosomal dominant focal segmental glomerulosclerosis (FSGS), which tends to have a high rate of progression to renal insufficiency. TRPC6 (Option D): Mutations in the TRPC6 gene, which encodes a calcium-permeable ion channel in podocytes , have been identified in some cases of familial FSGS. However, TRPC6 mutations are not typically linked to childhood-onset steroid-resistant nephrotic syndrome.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 915

↑ *Back to this question in Part A*

@Neet_pg_bot

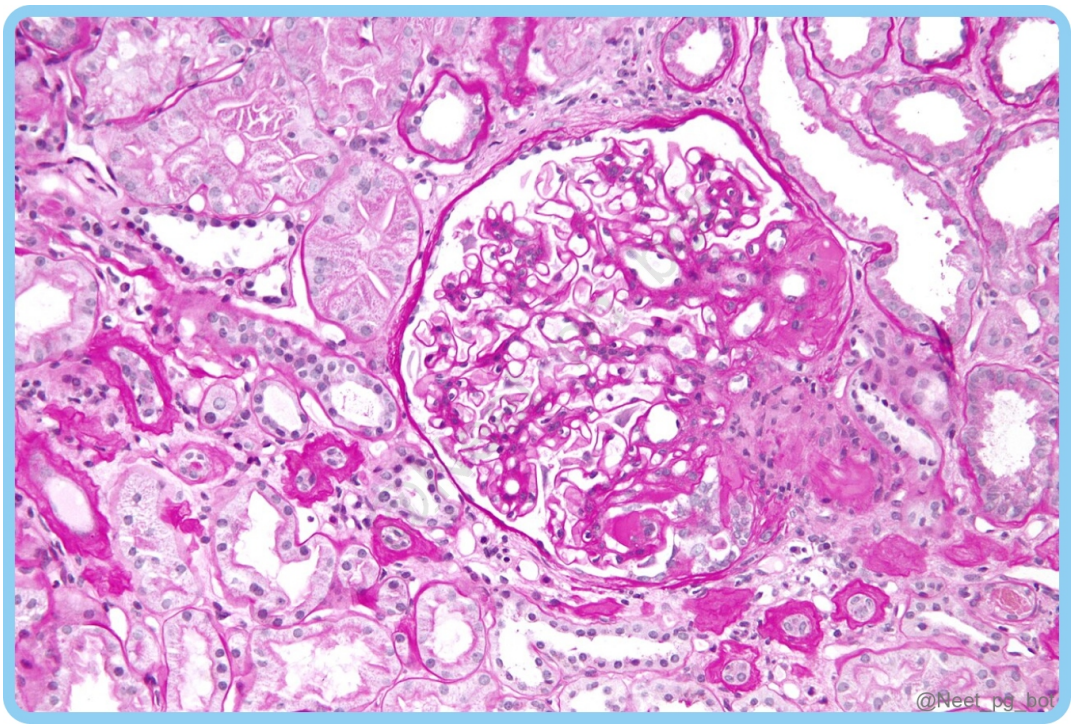
Q8: A 35-year-old man presents with swelling around his eyes, ankles, and abdomen, along with frothy urine. Urinalysis shows proteinuria, elevated serum creatinine, and BUN levels. Image of renal biopsy is given below. Which of the following is not an established cause of this condition? (Q846665)

A. Diabetes mellitus

B. HIV infection

C. Hypertension

D. Sickle cell anaemia



Correct Answer: A. Diabetes mellitus

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the given clinical scenario and HPE image (segmental sclerosis, glomerular hyalinosis, and tubular atrophy, with negative immunofluorescence), the most likely diagnosis is Focal Segmental Glomerulosclerosis (FSGS), the most common cause of nephrotic syndrome in adults. Diabetes mellitus primarily causes diabetic nephropathy, characterised by diffuse glomerulosclerosis rather than the focal and segmental pattern seen in FSGS. Causes of FSGS: 1. Primary (Idiopathic) FSGS. 2. Secondary FSGS: Mnemonic- H3R3S1 H ypertension (Option C) H IV associated nephropathy (Option B) H eroine drug abuse R eflux nephropathy R enal tissue loss S ickle cell anaemia (Option D) 3. Inherited forms: Genetic mutations affecting slit diaphragm proteins like nephrin, podocin, α-actinin 4, and TRPC6.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 914, 915, 1110, 1111

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 6-year-old boy presents with sudden generalised oedema and frothy urine. Urinalysis reveals heavy proteinuria without hematuria. Renal biopsy widespread effacement of podocyte foot processes on electron microscopy. Which of the following is true regarding this condition? (Q846664)

A. Lipid deposition within glomerular capillaries (tubular cells)

B. Immunofluorescence microscopy reveals granular deposition of IgG and C3 in the glomeruli.

C. Good response to corticosteroid therapy

D. Non-selective proteinuria

Correct Answer: C. Good response to corticosteroid therapy

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical and electron microscope findings suggest the diagnosis as Minimal Change Disease (MCD) , characterised by diffuse effacement of foot processes of podocytes in glomeruli. It primarily affects children aged 2-6 years. MCD typically responds rapidly to corticosteroid therapy, especially in children (>90%), leading to complete remission of proteinuria and resolution of symptoms. Lipid deposition within glomerular capillaries (Option A): Lipid deposition within glomerular capillaries is not observed in MCD. Instead, protein and lipid deposition may occur in the proximal tubules due to tubular reabsorption of lipoproteins passing through diseased glomeruli, leading to the historical term "lipoid nephrosis" for this disease. Immunofluorescence microscopy reveals granular deposition of IgG and C3 in the glomeruli (Option B) Immunofluorescence studies in MCD typically show no significant immune complex deposition or granular staining patterns. This distinguishes MCD from immune complex-mediated glomerular diseases like IgA nephropathy or lupus nephritis, where IgG and C3 deposits are commonly observed. Non-selective proteinuria (Option D) Minimal Change Disease (MCD) typically presents with highly selective proteinuria , mostly albumin . Renal function remains good despite massive proteinuria, with no hypertension or hematuria commonly.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 914

↑ *Back to this question in Part A*

@Neet_pg_bot

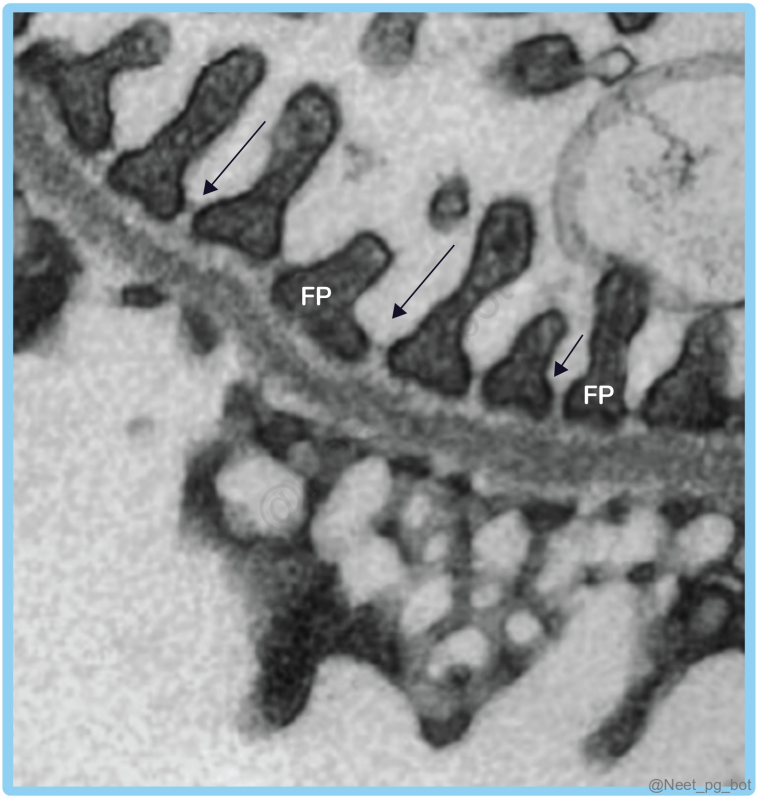
Q10: A 7-year-old girl with a recent upper respiratory tract infection presents with generalised swelling and reduced urine output. Urinalysis reveals proteinuria without blood cells or casts. Electron microscopy findings show flattening, retraction, and swelling of podocytes. Which light microscopy findings is characteristic of this condition? (Q846663)

A. Glomerulosclerosis

B. Normal glomeruli

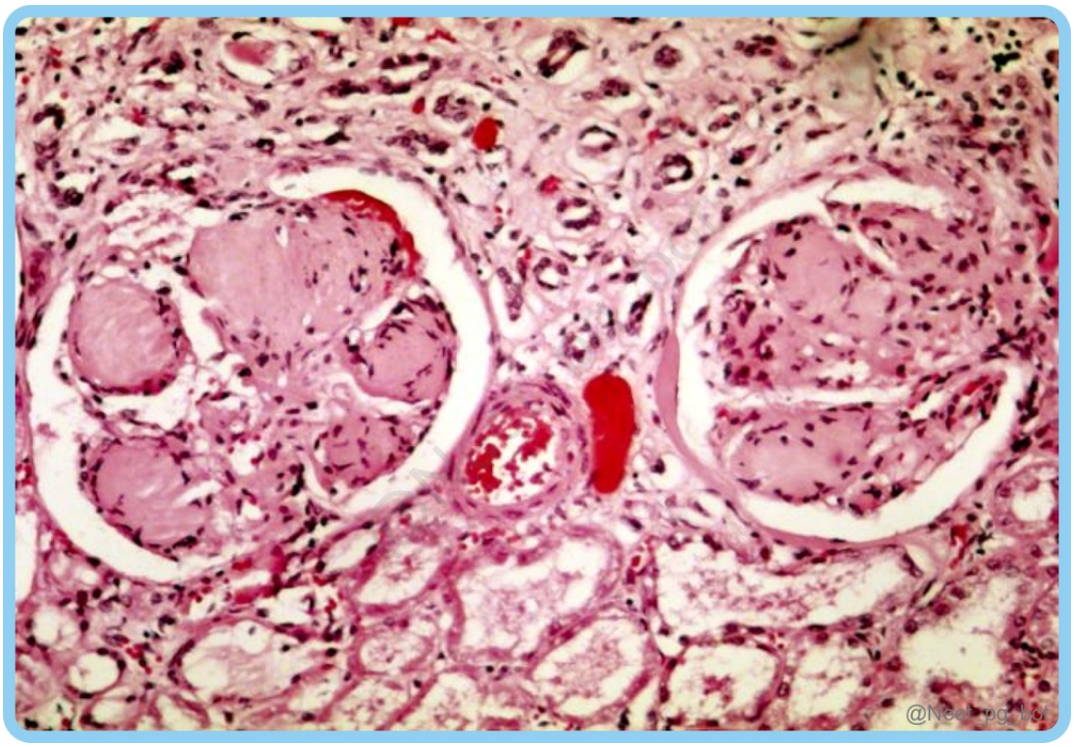
C. Fibrinoid necrosis in glomeruli

D. Wire looping of capillaries



Correct Answer: B. Normal glomeruli

Explanation: The above clinical presentation and EM finding of podocyte effacement is characteristic of Minimal change disease. It is marked by the widespread flattening of podocytes, seen only on electron microscopy, while light microscopy shows normal glomeruli with lipids in proximal tubules. This alteration in podocyte structure leads to increased permeability of the glomerular filtration barrier, resulting in the loss of large amounts of protein in the urine. Glomerulosclerosis (Option A) Observed in diabetic nephropathy. Diffuse glomerulosclerosis Diffuse glomerulosclerosis Focal segmental glomerulosclerosis Fibrinoid necrosis in the glomeruli (Option C) : Vasculitis or immune complex-mediated glomerulonephritis. Wire looping of capillaries (Option D) : Wire looping of capillaries is seen in diffuse proliferative glomerulonephritis, often due to SLE (lupus nephritis).



@Neet_pg_16

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 15-year-old boy presents with complaints of blurred vision, hearing loss, and recurrent episodes of hematuria. Genetic testing reveals a mutation in Type 4 collagen. Which of the following genetic mutations is observed in the patient? (Q846661)

A. COL4A3 gene

B. COL4A4 gene

C. COL4A5 gene

D. All of the above

Correct Answer: C. COL4A5 gene

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This is the classic X- linked Alport syndrome COL4A5 has X-linked dominant trait - males are affected more severely whereas females have milder form of disease Alport syndrome is caused by defective COL4A3, COL4A4, and COL4A5 genes, which lead to impaired production and deposition of the Type 4 collagen α345 chain network in the basement membranes of the glomerulus, cochlea, and eyes. COL4A3, COL4A4 has autosomal recessive trait - both males and females are affected (Option A, B) It has a triad of symptoms. Blurred vision due to Anterior lenticonus, lens dislocation, posterior cataracts, and corneal dystrophy. Recurrent hematuria can lead to renal failure. Bilateral sensorineural hearing loss.

Robbins and Cotran Pathologic Basis of Disease, 10th edition, page 922 Alport Syndrome-PMC(NIH.gov) https://www.ncbi.nlm.nih.gov/books/NBK470419/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 32-year-old male presents with painless hematuria post-upper respiratory infections, normal vital signs, and no oedema. Urinalysis reveals red blood cell casts and further investigation shows elevated serum creatinine and mild proteinuria. Renal biopsy confirms glomerulonephritis. What is the most common type of glomerulonephritis in this case? (Q846660)

A. IgA nephropathy

B. Post-Streptococcal glomerulonephritis

C. Minimal change disease

D. Membranous nephropathy

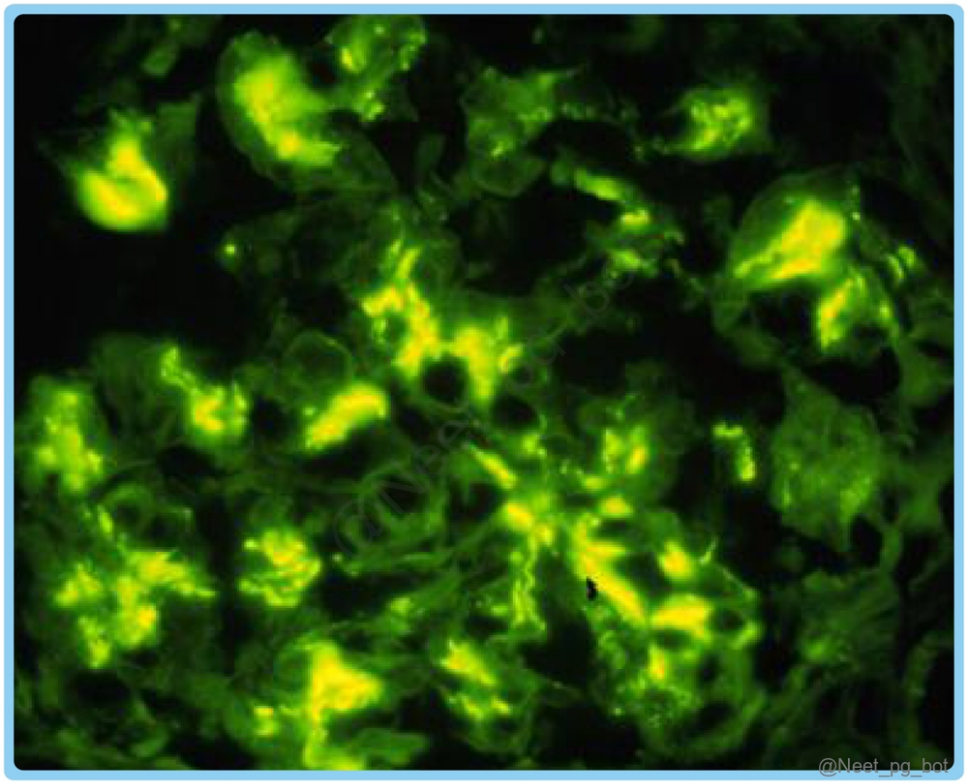
Correct Answer: A. IgA nephropathy

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: IgA nephropathy, or Berger’s disease , is the most common type of glomerulonephritis in adults and worldwide. It presents with gross hematuria in adults, usually 2-3 days after an upper respiratory infection. It can progress to acute renal failure, causing ankle oedema, facial puffiness, and hypertension. It occurs due to the formation of aberrant IgA molecules that deposit in the mesangial regions. Post-streptococcal glomerulonephritis (Option B) It is the most common type of glomerulonephritis in children and presents with fever, oliguria, hypertension, periorbital oedema, and hematuria. It usually occurs 1 to 2 weeks after recovery from an upper respiratory infection, which causes an inflammatory response (type III hypersensitivity reaction). Minimal change

disease (Option C) It is the most common type of nephrotic syndrome in children. It presents with massive proteinuria(>3.5g/24hrs) due to immunological damage to epithelial cells. Membranous nephropathy (Option D) It is the most common type of nephrotic syndrome in the elderly. It is immune complex-mediated and can be caused by malignancy(colon, lung, melanoma), infections(malaria, hepatitis B, C, syphilis, schistosomiasis), drugs(gold, penicillamine), or autoimmune conditions(SLE).



References:

Robbins and Cotran Pathologic Basis of Disease, 10th edition, pages 920-922, 912, 914, 909 IgA Nephropathy (Berger Disease)-PMC(NIH.gov) https://www.ncbi.nlm.nih.gov/books/NBK538214/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 45-year-old male presents with recurrent hematuria following upper respiratory infections and intermittent proteinuria. Renal biopsy shows mesangial IgA deposits on immunofluorescence and electron-dense deposits in the mesangium on electron microscopy. What is the most likely diagnosis? (Q846659)

A. Berger's Disease

B. Alport syndrome

C. Membranous nephropathy

D. Buerger's Disease

Correct Answer: A. Berger’s Disease

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical and histopathological findings suggest the diagnosis of Berger’s disease or IgA nephropathy , characterised by the deposition of IgA antibodies in the mesangial regions of the glomeruli, leading to recurrent episodes of hematuria. Electron microscopy reveals electron-dense deposits predominantly localised in the mesangium. The characteristic immunofluorescent picture shows mesangial deposition of IgA , often with C3 and properdin and lesser amounts of IgG or IgM. Alport syndrome (Option B) It is a genetic disorder characterised by abnormalities in type IV collagen, leading to progressive kidney disease, hearing loss, and eye abnormalities. Electron microscopy reveals irregular thickening of the glomerular basement membrane with lamellation and splitting. Membranous nephropathy (Option C) It is caused by the deposition of immune complexes (primarily IgG and C3) on the outer (subepithelial) side of the glomerular basement membrane. Buerger's Disease (Option D) It is also called Thromboangiitis obliterans, it is a vascular disease causing extremity ischemia and is unrelated to renal involvement or immune deposits in the kidney. It does not present with hematuria or proteinuria.

@Neet_pg_bot

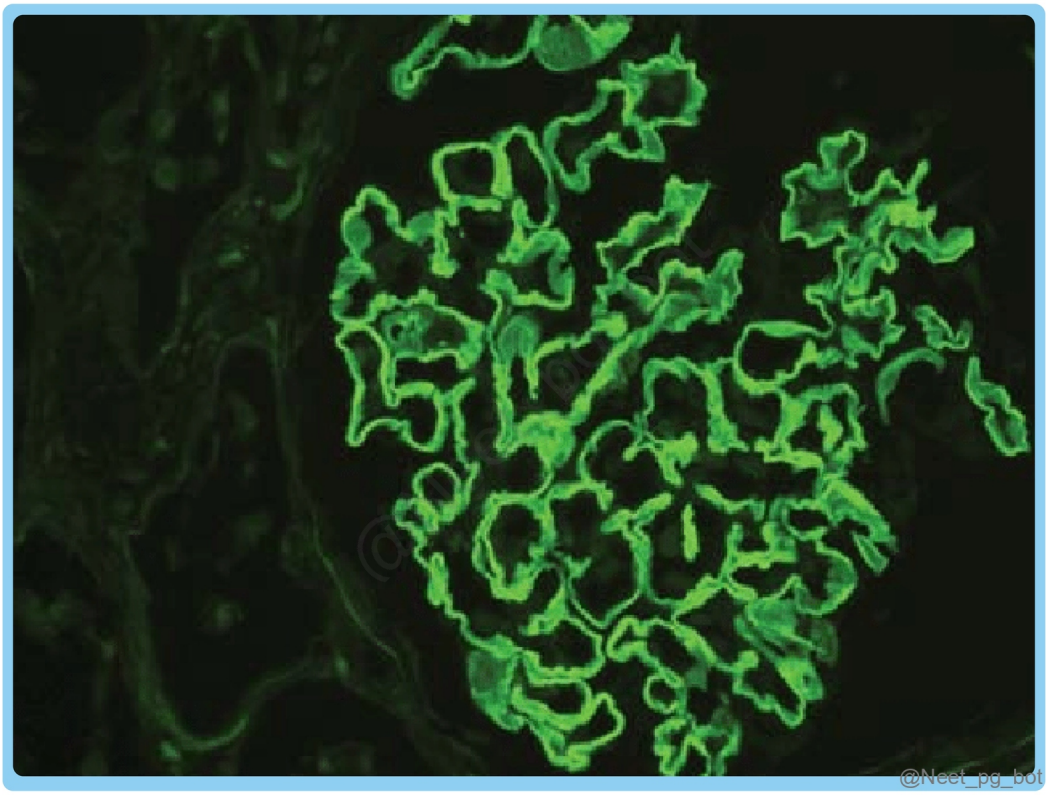
Q14: A 30-year-old male presents with increasing shortness of breath and hemoptysis. Lab tests show elevated serum creatinine and hematuria. Renal biopsy reveals linear immunofluorescence along the glomerular basement membrane and subepithelial and intramembranous electron-dense deposits on electron microscopy. Which of the following statements regarding the diagnosis is not true? (Q846658)

A. It is a Type III hypersensitivity reaction

B. Defective α3 chain of collagen IV

C. Linear immunofluorescence is due to IgG deposition

D. The most common cause of death is uremia.

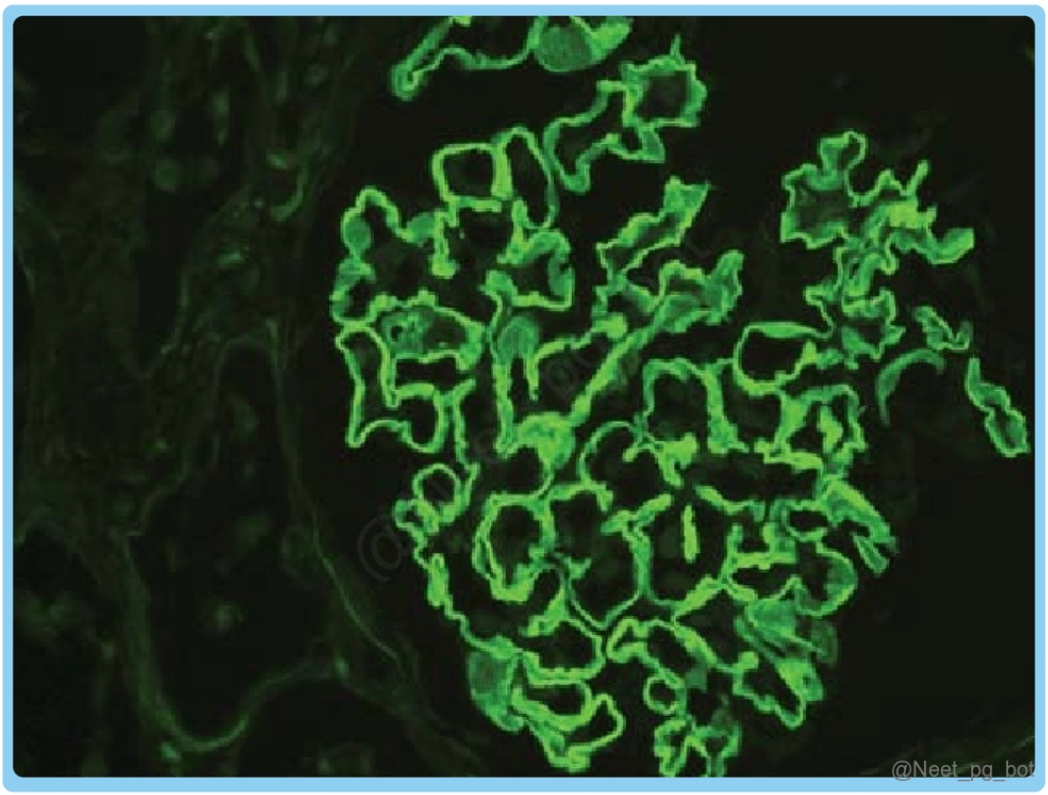


Correct Answer: A. It is a Type III hypersensitivity reaction

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Above mentioned scenario is a case of Goodpasture Syndrome It can be learnt as 1, 2, 3, 4 It is RPGN type 1 It is hypersensitivity type II and 4. Caused due to antibiotics against alpha 3 chain of type IV collagen. Immunofluorescence shows linear deposit of IgG and C3. (Picture below) Electron microscopy shows rupture and wrinkling of the basement membrane. Clinical Features: Lung involvement- haemoptysis, Renal involvement- haematuria. Most common cause of death: Uremia.



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 909

↑ *Back to this question in Part A*

@Neet_pg_bot

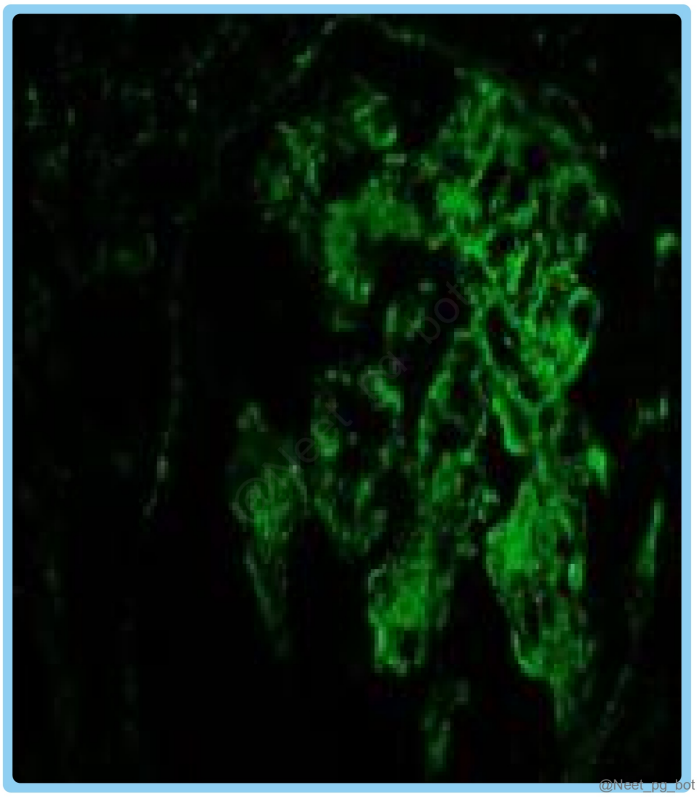
Q15: A 9-year-old boy presents with a recent sore throat, dark urine, fatigue, eye puffiness, and mild limb swelling. Urinalysis reveals hematuria, proteinuria, and red blood cell casts. Serum creatinine levels are slightly elevated. A renal biopsy shows the immunofluorescence image provided below. Which condition is not typically associated with this pattern of rapidly progressive glomerulonephritis? (Q846657)

A. Wegeners granulomatosis

B. Henoch-Schonlein purpura

C. Systemic lupus erythematosus

D. Ig A Nephropathy



Correct Answer: A. Wegeners granulomatosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario indicates post-streptococcal glomerulonephritis (PSGN), a Type 2 RPGN (Rapidly progressive glomerulonephritis) associated with granular immunofluorescence. Wegener's granulomatosis is Type 3 RPGN , characterised by pauci-immune glomerulonephritis with no immune deposits. Type I RPGN (Anti-GBM antibody-mediated) Type II RPGN (Immune complex-mediated) Type III RPGN (Pauci-immune) (M/C type) Includes: Idiopathic Goodpasture syndrome Includes: Idiopathic Postinfectious glomerulonephritis Lupus (SLE) nephritis Henoch-Schönlein purpura IgA nephropathy Includes: ANCA-associated Idiopathic Granulomatosis with polyangiitis (formerly Wegener granulomatosis) Microscopic polyangiitis IF finding: Linear/ribbon pattern (Linear GBM deposits of IgG and C3) IF finding: Lumpy Bumpy/ Granular/ Starry Sky/Garland Pattern (granular antibody deposits) IF finding: No deposits Electron microscopy: R PGN causes R upture and w R inkling of GBM

↑ *Back to this question in Part A*

@Neet_pg_bot

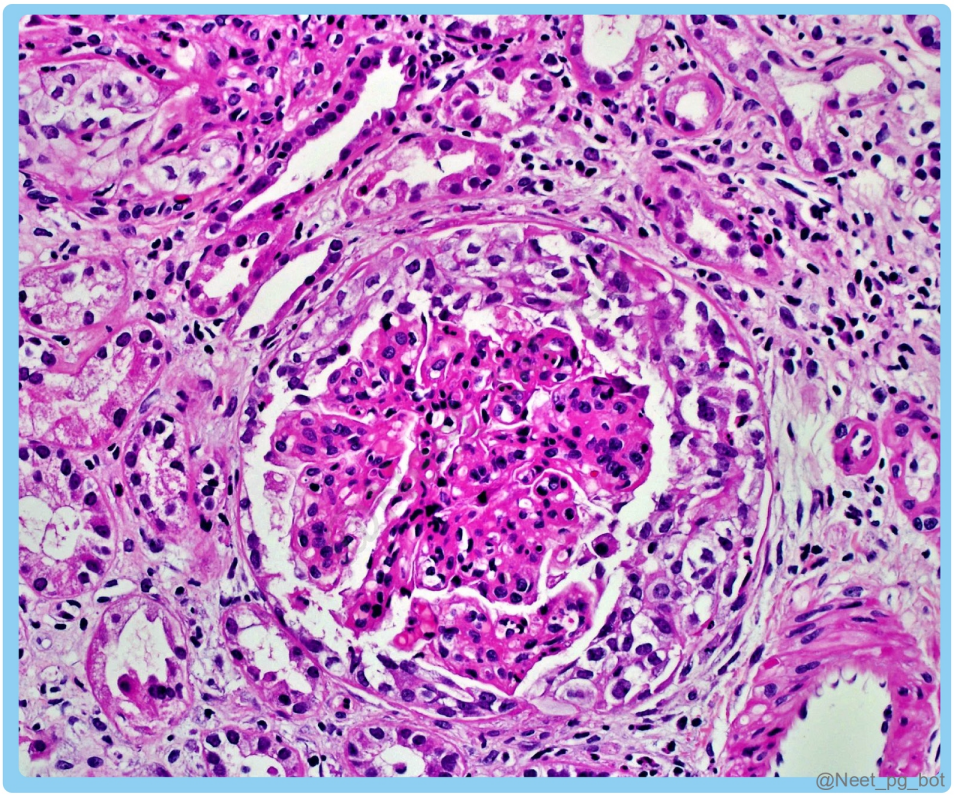
Q16: A 32-year-old woman with a history of SLE presents with fatigue, decreased urine output, and facial swelling. Lab tests show elevated serum creatinine, proteinuria, and hematuria. A renal biopsy is performed, and the histopathological examination image is attached. Which statement is true regarding this condition? (Q846656)

A. >50% of glomeruli showing crescents is diagnostic.

B. More the number of crescents, better the prognosis.

C. Crescents are composed solely of endothelial cells.

D. Primarily caused by bacterial infections.



Correct Answer: A. >50% of glomeruli showing crescents is diagnostic.

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The provided clinical scenario and the histopathological image suggest a Rapidly Progressive Glomerulonephritis (RPGN) diagnosis in a patient with systemic lupus erythematosus (SLE). Crescentic glomerulonephritis (or RPGN) is characterised by the presence of crescents in more than 50% of glomeruli on renal biopsy. More the number of crescents, the better the prognosis (Option B): In RPGN, more crescents generally indicate a poor prognosis Crescents are composed solely of endothelial cells (Option C) : Crescents are composed of fibrin, leucocytes, parietal and visceral layers of Bowman capsule. Primarily caused by bacterial infections (Option D) : RPGN Type I, II, III can be due to varied causes.

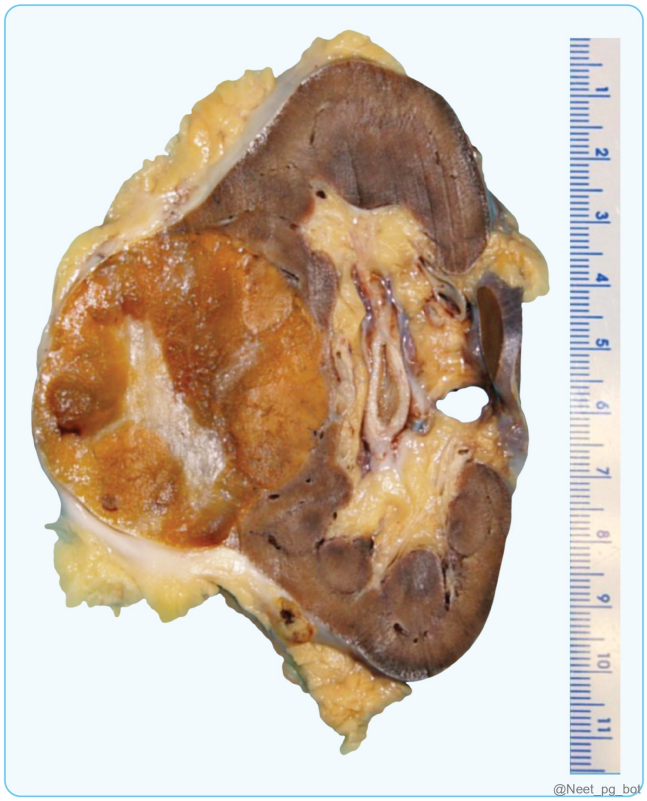
Q1: A 65-year-old diabetic male presented to the hospital complaining of chronic abdominal discomfort and unexplained weight loss over the past few months. A palpable firm mass was detected on the left upper quadrant upon physical examination. Ultrasound revealed a large mass in the left upper pole of the kidney. Due to suspicion of renal malignancy, the patient underwent a left nephrectomy. Based on the specimen obtained, what is the most likely diagnosis? {{caption_text}} (Q845695)

A. Renal oncocytoma

B. Epithelioid angiomyolipoma

C. Clear cell carcinoma

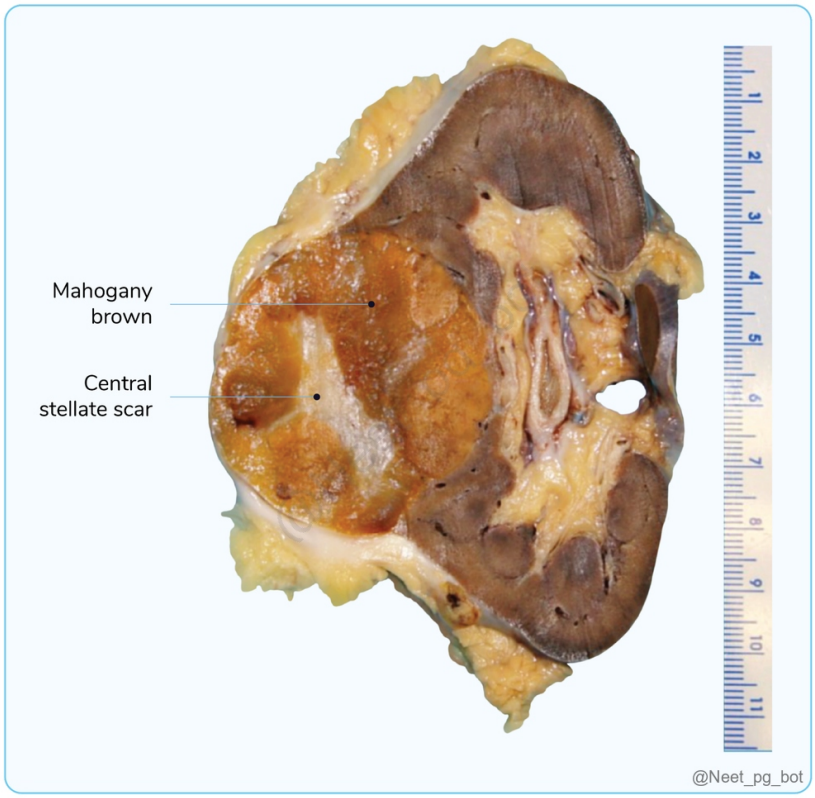
D. Urothelial carcinoma



Correct Answer: A. Renal oncocytoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Renal Oncocytoma: It is a benign tumor most commonly seen in > 50-year-old adults. It arises from the intercalated cells of the collecting ducts. Gross appearance: A well-circumscribed tumot which has classical tan or mahogany brown colour , with a central whitish scar called as Central stellate scar. Microscopy: Composed of dense, pink eosinophilic cells with small, round, benign-appearing nuclei. Electron microscope: Numerous mitochondria (granular appearance) Chromophobe RCC is a very close mimicker of renal oncocytoma because it also shows a central stellate scar. Chromophobe RCC shows classical plant cells, while Renal oncocytomas show benign-looking oncotic cells. {{caption_text}} {{caption_text}} {{caption_text}} Epithelioid angiomyolipoma (Option B) is a rare variant of angiomyolipoma composed of smooth muscle cells, fat, and blood vessels. Clear cell carcinoma (Option C) would typically present with more aggressive features like hematuria, anemia, and vascular invasion. This patient's presentation along with a well-circumscribed mass is more typical of a benign tumor. Urothelial carcinoma (Option D) is a bladder cancer and not a renal cancer.



Mahogany brown
Central stellate scar

Q2: A child presents with hematuria and fever for the past 4 months. On examination, a mass-like structure was felt at the right flank. Which of the following features is not associated with this condition? (Q845709)

A. Gonadal dysgenesis and renal failure

B. Cryptorchidism and absent iris

C. Bilateral malar and mandibular hypoplasia

D. Adrenal cytomegaly and macroglossia

Correct Answer: C. Bilateral malar and mandibular hypoplasia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical vignette of a child with fever, hematuria, and abdominal mass in the right flank is suggestive of Wilm’s tumour or nephroblastoma. Bilateral malar and mandibular hypoplasia are characteristic of Treacher-Collins syndrome (not Wilms tumour). Wilm's tumor is the most common pediatric renal tumor. Clinical triad of Wilm's tumor: Mass in the flank Hematuria Fever Syndromes associated with Wilm’s tumour are : Mutation Syndrome Features WT1 WAGR syndrome Wilms tumour. Aniridia (absent iris) (Option B) . Gonadal anomalies (like cryptorchidism) (Option B) . Intellectual disability. Denys-Drash syndrome Gonadal dysgenesis (male pseudohermaphroditism) (Option A) . Early-onset nephropathy (leading to renal failure) (Option A) . WT2 Beckwith-Widemann syndrome Organomegaly. Macroglossia (Option D) . Hemihypertrophy. Omphalocele. Abnormal large cells in the adrenal cortex (adrenal cytomegaly) (Option D) .

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 481

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A renal biopsy specimen has to be examined under microscopy for the presence of nephroblastoma. Presence of which of the following findings is less likely suggestive of the same? (Q845713)

A. Neuropils

B. Small blue cells

C. Adipose tissue

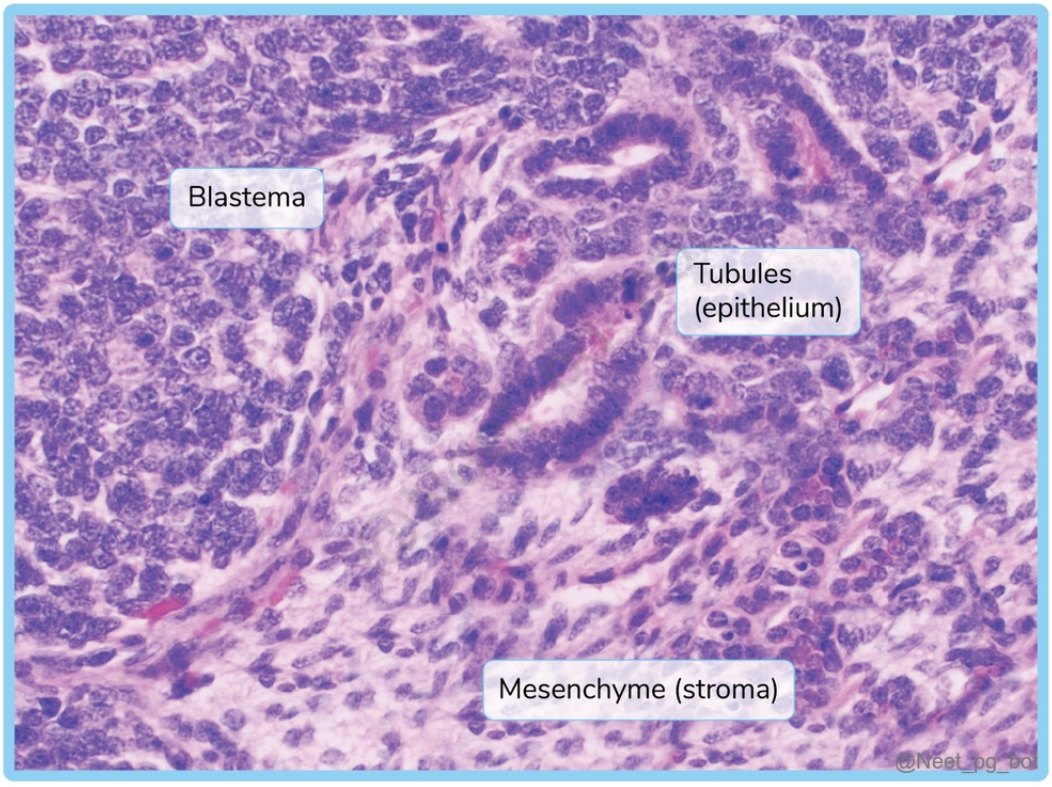
D. Myxoid stroma

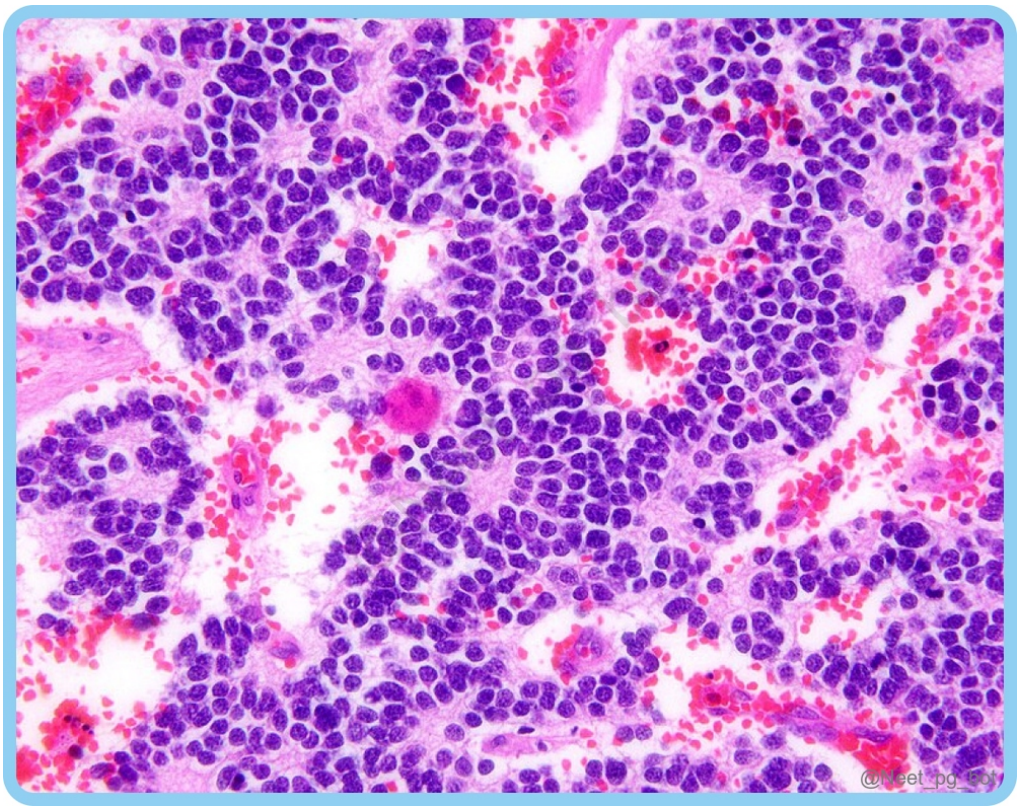
Correct Answer: A. Neuropils

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Neuropils are pinkish coloured eosinophilic fibrillary material surrounded by concentric groups of tumour cells (Homer-Wright pseudorosettes) commonly seen in brain tumors such as medulloblastoma. They are not seen in Wilm’s tumour/Nephroblastoma. Wilm's tumor is a triphasic tumor because it shows 3 things under the microscope: Epithelial: Cells like glomeruli or tubules. Mesenchymal: Adipose tissue and myxoid stroma are seen Blastemal: Blue cells Characteristics Wilms Tumor Neuroblastoma Location Kidney Most common abdominal tumor in childhood Common site: adrenal medulla, Also seen in abdomen, pelvis & neck. Most common primary renal tumor in childhood. Histological features Blastemal : Small blue cells. (Option B ruled out) Epithelial : Abortive tubules/glomeruli. Stromal : Fibroblastic or myxoid. (Option D ruled out) Small blue cells with neuroblasts, neurofibrils (neuropils) (Option A) , and mature ganglion cells Pseudo-rosettes (arrangements of small, round neuroblastic cells around a central fibrillary core) Histological image {{caption_text}} {{caption_text}}





References:

Robbins and Cotran, Pathologic Basis of Disease, 10 Edition, Page 482.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A histopathological report of renal biopsy done on a child states, “tumour cells suggestive of nephroblastoma along with adjacent sclerotic rests”. What is the risk associated with the presence of such sclerotic rests? (Q845744)

A. Presence of anaplasia

B. Pulmonary metastasis

C. Contralateral tumour

D. Associated lymphoma

Correct Answer: C. Contralateral tumour

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Nephrogenic rests if present along with Wilms tumours in the same kidney will indicate occurence of the tumor in same kidney previously also. Hence, It is important to document the presence of nephrogenic rests in the resected specimen because these patients are at an increased risk of developing Wilms tumours in the contralateral kidney and require frequent and regular surveillance for many years.

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 482

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following statements regarding renal cell carcinoma is false? (Q845745)

A. Clear cell RCC is the most common type overall.

B. Papillary RCC is most commonly associated with dialysis patients.

C. Medullary RCC is commonly seen in sickle cell trait patients.

D. Papillary RCC has the best prognosis.

Correct Answer: D. Papillary RCC has the best prognosis.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Clear cell RCC is the most common type overall and is associated with deletion of chromosome 3p, known as Von Hippel-Lindau (VHL) syndrome. (Option A) Papillary RCC is most commonly associated with dialysis patients. (Option B) It can also be associated with: Trisomy 7, trisomy 17 and loss of chromosome Y. Medullary RCC is commonly seen in sickle cell trait patients and in black patients. (Option C) Chromophobe RCC has the best prognosis. Bellini duct or collecting duct RCC has the worst prognosis. Renal cell carcinoma: Age group Most common in the 6th and 7th decades. Male: Female ratio 2:1 Site of origin Proximal convoluted tubule. Risk factors Cigarette smoking (most important). Obesity (particularly in women) and hypertension. Unopposed estrogen therapy. Exposure to asbestos, petroleum products, and heavy metals. End-stage renal disease. Chronic kidney disease. Acquired cystic disease. Tuberous sclerosis. Classification Sporadic: Most common type. Hereditary: Autosomal dominant, young age affected. Von-Hippel-Lindau syndrome. Hereditary leiomyomatosis & renal cell cancer syndrome. Hereditary papillary carcinoma. Birt-Hogg-Dube syndrome. Histological classification: Clear cell carcinoma (most common type) (Option A ruled out) . Papillary cell carcinoma (associated with dialysis patients) (Option B ruled out) . Chromophobe carcinoma (best prognosis) (Option D) . Bellini duct (collecting duct) carcinoma. Xp11 translocation carcinoma. Medullary carcinoma (seen in patients with sickle cell trait) (Option C ruled out) .

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 948-952

↑ *Back to this question in Part A*

@Neet_pg_bot

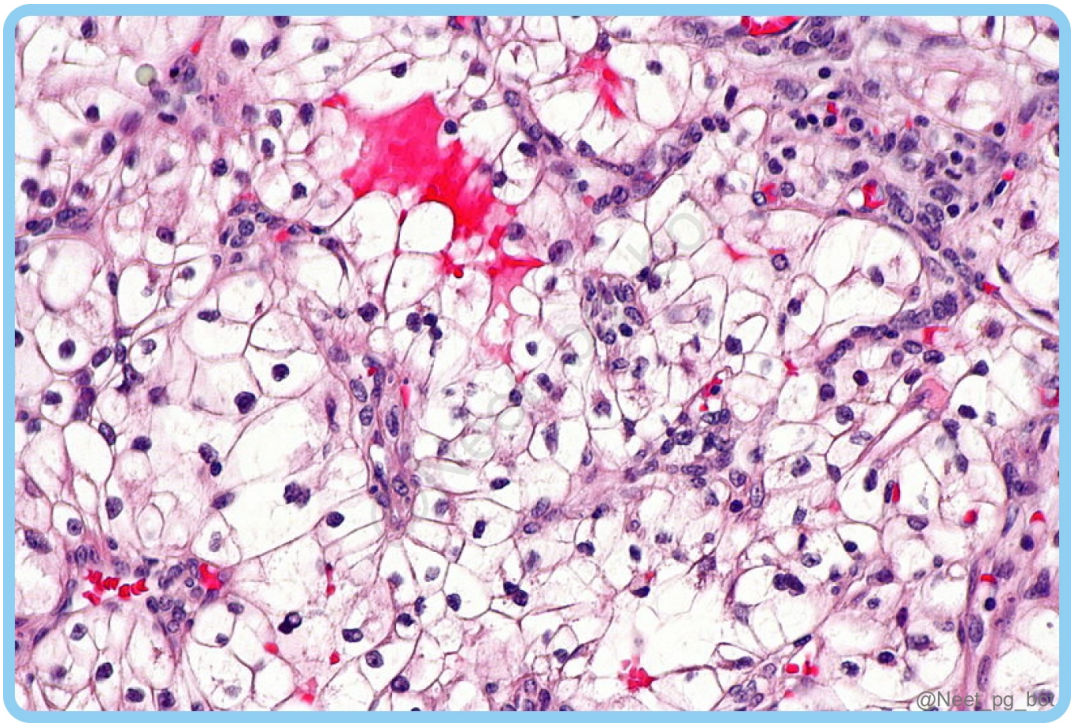
Q6: A 45-year-old female died within a few months after being diagnosed with renal cell carcinoma. The autopsy revealed a yellowish, spherical neoplasm in one pole of the kidney. The tumour cells invaded the renal vein and inferior vena cava. Histopathology is shown below. What is the most likely diagnosis? {{caption_text}} (Q845896)

A. Collecting duct RCC

B. Papillary RCC

C. Clear cell RCC

D. Chromophobe RCC



Correct Answer: C. Clear cell RCC

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario and the histopathology image is suggestive of Clear cell carcinoma Clear cell carcinoma: Classical clearing of cells is due to the accumulation of glycogen and lipids. It is a yellowish neoplasm due to prominent lipid accumulation. It is the most common renal cell carcinoma and is associated with the deletion of chromosome 3p which leads to Von Hippel-Lindau (VHL) syndrome

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 952

↑ *Back to this question in Part A*

@Neet_pg_bot

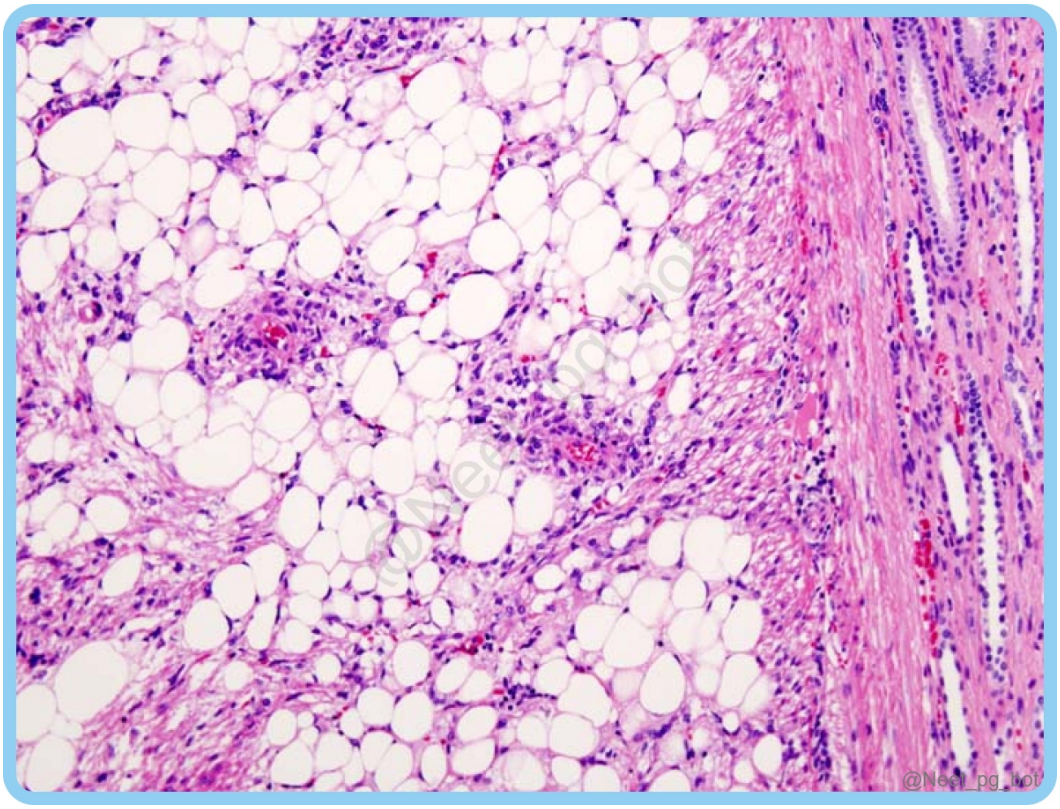
Q7: A 36-year-old woman presents with intermittent flank pain and occasional gross hematuria. Laboratory tests show normal renal function. A renal biopsy of a mass lesion reveals a mixture of mature adipose tissue, thick-walled blood vessels, and bundles of smooth muscle cells. All are true regarding this condition except: {{caption_text}} (Q846649)

A. Commonly associated with tuberous sclerosis

B. More prevalent in males than females

C. Mostly a benign tumor

D. High susceptibility to spontaneous hemorrhage



Correct Answer: B. More prevalent in males than females

Explanation: The history, findings and image point to a diagnosis of renal angiomyolipoma. Renal angiomyolipoma : Benign neoplasm consists of vessels, smooth muscle, and fat originating from perivascular epithelioid cells (Option C) . It is most often detected incidentally and has a female preponderance (Option B ruled out) . They are present in 25% to 50% of patients with tuberous sclerosis (Option A) . It has a high susceptibility for bleeding (can present as loin pain) (Option D) . Marker: HMB-45 positive Histology: Circular blood vessels, muscles, and fat; perivascular epithelioid cells with dense eosinophilic cytoplasm and mitotic figures.
{{caption_text}}

@Neet_pg_bot

Q8: Hobnail nuclei are seen in which type of renal cell carcinoma? (Q846650)

A. Clear cell renal cell carcinoma.

B. Papillary renal cell carcinoma.

C. Chromophobe renal cell carcinoma.

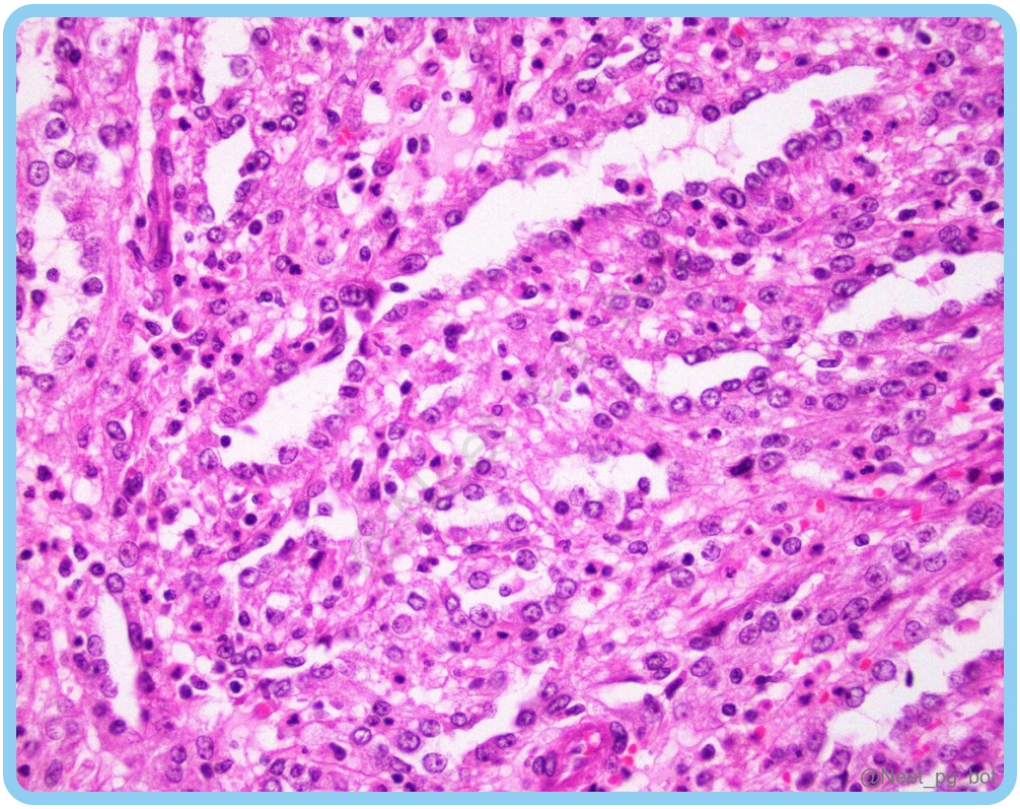
D. Collecting duct carcinoma.

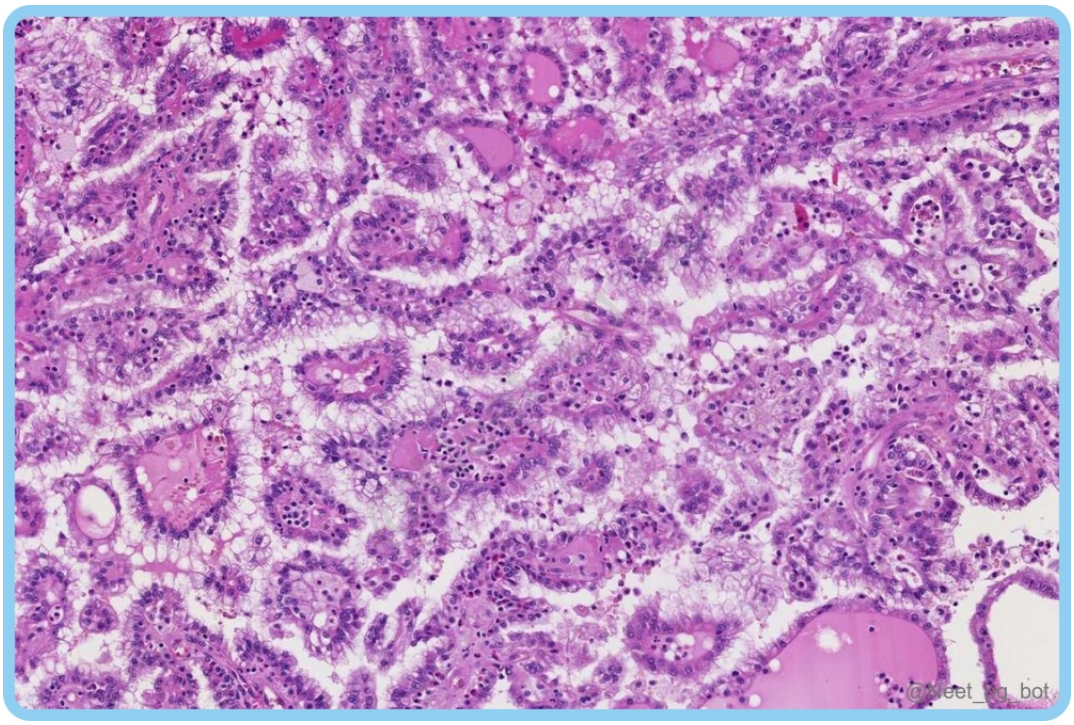
Correct Answer: D. Collecting duct carcinoma.

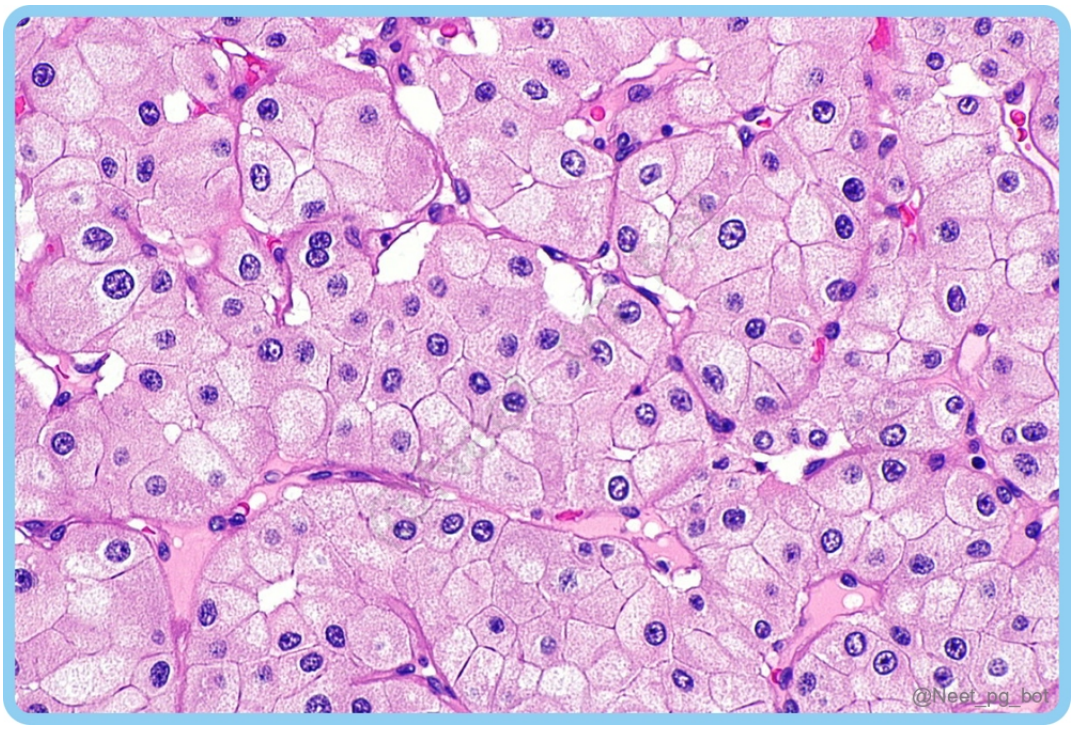
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hobnail nuclei are a characteristic feature of collecting duct carcinoma/ Bellini duct carcinoma. Hobnail nuclei: Nuclei are seen projecting out of the cell or into the lumen. It's the renal cell carcinoma with the worst prognosis. {{caption_text}} Clear cell renal cell carcinoma. (Option A): Shows white clear cells. Papillary renal cell carcinoma (Option B): Shows papillary projections along with psammoma bodies. {{caption_text}} Chromophobe renal carcinoma (Option C): Shows plant cells. {{caption_text}}







References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 952

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: On histological examination, which of the following types of renal cell carcinoma shows large cells with a plant-cell-like appearance with a perinuclear halo? (Q846651)

A. Papillary RCC

B. Clear cell RCC

C. Chromophobe RCC

D. Medullary RCC

Correct Answer: C. Chromophobe RCC

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Chromophobe renal cell carcinoma shows large cells having plant-cell-like appearance with a perinuclear halo. These are positive for Hale's Colloidal iron. Plant cells: Have a very well-defined outline and nucleus is shriveled like a raisin, known as raisinoid nucleus . A pernuclear halo is present around the nucleus. Special stain: Hale's Colloidal iron Among renal cell carcinomas, chromophobe renal cell carcinoma has the best prognosis. The histological image of chromophobe renal cell carcinoma:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 952

↑ *Back to this question in Part A*

Q10: Multiple losses of entire chromosomes are seen in which type of Renal Cell Carcinoma? (Q846652)

A. Papillary RCC

B. Clear cell RCC

C. Chromophobe RCC

D. Collecting duct RCC

Correct Answer: C. Chromophobe RCC

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Chromophobe RCC: Mnemonic: Chromo: Chromosome Phobe : Phobia There are multiple chromosome losses seen in chromophobe RCC. It is associated with Birt-Hogg-Dubé syndrome. Gross appearance: Shows a central stellate scar Microscopic appearance: Shows plant cells (Cells having very well-defined outlines, raisinoid nucleus and a perinuclear halo) Stain positive for RCC is Hale's colloidal iron . Among renal cell carcinomas, chromophobe renal cell carcinoma has the best prognosis. Subtypes of renal cell carcinoma: Type of RCC Causes Microscopy Features Clear Cell RCC (Option B) Associated with mutations in the VHL gene (von Hippel-Lindau syndrome) Cells with clear cytoplasm due to the accumulation of glycogen and lipids {{caption_text}} Papillary RCC (Option A) Associated with- MET gene mutations Hereditary Leiomyomatosis RCC Dialysis-related cystic disease Loss of Y Psammoma bodies may be present {{caption_text}} Chromophobe RCC Associated with Birt-Hogg-Dubé syndrome Loss of multiple chromosomes (Option C) (hypodiploidy) Cells with pale, eosinophilic cytoplasm, Perinuclear halos- Plant cells Hale’s colloidal iron +ve {{caption_text}} Collecting Duct (Bellini Duct) RCC Associated with mutations in multiple genes, including SMARCB1 Hobnail cells seen. Worst prognosis. {{caption_text}} Medullary RCC Strongly associated with sickle cell trait. Poorly differentiated cells {{caption_text}}

Q11: Which of the following statements regarding Wilms' tumour is incorrect? (Q889878)

A. It is associated with WAGR syndrome

B. Associated with triphasic morphology

C. The most common renal tumour in children

D. WT1 mutations are present in >80% of sporadic cases

Correct Answer: D. WT1 mutations are present in >80% of sporadic cases

Explanation: WT1 mutations occur in only ~10% of sporadic Wilms tumours, not the majority. Wilms Tumour (Nephroblastoma): The most common renal tumour in children (Option D) Peak: 2-5 years Cure rate ≈ 90% Associated syndromes: Syndrome Key Features Genetic Basis WAGR (Option A) W ilms, A niridia, G enitourinary anomalies, R etardation Germline deletion of 11p13 (WT1 & PAX6) Denys-Drash Gonadal dysgenesis, early-onset nephropathy Point mutation in WT1 (dominant-negative) Beckwith-Wiedemann

Organomegaly, macroglossia, hemihypertrophy 11p15.5 (WT2) ; IGF2 over-expressio Morphology (Triphasic) (Option B): Blastemal - small, round, blue cells Epithelial - abortive tubules/glomeruli Stromal - fibroblastic/myxoid ± skeletal muscle

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 437 - 439

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 4-year-old child undergoes nephrectomy for a Wilms tumour. Histology shows large hyperchromatic pleomorphic nuclei with abnormal mitotic figures. The tumour shows a poor response to preoperative chemotherapy. Which of the following best explains the chemotherapy resistance in this tumour? (Q889881)

A. Gain-of-function mutation in β-catenin

B. Loss of the WT1 tumour suppressor gene

C. Mutation of TP53 leading to defective apoptosis

D. IGF2 overexpression due to an imprinting abnormality

Correct Answer: C. Mutation of TP53 leading to defective apoptosis

Explanation: The histological description of large hyperchromatic pleomorphic nuclei with abnormal mitotic figures indicates anaplastic Wilms tumour , an uncommon but clinically important variant associated with poor prognosis and resistance to chemotherapy . Most cases of anaplastic Wilms tumour harbour mutations in the TP53 gene . The p53 protein normally acts as a tumour suppressor by inducing cell cycle arrest or apoptosis in response to DNA damage , including damage caused by cytotoxic chemotherapy. When TP53 is mutated , this apoptotic response is impaired, allowing tumour cells to survive despite chemotherapy , resulting in treatment resistance and a worse prognosis. Gain-of-function mutation in β-catenin (Option A): Mutations in the CTNNB1 gene (β-catenin) occur in a subset of Wilms tumours and contribute to tumour development through abnormal WNT signalling Loss of the WT1 tumour suppressor gene (Option B): WT1 mutations are involved in the initiation of Wilms tumour and are seen in conditions such as WAGR syndrome and Denys-Drash syndrome IGF2 overexpression due to an imprinting abnormality (Option D): IGF2 overexpression occurs in Beckwith-Wiedemann syndrome due to abnormalities at chromosome 11p15 , contributing to tumour growth

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 438

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 4-year-old child is diagnosed with Wilms tumour. Histology and genetic studies are reviewed to assess prognosis. Which of the following is not associated with poor prognosis in Wilms tumour? (Q889883)

A. Anaplastic histology

B. Loss of heterozygosity at chromosomes 1p and 16q

C. Gain of chromosome 1q

D. Triphasic histology

Correct Answer: D. Triphasic histology

Explanation: The classic triphasic histology of Wilms tumour consists of blastemal, epithelial, and stromal components . When this pattern occurs without anaplasia , it represents favourable histology , which is associated with a good response to therapy and an excellent prognosis . Most children with favourable histology Wilms tumour have survival rates approaching 90% or higher with modern treatment. In contrast, several histological and genetic features are associated with poor prognosis : Anaplastic histology (Option A): This is the most important adverse prognostic factor in Wilms tumour. Anaplasia is characterised by marked nuclear enlargement, hyperchromasia, and abnormal mitotic figures , and is often associated with TP53 mutations and chemotherapy

resistance . Loss of heterozygosity at chromosomes 1p and 16q (Option B): This genetic abnormality is associated with increased risk of relapse and poorer survival , and it is used in risk stratification in modern treatment protocols. Gain of chromosome 1q (Option C): Gain of 1q is one of the most common cytogenetic abnormalities in Wilms tumour and is also associated with higher relapse rates and worse outcomes .

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 439

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following most reliably differentiates renal papillary adenoma from papillary renal cell carcinoma? (Q889885)

A. Presence of papillary architecture

B. Low-grade nuclear features

C. Tumour size cut-off

D. Presence of psammoma bodies

Correct Answer: C. Tumour size cut-off

Explanation: The most reliable criterion used to distinguish renal papillary adenoma from papillary renal cell carcinoma (pRCC) is the maximum tumour size . According to the WHO classification , papillary renal tumours measuring ≤ 1.5 cm are classified as papillary adenomas , while lesions > 1.5 cm are considered papillary renal cell carcinomas . Histologically and cytogenetically, these lesions are often very similar, suggesting that papillary adenomas may represent precursor lesions of papillary RCC . Both papillary adenomas and papillary RCC show papillary architecture (Option A) Both may exhibit low-grade nuclear features (Option B) , so these characteristics cannot reliably distinguish the two. Similarly, psammoma bodies (Option D) may be present in papillary tumours but are not specific for carcinoma . Both papillary adenomas and papillary RCC frequently show similar cytogenetic abnormalities, particularly trisomy of chromosomes 7 and 17 and loss of the Y chromosome , further supporting their biological relationship. Papillary renal cell carcinoma is the second most common subtype of renal cell carcinoma , accounting for approximately 15-20% of RCC cases . Two major histologic patterns are recognised: Type 1: Papillae lined by a single layer of small basophilic cells with low-grade nuclei. Type 2: Larger eosinophilic cells with higher nuclear grade , generally associated with more aggressive behaviour and poorer prognosis.

@Neet_pg_bot

Q15: A 50-year-old man with recurrent pneumothorax and multiple facial fibrofolliculomas is found to have bilateral renal masses. Genetic testing reveals an FLCN mutation. Which renal cell carcinoma (RCC) is most commonly associated with the most probable condition? (Q889889)

A. Clear cell RCC

B. Papillary RCC

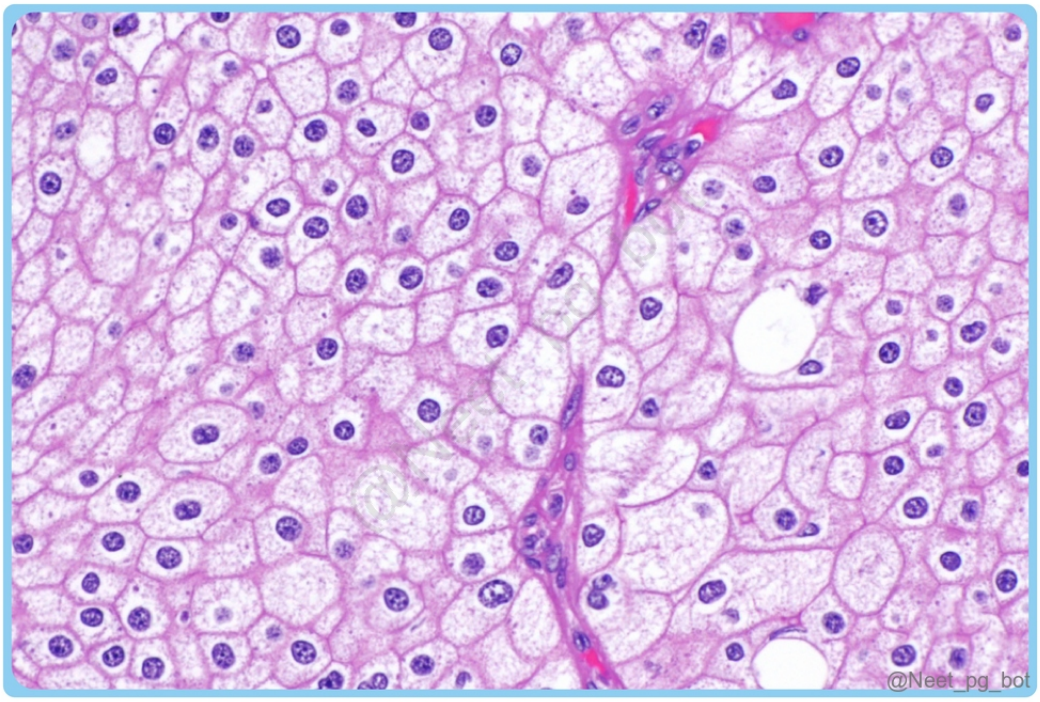
C. Chromophobe RCC

D. Collecting duct carcinoma

Correct Answer: C. Chromophobe RCC

Explanation: The clinical features described - recurrent pneumothorax, facial fibrofolliculomas, and renal tumours with an FLCN mutation are characteristic of Birt-Hogg-Dubé syndrome , an autosomal dominant disorder caused by mutations in the FLCN gene (folliculin) . This syndrome is associated with a characteristic triad: Skin lesions: fibrofolliculomas, trichodiscomas, and acrochordons Pulmonary manifestations: lung cysts and spontaneous

pneumothorax Renal tumours: most commonly chromophobe RCC and hybrid oncocytic/chromophobe tumours Chromophobe Renal Cell Carcinoma (ChRCC): Origin: Intercalated cells of the collecting duct Cytogenetics: Multiple chromosome losses (e.g., 1, 2, 6, 10, 13, 17, 21) Prognosis: Better than clear cell RCC Histology: Composed of pale eosinophilic cells Prominent perinuclear halo Arranged in solid sheets Tendency for larger cells to cluster around blood vessels Distinct cell borders → “plant cell-like” appearance Cytoplasm may show reticular clearing Clear cell renal cell carcinoma (Option A) : Most common sporadic RCC and classically associated with Von Hippel-Lindau disease , not Birt-Hogg-Dubé syndrome. Papillary renal cell carcinoma (Option B) : More commonly linked to Hereditary papillary renal carcinoma due to MET proto-oncogene mutations. Collecting duct carcinoma (Option D) : A rare, aggressive RCC subtype not characteristically associated with Birt-Hogg-Dubé syndrome.



References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 863

https://pmc.ncbi.nlm.nih.gov/articles/PMC6942440/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 13-year-old girl presents with painless hematuria. Imaging shows a renal mass. Biopsy reveals nested and tubulopapillary architecture. Immunostaining is positive for TFE3. What is the most likely diagnosis? (Q889892)

A. Clear cell renal cell carcinoma

B. Papillary renal cell carcinoma

C. Chromophobe renal cell carcinoma

D. Xp11 translocation renal cell carcinoma

Correct Answer: D. Xp11 translocation renal cell carcinoma

Explanation: The most likely diagnosis is Xp11 translocation renal cell carcinoma, because this subtype commonly occurs in children and young patients , shows nested, solid, or tubulopapillary architecture , and is defined by TFE3 gene rearrangements , leading to positive TFE3 immunostaining . Xp11 Translocation Renal Cell Carcinoma (TFE3-Rearranged RCC): Genetically distinct subtype of RCC characterised by TFE3 gene rearrangement . Common in children and young adults Genetics: Translocation involving TFE3 gene at Xp11.2 Fusion with various partner genes Leads to the overexpression of the TFE3 transcription factor Morphology: Variable (depends on fusion partner) Patterns include: Nested Solid Tubulopapillary Clear cell renal cell carcinoma (Option A) : Associated with VHL gene mutation and chromosome 3p deletion. It typically shows clear cytoplasm with rich vascularity and is more common in adults. Papillary renal cell carcinoma (Option B) : Commonly associated with trisomy 7 and 17 and MET mutations. Although papillary architecture may be present, it lacks TFE3 rearrangement and usually occurs in older adults. Chromophobe renal cell carcinoma (Option C) : Characterised by pale eosinophilic cells with perinuclear halos and multiple chromosome losses; not associated with TFE3 translocation.

Q1: A 48-year-old man presents with facial puffiness, frothy urine, hypertension, a history of hepatitis B infection, and microscopic hematuria. A kidney biopsy reveals a spike and dome pattern. What is the most likely diagnosis? (Q855413)

A. Minimal change disease

B. Membranous nephropathy

C. Focal segmental glomerulosclerosis

D. PSGN-associated disease

Correct Answer: B. Membranous nephropathy

Explanation: The combination of frothy urine, hypertension, and the biopsy finding points to the diagnosis of Membranous nephropathy, which is a common cause of nephrotic syndrome in adults. It is often associated with hepatitis B and is characterised by the spike and dome pattern on kidney biopsy due to subepithelial immune complex deposition (primarily IgG and C3) . Membranous Nephropathy: M/C cause of nephrotic syndrome in elderly patients. It is immune complex-mediated and can be caused by malignancy (colon, lung, melanoma), infections(malaria, hepatitis B, C, syphilis, schistosomiasis), drugs (gold, penicillamine), or autoimmune conditions (SLE). {{caption_text}} {{caption_text}} In primary membranous nephropathy, antibodies primarily target the M-type phospholipase A2 receptor (PLA2R) located on the basal surface of podocytes. This triggers complement activation and subepithelial immune complex deposition , resembling Heymann nephritis lesions. Other less common target antigens include THSD7A and neutral endopeptidase (CD10) . The presence of anti-PLA2R antibodies is crucial for diagnosing the disease. Pathology Light Microscope Electron Microscope Immunofluorescence Membranous Nephropathy Diffuse capillary wall thickening Subepithelial deposits Granular IgG and C3; diffuse

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 40-year-old man has been diagnosed with solid cancer of the bowel. He also experienced massive proteinuria a few months after the initial diagnosis of cancer. What do you think is the likely cause of the development of urinary findings? (Q859258)

A. Membranous nephropathy

B. Focal segmental glomerulosclerosis

C. Membranoproliferative glomerulonephritis

D. Dense deposit disease

Correct Answer: A. Membranous nephropathy

Explanation: Characteristic Features of Membranous Nephropathy Feature Description Primary Cause Autoantibodies against phospholipase A2 receptor (PLA2R) on podocytes (most common in idiopathic cases). Secondary Causes Autoimmune diseases (SLE), infections (Hepatitis B/C), drugs (NSAIDs, penicillamine), and malignancies (lung, breast, colon cancer). Nephrotic Syndrome Features Massive proteinuria (>3.5 g/day), hypoalbuminemia, oedema, hyperlipidemia, lipiduria. Risk of Thrombosis Renal vein thrombosis is a known complication. Light Microscopy Diffuse thickening of the glomerular basement membrane (GBM) without hypercellularity. Electron Microscopy (EM) Subepithelial immune deposits create a "spike and dome" appearance . Immunofluorescence Granular IgG and C3 deposits along the GBM. PLA2R Antibodies Specific for primary membranous nephropathy and helps differentiate from secondary causes. Treatment ACE inhibitors/ARBs (reduce proteinuria), steroids + immunosuppressants (cyclophosphamide, rituximab) for severe cases. Prognosis ■ spontaneous remission, ■ persistent proteinuria, ■ progress to ESRD. {{caption_text}} Focal segmental glomerulosclerosis (Option B) (FSGS) is characterised by scarring and sclerosis of the glomeruli. While FSGS can occur in the setting of cancer, it is not commonly associated with solid cancer of the bowel. Membranoproliferative glomerulonephritis (Option C) (MPGN) is characterised by the thickening of the glomerular basement membrane and the proliferation of cells within the glomeruli.MPGN is not associated with solid cancer of the bowel. Dense deposit disease (Option D) , also known as C3 glomerulopathy, is characterised by the abnormal accumulation of complement component C3 within the glomeruli.Dense deposit disease is not associated with solid cancer of the bowel.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Pages 912 to 914

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Effacement of podocyte foot processes is seen in which of the following diseases? (Q858521)

A. Steroid-resistant glomerulonephritis

B. Minimal change disease

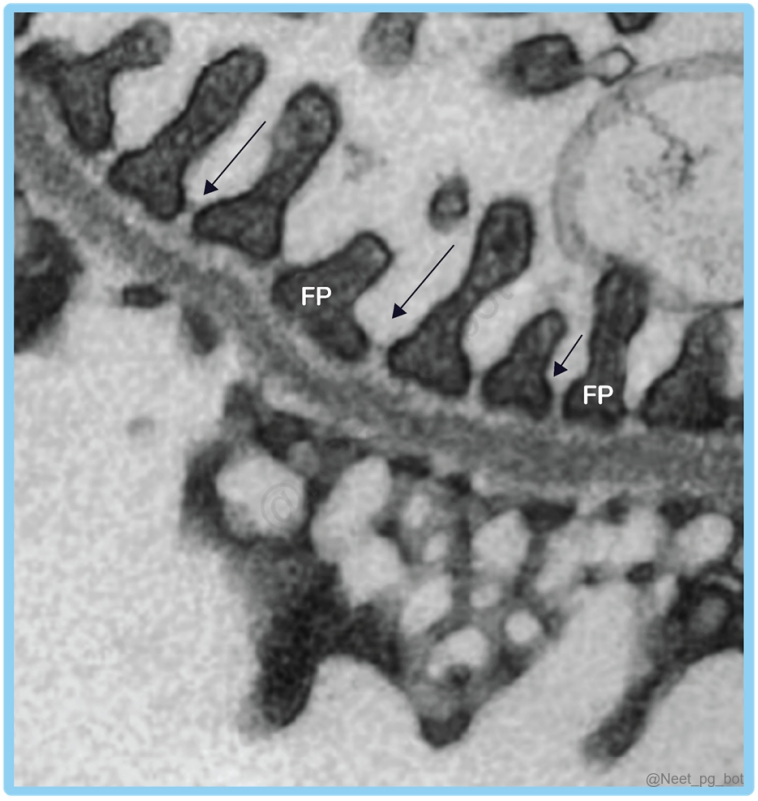
C. Rapidly progressive glomerulonephritis

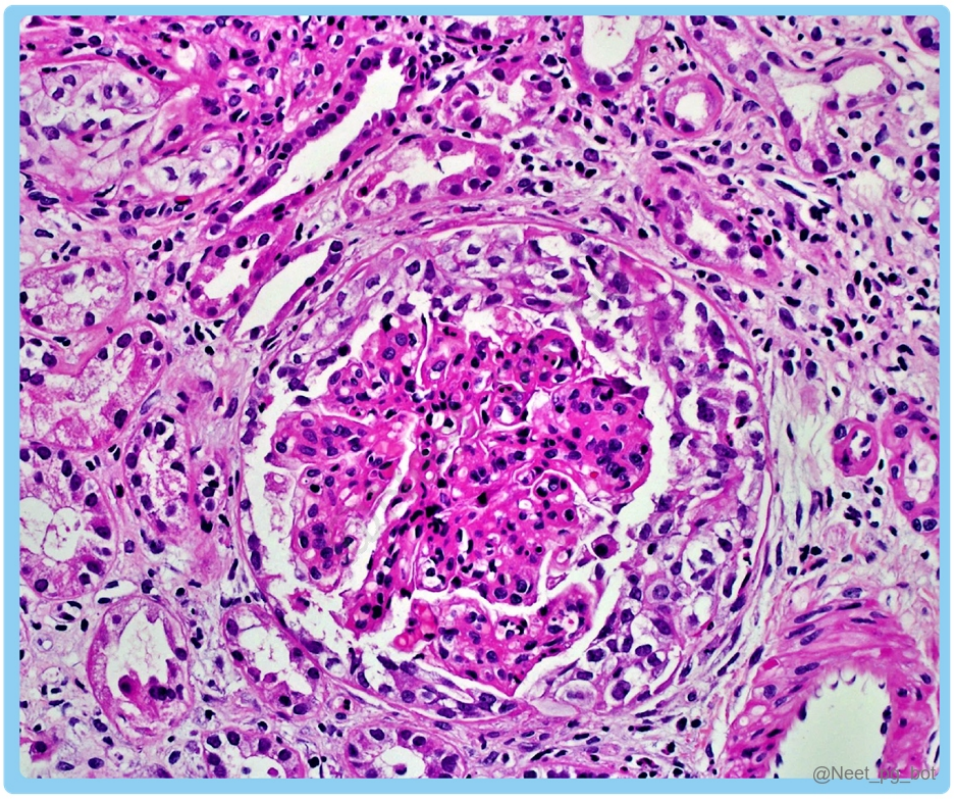
D. Chronic glomerulonephritis

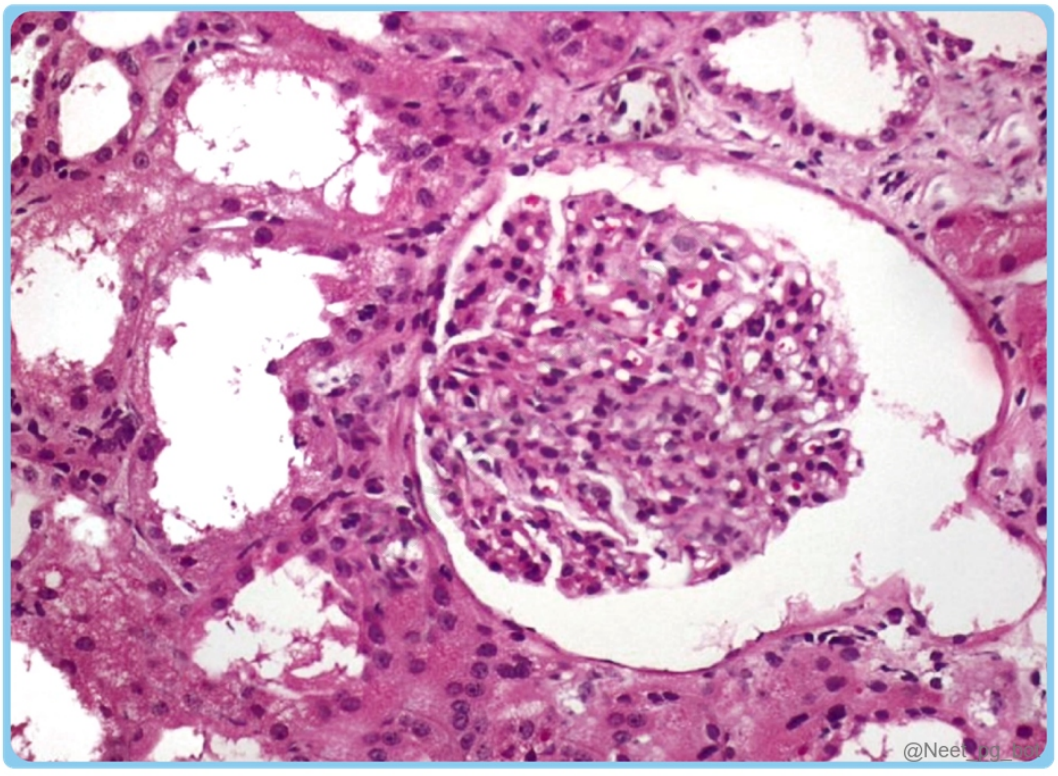
Correct Answer: B. Minimal change disease

Explanation: Effacement of podocyte foot processes refers to the flattening or loss of the foot processes of podocytes, specialized cells located in the kidney's glomerulus. This structural change is a hallmark of minimal change disease (also called minimal change nephrotic syndrome) . It presents with severe proteinuria, hypoalbuminemia, edema, and lipiduria. While the glomeruli appear normal under light microscopy, the characteristic finding of podocyte foot process effacement can only be observed under electron microscopy. It is

the most common cause of nephrotic syndrome in children (2-6 years) and responds well to corticosteroid therapy. {{caption_text}} Steroid-resistant glomerulonephritis (Option A) does not typically show effacement of podocyte foot processes. Instead, it may show more severe glomerular damage. Rapidly progressive glomerulonephritis (RPGN) (Option C) is marked by crescent formation in the glomeruli and is not typically associated with podocyte effacement. {{caption_text}} Chronic glomerulonephritis (Option D) is associated with sclerosis and fibrosis in the glomeruli, and effacement of podocyte foot processes is not a characteristic finding. {{caption_text}}







References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 911-920

↑ *Back to this question in Part A*

@Neet_pg_bot

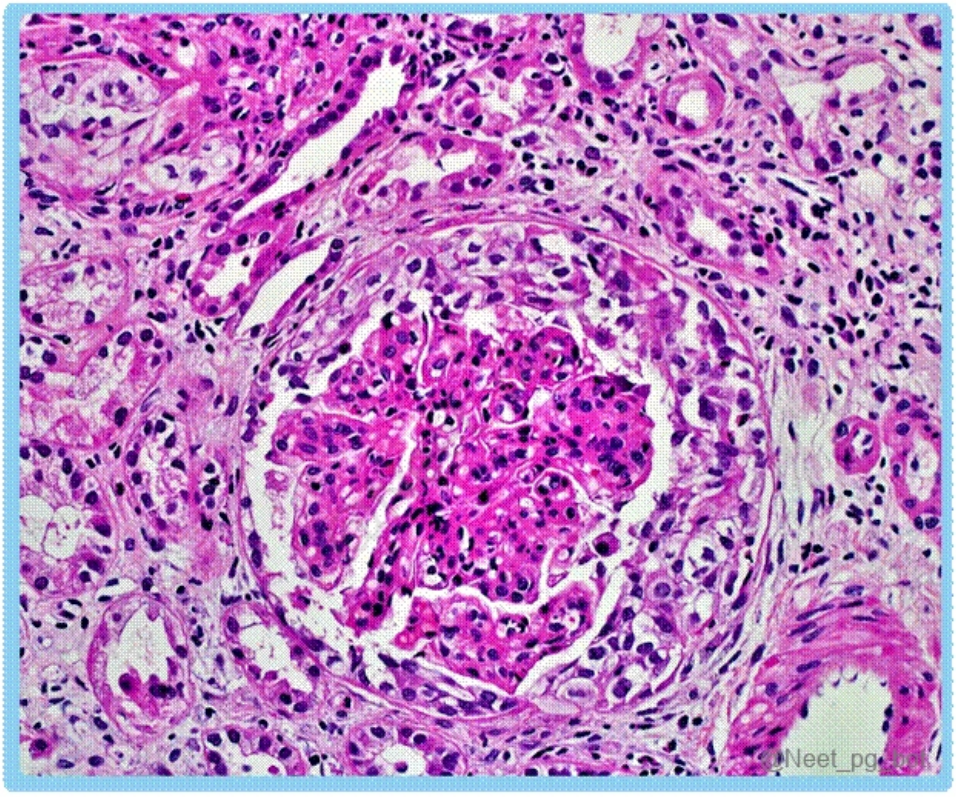
Q4: A 51-year-old male patient presents with complaints of hematuria. On examination, he is normotensive and has pedal edema. Investigations reveal that the patient has no glycosuria and a creatinine level of 9. His renal biopsy finding is given below. Which of the following investigations should be done to identify the disease? (Q854838)

A. ANA

B. Anti-GBM antibodies

C. HIV RNA

D. Urine immunoelectrophoresis



Correct Answer: B. Anti-GBM antibodies

Explanation: The presence of crescents on the renal biopsy & clinical presentation suggests rapidly progressive glomerulonephritis (RPGN) . This condition can be caused by an anti-glomerular basement membrane

(Anti-GBM) . Anti-GBM antibodies are used to confirm the diagnosis of Goodpasture syndrome , a form of RPGN. Rapidly progressive glomerulonephritis (RPGN): Type I RPGN (Anti-GBM Ab-mediated) Type II RPGN (Immune complex-mediated) Type III RPGN (Pauci-immune) (M/C type) Includes: Idiopathic Goodpasture syndrome Includes: Idiopathic Postinfectious glomerulonephritis Lupus (SLE) nephritis Henoch-Schönlein purpura IgA nephropathy Includes: ANCA-associated Idiopathic Granulomatosis with polyangiitis (formerly Wegener granulomatosis) Microscopic polyangiitis IF finding: Linear/ribbon pattern (Linear GBM deposits of IgG and C3) {{caption_text}} IF finding: Lumpy Bumpy/ Granular/ Starry Sky/Garland Pattern (granular antibody deposits) {{caption_text}} IF finding: No deposits Electron microscopy: R PGN causes R upture and w R inkling of GBM {{caption_text}} Antinuclear antibodies (ANA) (Option A) are typically associated with systemic autoimmune diseases such as SLE. While SLE can cause glomerulonephritis and affect the kidneys, the presence of crescents on the renal biopsy suggests a more acute and rapidly progressive disease, making SLE a less likely diagnosis in this case. HIV RNA (Option C): HIV infection can cause renal complications, including HIV-associated nephropathy, which is typically characterised by collapsing focal segmental glomerulosclerosis (FSGS) on renal biopsy. However, the patient’s presentation with hematuria, pedal oedema, and crescent formation on the renal biopsy makes Goodpasture syndrome (anti-GBM disease) a more likely diagnosis than HIV-associated nephropathy in this case. Urine immunoelectrophoresis (Option D) detects monoclonal immunoglobulins in conditions like multiple myeloma and amyloidosis. However, the biopsy findings suggest Goodpasture syndrome, which is better diagnosed with tests such as anti-GBM antibodies.

@Neet_pg_bot

Q5: Membranoproliferative glomerulonephritis is seen in which of the following conditions? HIV SLE CLL Hepatitis B (Q856912)

A. 1, 2, 3

B. 1, 2, 3, 4

C. 2, 3, 4

D. 1, 2

Correct Answer: B. 1, 2, 3, 4

Explanation: Membranoproliferative glomerulonephritis can be associated with human immunodeficiency virus (HIV), systemic lupus erythematosus (SLE), chronic lymphocytic leukaemia (CLL), and hepatitis B virus (HBV). Causes of MPGN: Primary MPGN: Idiopathic Secondary Membranoproliferative Glomerulonephritis (MPGN) (typically type I) is more common in adults and occurs in the following conditions: Chronic immune complex disorders, including SLE, hepatitis B and C infections (especially with cryoglobulinemia), endocarditis, infected ventriculoatrial shunts, chronic visceral abscesses, HIV infection , and schistosomiasis. α1-Antitrypsin deficiency. Malignant diseases, particularly lymphoid tumours, like chronic lymphocytic leukaemia . Pathology Light Microscope Electron Microscope Immunofluorescence Type I MPGN Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening and Splitting. (Double-contour or tram track appearance). {{caption_text}} Subendothelial and mesangial deposits. {{caption_text}} IgG ++ C3 (C1q ++ C4 may also present) Type II MPGN (Dense Deposit Disease) Dense intramembranous deposits. C3; no C1q or C4 Membranous Nephropathy Diffuse capillary wall thickening. {{caption_text}} Subepithelial deposits. {{caption_text}} Granular IgG and C3; diffuse Focal Segmental Glomerulosclerosis (FSGS) Focal and segmental sclerosis and hyalinosis. {{caption_text}} Effacement of foot processes; epithelial denudation. Q6: What type of urinary casts would you expect in a patient diagnosed with Fabry's disease? (Q856895)

A. Waxy cast

B. RBC cast

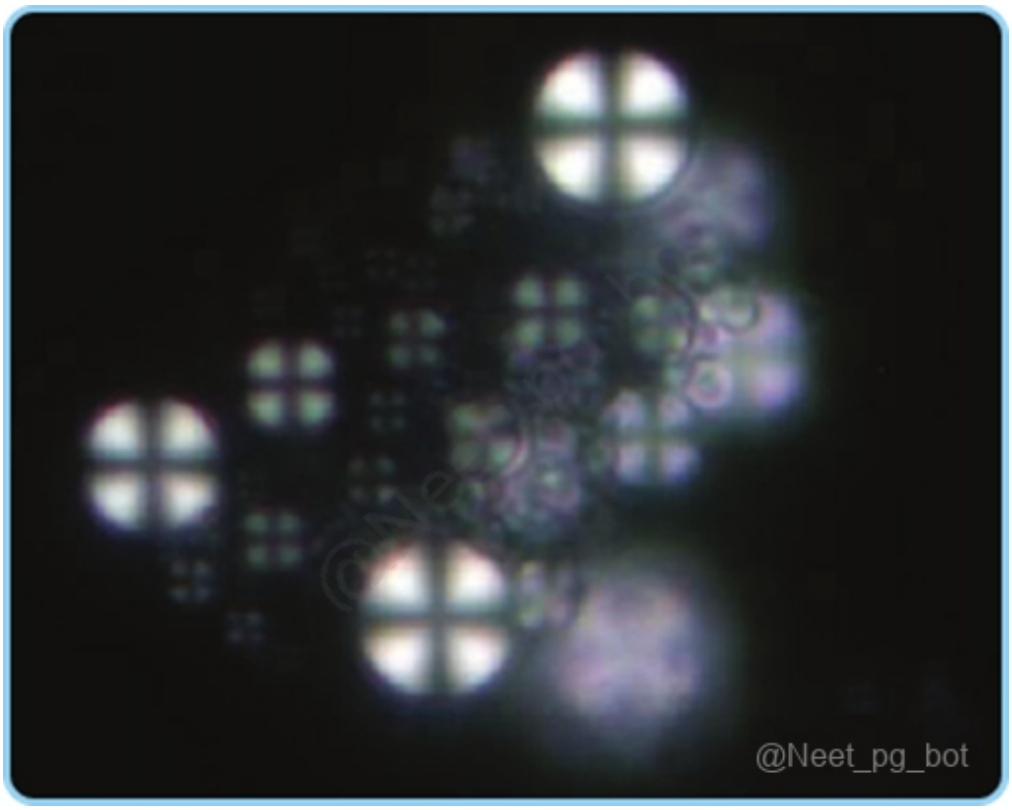
C. WBC cast

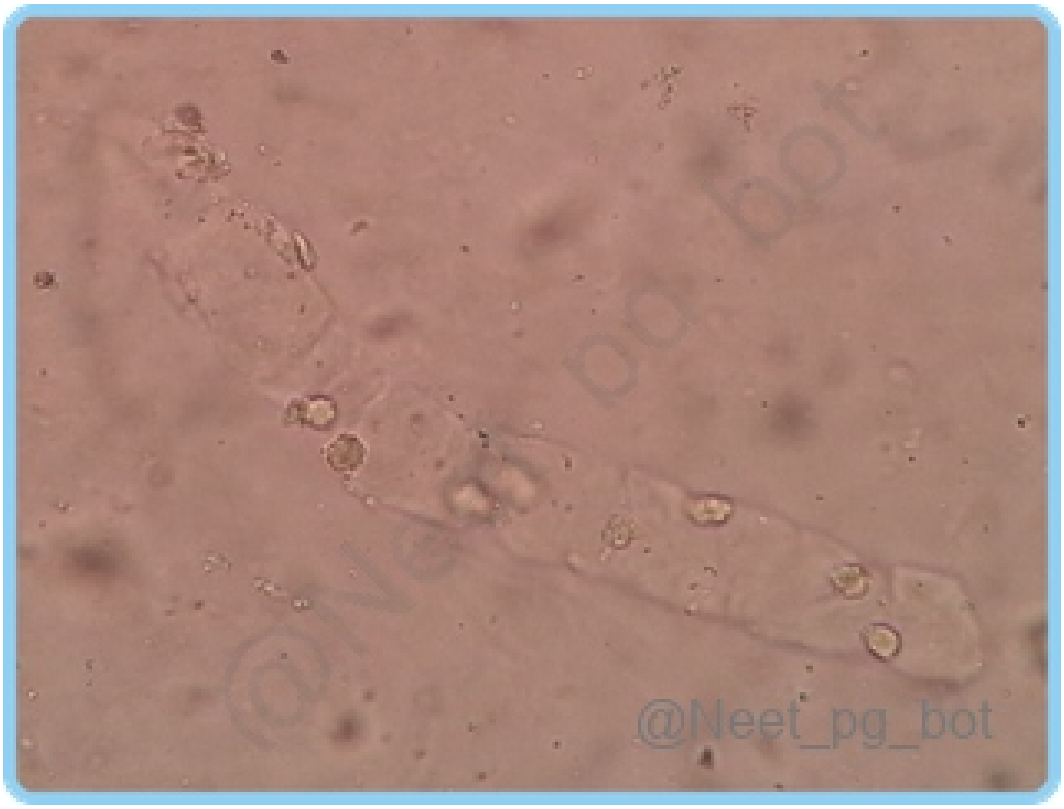
D. Maltese cross cast

Correct Answer: D. Maltese cross cast

Explanation: Fabry's disease is a rare genetic disorder caused by alpha-galactosidase A deficiency , leading to globotriaosylceramide (Gb3) accumulation in tissues, including the kidneys. {{caption_text}} A characteristic finding in the urinalysis of patients with Fabry's disease is the presence of Maltese cross casts, also referred to as "corneal-shaped" or "glycolipid" casts. These casts form when Gb3 precipitates within the renal tubules and appear as refractile, yellowish-brown structures with a cross-like pattern when observed under polarized light. Renal Cast

Type Condition Associated Images Hyaline casts Normal conditions, Fever, Pregnancy {{caption_text}} Muddy Brown casts Acute tubular necrosis {{caption_text}} Waxy casts Chronic renal failure {{caption_text}} Fatty casts Nephrotic syndrome {{caption_text}} RBC casts Glomerulonephritis {{caption_text}} WBC casts Pyelonephritis, interstitial nephritis {{caption_text}} Epithelial casts Renal epithelial injury {{caption_text}} Broad casts Chronic renal disease {{caption_text}}





@Neet_pg_bot

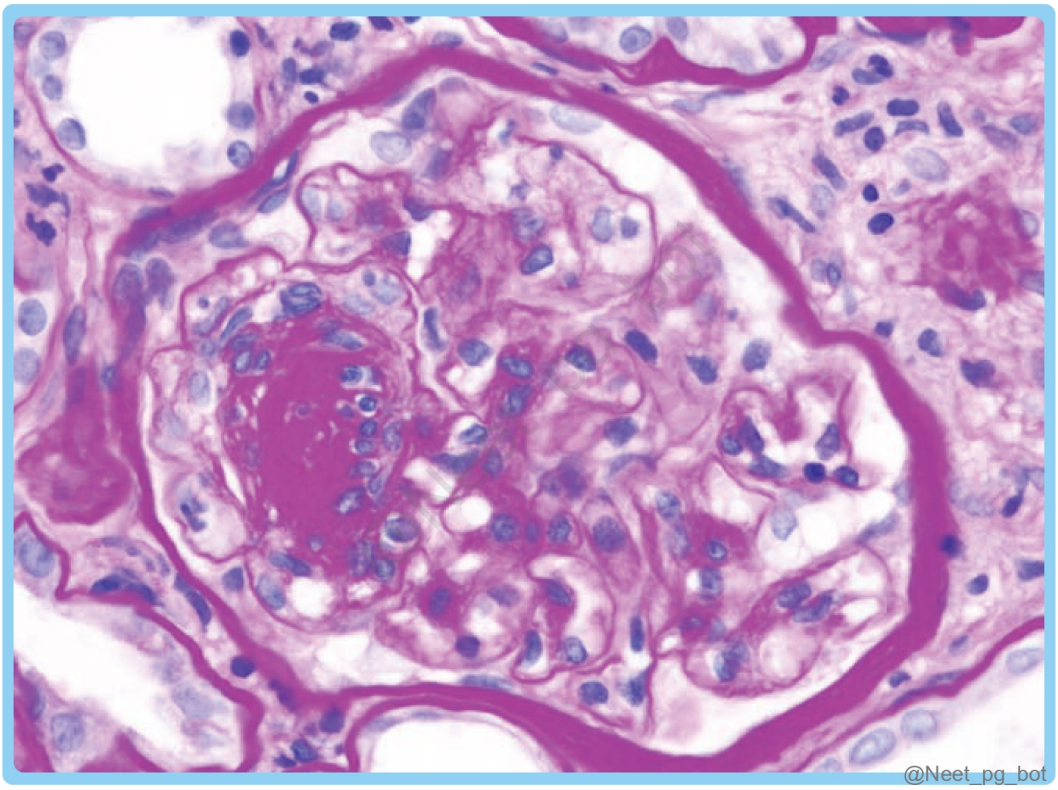
Q7: What is the most characteristic feature of diabetic nephropathy, as shown below? {{caption_text}} (Q857168)

A. Kimmelstiel Wilson nodules

B. Armanni Ebstein change

C. Aschoff nodule

D. Anitschkow cell



Correct Answer: A. Kimmelstiel Wilson nodules

Explanation: Kimmelstiel-Wilson nodules (aka Nodular glomerulosclerosis) are a hallmark of diabetic nephropathy. They are ovoid or spherical , PAS-positive nodules found in the mesangial core of glomeruli. They are often accompanied by mesangiolysis and sometimes surrounded by dilated capillary loops. {{caption_text}} {{caption_text}} Armanni Ebstein change (Option B) refers to glycogen accumulation in renal tubular epithelial cells, seen in severe or poorly controlled diabetes, but it is not specific to diabetic nephropathy. Aschoff nodule (Option C) is a histological hallmark of rheumatic fever, typically found in the myocardium. Anitschkow cell

(Option D) is a macrophage with a characteristic caterpillar-like nucleus, seen in rheumatic fever, not diabetic nephropathy.

@Neet_pg_bot

Q8: Which of the following statements is/are true regarding clear cell carcinoma of the kidney? Most common primary renal malignancy Associated with the loss of the short arm of chromosome 3 Not associated with paraneoplastic syndrome The classic triad of flank pain, palpable mass, and hematuria is seen. (Q855070)

A. 1, 2, 4

B. 2, 3

C. 1, 3

D. 1, 4

Correct Answer: A. 1, 2, 4

Explanation: Clear cell carcinoma is associated with paraneoplastic syndromes, including hypercalcemia, erythrocytosis, and hypertension. Clear cell carcinoma: Prevalence : Accounts for 70% to 80% of renal cell cancers. (Most common) Tumour Characteristics : Composed of cells with clear or granular cytoplasm and a nonpapillary pattern. Familial vs. Sporadic : Primarily sporadic (95%), but can also be familial. Genetic Alterations : Loss of sequences on the short arm of chromosome 3 in 98% of cases. The VHL gene, located in this region, is a key tumour suppressor gene. Classic triad of flank pain, palpable mass, and hematuria is commonly observed in kidney tumours, although it may not be present in all cases. Morphology: Origin : Arises from proximal tubular epithelium. Gross Appearance : Bright yellow-gray-white spherical masses. Yellow colour due to lipid accumulation in tumour cells. It may have areas of necrosis, haemorrhage, and cystic regions. Histopathology: {{caption_text}} Most tumours are well-differentiated & some may show nuclear atypia, bizarre nuclei, and giant cells. The growth pattern varies from solid to trabecular (cordlike) or tubular (resembling tubules). The tumour cells have a rounded or polygonal shape and abundant clear or granular cytoplasm containing glycogen and lipids. The tumours have delicate branching vasculature and may show cystic and solid areas.

https://pubmed.ncbi.nlm.nih.gov/8946620/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Tamm-Horsfall protein is a major component of which of the following? (Q858118)

A. Mural thrombi

B. Curschmann spirals

C. Renal casts

D. Bence-Jones proteins

Correct Answer: C. Renal casts

Explanation: Tamm-Horsfall protein, produced in the ascending limb of the loop of Henle, is the most abundant protein in normal urine and serves as a marker of tubular function. It plays a key role in preventing urinary tract infections and is the primary component of hyaline casts, the most common type of urinary casts. Incorrect

Options: Mural thrombi (Option A) are blood clots that stick to the walls of blood vessels or the heart. They are not related to the Tamm-Horsfall protein , which is specific to renal tubular function and not involved in thrombus formation. Curschmann spirals (Option B) are mucus plugs found in the sputum of patients with asthma or other obstructive pulmonary diseases. Bence-Jones proteins (Option D) are free immunoglobulin light chains found in urine and are linked to multiple myeloma. Unlike the Tamm-Horsfall protein, which is a normal renal protein involved in renal casts, Bence-Jones proteins are abnormal products resulting from plasma cell malignancies.

References:

Harrison's Principles of Internal Medicine, 21st Edition, Volume I, Page 2304. 686

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A patient with renal disease undergoes a biopsy. On Congo red staining, the deposits show apple-green birefringence under polarised light. What is the most likely diagnosis? (Q866678)

A. Amyloidosis

B. Minimal change disease

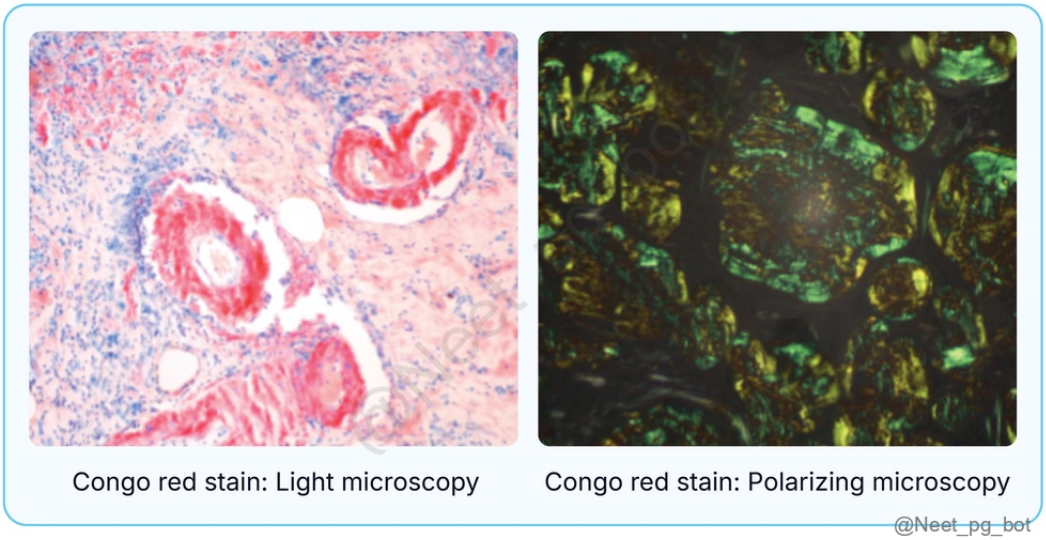
C. Diabetic nephropathy

D. Membranous nephropathy

Correct Answer: A. Amyloidosis

Explanation: The clinical presentation of a patient with renal disease undergoing a biopsy and on Congo red staining, the deposits showing apple-green birefringence under polarized light points towards a diagnosis of AA amyloidosis , where chronic inflammation leads to the production of SAA , resulting in amyloid deposition in various organs. The most appropriate staining technique for confirming the diagnosis in this patient is by Congo red stain. Investigations in amyloidosis: The diagnosis depends on the histologic demonstration of amyloid deposits in tissues. The most common sites biopsied are the kidney when renal manifestations are present or rectal or gingival tissues in patients suspected of having systemic amyloidosis. Examination of abdominal fat aspirates stained with Congo red can also be used for the diagnosis of systemic amyloidosis. Staining: Stains/technique Appearance Congo red Most widely used and specific. Light microscopy: Salmon pink/red stains. Polarizing microscopy: Apple-green birefringence. H & E Eosin & hematoxylin staining on light microscopy. Amorphous , eosinophilic , extracellular substance. Thioflavin T Fluorescent stain. Yellow color under UV light. Electron microscopy Non-branching fibrils of indefinite length. Diameter: 7.5-10 nm. X-ray crystallography & infrared spectroscopy Cross-β-pleated sheet conformation. Methyl violet Crystal violet PAS Amyloid positive. Abdominal fat aspiration is preferred over rectal biopsy. In suspected cases of AL amyloidosis, serum and urine protein electrophoresis and immunoelectrophoresis should be performed. Bone marrow aspirates in such cases often show monoclonal plasmacytosis , even in the absence of overt multiple myeloma. Scintigraphy with radiolabeled serum amyloid P component is a rapid and specific test since it binds to the amyloid deposits and reveals their presence.

It also gives a measure of the extent of amyloidosis and can be used to follow patients undergoing treatment. The given images below show Congo red staining in amyloidosis. Incorrect Options: Minimal change disease (Option B): normal light microscopy; EM shows foot process effacement; Congo red negative. Diabetic nephropathy (Option C): nodular glomerulosclerosis (Kimmelstiel–Wilson lesions); no Congo red positivity. Membranous nephropathy (Option D): thickened GBM and subepithelial immune deposits; Congo red negative.



Congo red stain: Light microscopy

Congo red stain: Polarizing microscopy

@Neet_pg_bot

Q11: Which of the following will increase in size on electrophoresis in Nephrotic syndrome? (Q854702)

A. Gamma globulin

B. Alpha 2 globulin

C. Beta globulin

D. Albumin

Correct Answer: B. Alpha 2 globulin

Explanation: Nephrotic syndrome is characterized by proteinuria , hypoalbuminemia , edema , and hyperlipidemia, and the electrophoresis shows decreased albumin levels and increased levels of alpha-2 globulin. The increase in alpha-2 globulin is due to an increase in macroglobulin, which is a larger protein , and its increase in the

bloodstream serves as a compensatory mechanism in nephrotic syndrome to counteract the loss of albumin . Gamma globulin (Option A) does not increase significantly . An increase in gamma globulins is seen in conditions like multiple myeloma or chronic inflammatory conditions , not in nephrotic syndrome. Beta globulin (Option C) increases, but this increase is typically modest compared to the marked rise in alpha-2 globulins . Albumin (Option D) is the major protein that decreases in size on electrophoresis in nephrotic syndrome due to its significant loss in the urine, leading to hypoalbuminemia .

@Neet_pg_bot

Q12: A 47-year-old male with 400 ml urine output per 24 hrs. On histology, he had RPGN with Pauci immune glomerulonephritis with crescents. What is the main etiology? (Q854698)

A. Anti GBM

B. ANCA

C. Anti PLA2R

D. ANA

Correct Answer: B. ANCA

Explanation: The clinical presentation of RPGN with pauci-immune glomerulonephritis and crescents on histology strongly suggests an ANCA-associated vasculitis . Pauci-immune means that there are few immune complexes present in the glomeruli, which is typical of ANCA-associated vasculitis. ANCA are commonly associated with granulomatosis with polyangiitis (Wegener's) , microscopic polyangiitis , and Churg-Strauss syndrome , which can lead to pauci-immune RPGN . Type I RPGN (Anti-GBM antibody-mediated) Type II RPGN (Immune complex-mediated) Type III RPGN (Pauci-immune) (M/C type) Includes: Idiopathic Goodpasture syndrome- the presence of Anti GBM. (Option A ruled out) Includes: Idiopathic Postinfectious glomerulonephritis Lupus (SLE) nephritis - ANA positive (Option D ruled out) Henoch-Schönlein purpura IgA nephropathy Includes: ANCA-associated Idiopathic Granulomatosis with polyangiitis (formerly Wegener granulomatosis) Microscopic polyangiitis IF finding: Linear/ribbon pattern (Linear GBM deposits of IgG and C3) {{caption_text}} IF finding: Lumpy Bumpy/ Granular/ Starry Sky/Garland Pattern (granular antibody deposits) {{caption_text}} IF finding: No deposits Electron microscopy: R PGN causes R upture and w R inkling of GBM {{caption_text}} Anti PLA2R (Option C) antibody is primarily associated with membranous nephropathy, which presents with nephrotic syndrome, not RPGN. The histological findings do not align with membranous nephropathy , which typically shows thickening of the glomerular basement membrane without hypercellularity on light microscopy and a "spike and dome" appearance of subepithelial deposits on electron microscopy. glomerulonephritis in an infant. Saudi journal of kidney diseases and transplantation : an official publication of the Saudi Center for Organ Transplantation, Saudi Arabia. 24. 546-8. 10.4103/1319-2442.111061. @Neet_pg_bot

Q13: What is the most likely diagnosis for a 9-year-old boy who presents with hematuria, hypertension, facial puffiness for 3 days, and a recent history of throat infection two weeks ago, with urine examination showing albumin positivity? (Q830713)

A. Group B beta-hemolytic streptococci

B. Staphylococcus aureus

C. Group A beta-hemolytic streptococci

D. Staphylococcus epidermidis

Correct Answer: C. Group A beta-hemolytic streptococci

Explanation: Correct Option C - Group A beta-hemolytic streptococci: This is the correct option. Group A streptococci, particularly Streptococcus pyogenes, are known to cause post-streptococcal glomerulonephritis, which can manifest with symptoms like hematuria, hypertension, and facial puffiness following a throat infection. It's a classic scenario for post-streptococcal glomerulonephritis(PSGN). Incorrect Options: Option A - Group B beta-hemolytic streptococci: While Group B streptococci are associated with various infections, including neonatal sepsis and meningitis, they are not typically linked to post-streptococcal glomerulonephritis, which is a more common presentation in the scenario described. Option B - Staphylococcus aureus: Staphylococcus aureus is a bacterium responsible for various infections, such as skin and soft tissue infections, but it is not a common cause of post-streptococcal glomerulonephritis. Option D - Staphylococcus epidermidis: Staphylococcus epidermidis is a bacterium commonly associated with medical device-related infections and biofilm formation. It is not typically linked to post-streptococcal glomerulonephritis.

↑ *Back to this question in Part A*

@Neet_pg_bot

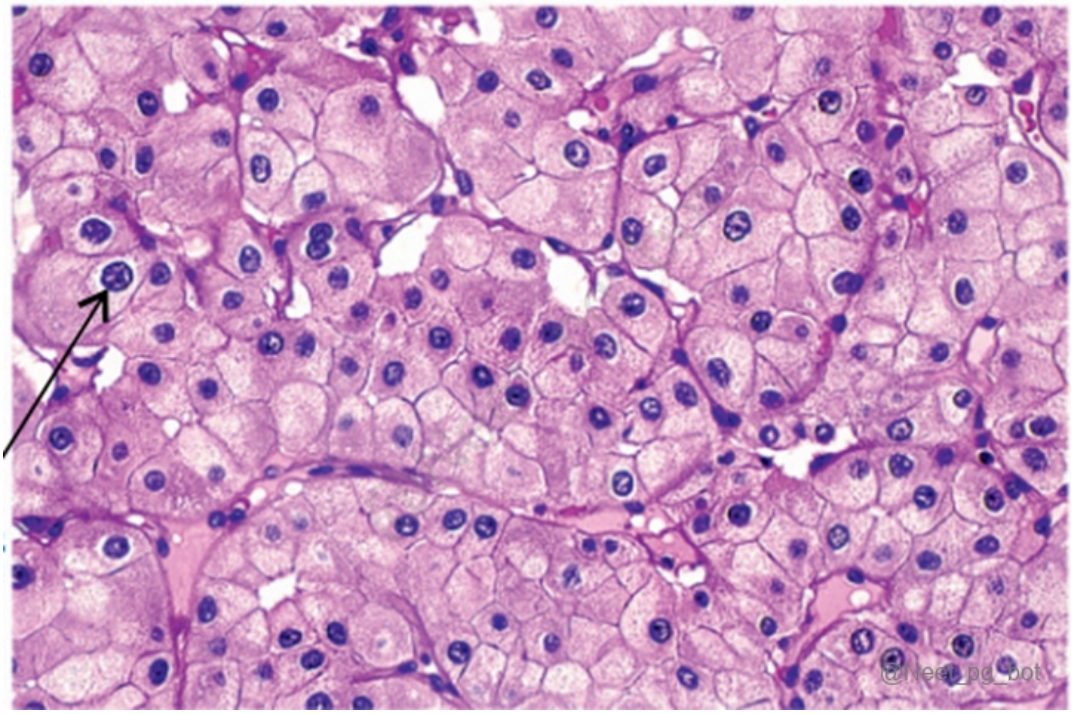
Q14: A patient presents with hematuria and flank pain. A renal mass is shown in the image provided. What is the likely diagnosis? (Q844158)

A. Clear cell carcinoma

B. Papillary renal cell carcinoma

C. Chromophobe renal cell carcinoma

D. Bellini duct carcinoma



Correct Answer: C. Chromophobe renal cell carcinoma

Explanation: Correct Option C - Chromophobe renal cell carcinoma: Chromophobe RCC has a distinct histological appearance, which shows plant cells, perinuclear halos, and raisinoid nuclei. It also shows positivity with Hale's colloidal iron stain and has a better prognosis compared to other RCC types. Incorrect Options: Options A, B, and D do not show plant cells.

References:

.

@Neet_pg_bot

Q15: A patient presents with a cerebellar mass and a renal tumor, along with a similar family history. Which of the following is responsible for his findings? (Q844087)

A. VHL disease

B. NF

C. TSC

D. Li Fraumeni syndrome

Correct Answer: A. VHL disease

Explanation: VHL is an autosomal dominant disorder. Classic tumors include cerebellar hemangioblastomas and renal cell carcinoma (clear cell type). Pheochromocytomas and pancreatic cysts can also occur. Family history of similar tumors is typical due to the dominant inheritance. On imaging, cerebellar masses are usually hemangioblastomas. Early diagnosis allows surveillance for RCC and CNS tumors. VHL gene mutation on chromosome 3p25-26 is responsible. Incorrect Options: Option B) Neurofibromatosis (NF): NF1: café-au-lait spots, neurofibromas, optic gliomas. NF2: bilateral vestibular schwannomas, meningiomas. Not associated with RCC or cerebellar hemangioblastomas. Option C) Tuberous sclerosis complex (TSC): Causes cortical tubers, subependymal giant cell astrocytomas, cardiac rhabdomyomas, renal angiomyolipomas. Does not cause cerebellar hemangioblastomas or clear cell RCC. Option D) Li-Fraumeni syndrome: Predisposes to breast cancer, sarcomas, leukemia, brain tumors (medulloblastoma, gliomas). Cerebellar hemangioblastomas and RCC are not typical.

@Neet_pg_bot

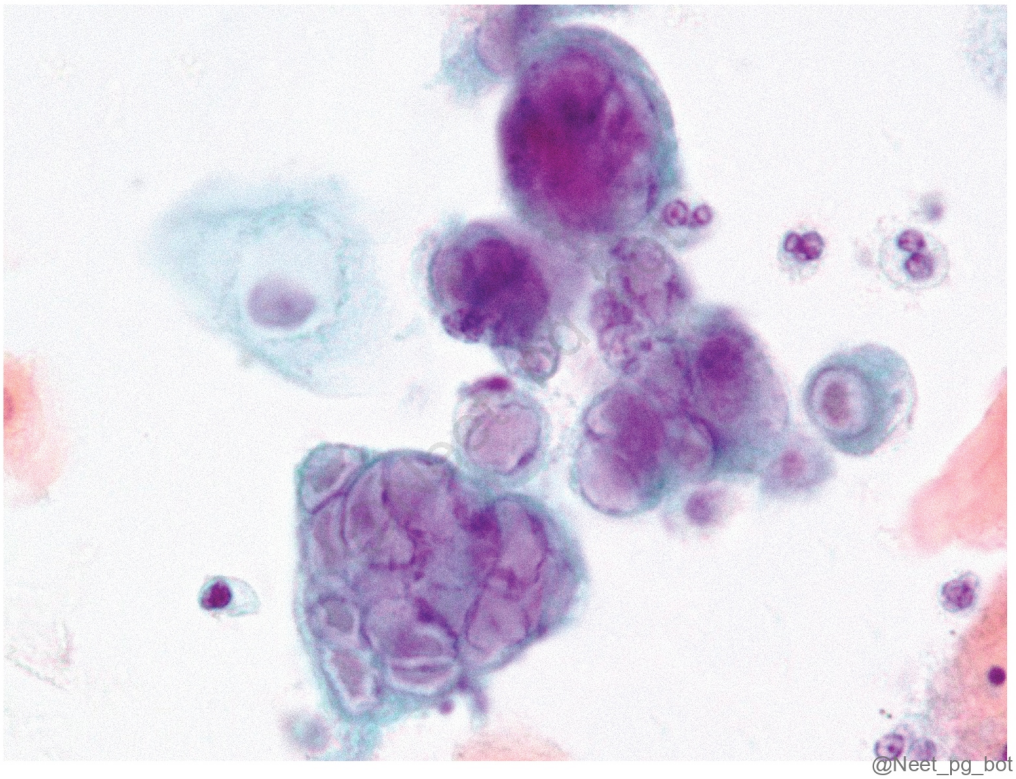
Q16: A female presents to the OPD with complaints of dysuria. Based on the microscopic examination, what is the most likely diagnosis? (Q844068)

A. HSV

B. CMV

C. HPV

D. Trichomonas



Correct Answer: A. HSV

Explanation: Correct Option A – HSV: The given image shows herpes simplex virus giant cells as they show: Multinucleated Moulding of nuclei Margination of the nucleus Incorrect Options: Options B, C, and D are not consistent with the microscopic examination findings.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: A pediatric patient presents with cola-coloured urine, high blood pressure, and periorbital oedema. Laboratory tests reveal a creatinine level of 2.5 mg/dL, which rises to 4.5 mg/dL after 3 weeks despite treatment. What electron microscopic finding is most likely in this patient? (Q855409)

A. Subendothelial deposits

B. Subepithelial deposits

C. Crescent formation

D. Mesangial deposits

Correct Answer: B. Subepithelial deposits

Explanation: The clinical presentation, including cola-coloured urine , hypertension , edema , and rising creatinine levels, is highly suggestive of acute glomerulonephritis , particularly post-streptococcal glomerulonephritis (PSGN). Subepithelial deposits are characteristic of PSGN in electron microscopy. Pathological findings in PSGN Grossly Kidneys appear speckled or mottled due to numerous small haemorrhages (Flea-bitten appearance) . {{caption_text}} Light microscopy Hypercellular glomeruli are caused by infiltration by leukocytes (neutrophils and monocytes) and the proliferation of endothelial and mesangial cells . Electron microscope ‘Subepithelial electron-dense humps’ due to immune complex deposition beneath the epithelial cells of the glomerular basement membrane. {{caption_text}} Immunofluorescence Characteristic 'Starry sky appearance' by immune complex deposition. {{caption_text}} {{caption_text}} Incorrect Options: Given the worsening renal function (rising creatinine levels) over time and the risk of progression to Rapidly Progressive Glomerulonephritis (RPGN), a finding of crescent formation (Option C) in the glomeruli would be expected, but it is a histopathological finding & not an electron microscope finding. Subendothelial deposits (Option A) are typically seen in systemic lupus erythematosus (SLE) or membranoproliferative glomerulonephritis (MPGN) , not in post-streptococcal glomerulonephritis (PSGN) . Mesangial deposits (Option D) are often seen in conditions like IgA nephropathy , membranoproliferative glomerulonephritis (MPGN) , or diabetic nephropathy , but not typically in PSGN .

Q13 (p. 2247) *Q14 (p. 2248)* *Q15 (p. 2249)* *Q16 (p. 2251)* *Q17 (p. 2252)*

Q1: A 42-year-old male presents with testicular pain and swelling. Physical examination reveals a palpable mass. Subsequent biopsy of the mass provides important diagnostic insights. Which of the following statements regarding sex cord-stromal tumours in males are true? A) They are classified into three main subtypes: Leydig cell and Sertoli cell tumours and yolk sac tumours. B) Sertoli cell tumours are commonly associated with hormonal abnormalities. C) Histologically, Leydig cell tumors demonstrate golden pigment with reinke crystals with eosinophilic cytoplasmic inclusions. D) Sertoli cell tumours are often associated with Carney's complex and are typically malignant. (Q845855)

A. A, B, C

B. A, C, D

C. C

D. A, B, C, D

Correct Answer: C. C

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Sex cord-stromal tumours have two major subtypes: Leydig cell and Sertoli cell tumour. Yolk sac tumours are germ cell tumours. (Statement A ruled out) Pathological features correlating with malignancy include large size, necrosis, infiltrative borders, anaplasia, mitotic activity, vascular-lymphatic invasion, and extratesticular extension. Leydig cell tumour Sertoli cell tumour Hormonal involvement It often involves androgens, oestrogens, and corticosteroids. Hormonally silent. (Statement B ruled out) Conditions associated with Klinefelter syndrome. Cryptorchidism. Renal cell carcinoma. Carney complex. (Statement D ruled out) Peutz-Jeghers syndrome. Familial adenomatous polyposis. Histology The tumour cells resemble their normal counterparts. They are large in size and have round or polygonal cell outlines , abundant granular eosinophilic cytoplasm , and a round central nucleus. The cytoplasm frequently contains lipid droplets , vacuoles , or lipofuscin pigment and, most characteristically, rod-shaped Reinke crystalloids (25% of the tumours). The tumour cells are arranged in

distinctive trabeculae that tend to form cord-like structures and tubules. Image

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 32-year-old male presents with multiple, small, flesh-coloured growths on the shaft of his penis. A biopsy is performed, and histopathology reveals hyperkeratosis, acanthosis, and koilocytosis. Which of the following is the most likely causative agent of his condition? (Q845863)

A. HPV 6 and 11

B. Treponema pallidum

C. HSV 2

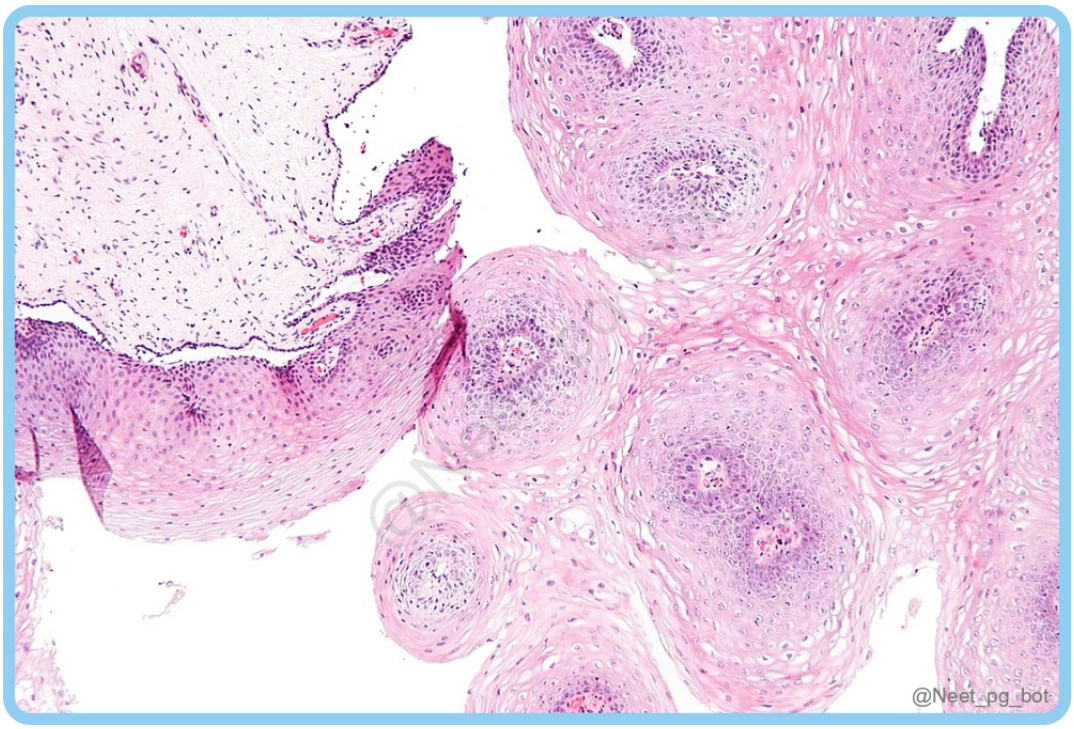
D. Chlamydia trachomatis

Correct Answer: A. HPV 6 and 11

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Condyloma acuminatum: It is a benign sexually transmitted wart caused by human papillomavirus (HPV). Low risk HPV serotypes (HPV 6 and, less frequently, HPV 11) are the most frequent cause. (Option A) Histopathology: Hyperkeratosis: increased production of stratum corneum or keratin. Acanthosis: increased epidermal thickness Koilocytosis: shriveled (“raisinoid”) nucleus + perinuclear halo (whitish clearing around nucleus) Treponema pallidum (Option B) causes syphilis, which can present with a painless genital ulcer (chancre). HSV type 2 (Option C) typically causes genital herpes, characterized by painful vesicles and ulcers on the genitalia. Chlamydia trachomatis (Option D): "Chlamydia trachomatis serovars L1, L2, and L3 cause lymphogranuloma venereum. It results in painless genital ulcer and painful swelling of the inguinal lymph nodes, known as buboes."



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 964.

↑ *Back to this question in Part A*

Q3: A 65-year-old male presents with difficulty in urination and frequent nocturia. Digital rectal examination reveals a firm, irregular prostate. A subsequent prostate-specific antigen (PSA) test shows elevated levels. A transrectal ultrasound-guided prostate biopsy is performed, and the pathology report provides a Gleason score. Which of the following statements regarding the Gleason score in prostate cancer diagnosis is correct for this patient? (Q845862)

A. The Gleason score indicates the stage of prostate cancer.

B. A Gleason score of 6 suggests a poorly differentiated tumor with a high risk of metastasis.

C. The Gleason score is determined by adding the two least common Gleason grades found in the tumor.

D. The Gleason score is irrelevant in determining the treatment approach for prostate cancer.

Correct Answer: A. The Gleason score indicates the stage of prostate cancer.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The Gleason score is a grading system used to evaluate the aggressiveness and prognosis of prostate cancer based on the microscopic appearance of tumor cells observed in biopsy samples. Multistep approach that we follow in Gleason score in the order of: Pattern → Score → Grade (Ruled out Option C) Grade group Score Description 1 ≤6 Only individual discrete well-formed glands. 2 3 + 4 Predominantly well-formed glands with a lesser component of poorly formed, fused or cribriform glands 3 4 + 3 Predominantly poorly formed/fused/cribriform glands with a lesser component of well-formed glands 4 (4 + 4/3 + 5/5 + 3) Only poorly formed/fused/cribriform glands or predominantly mix of well-formed glands and lack of glands 5 (4 + 5/5 + 4/5 + 5) Lack gland formation (or with necrosis) with or without poorly formed/fused/cribriform glands A Gleason score of 6 suggests a poorly differentiated tumor with a high risk of metastasis (Option B): It does not indicate a poorly differentiated tumor. The Gleason score is irrelevant in determining the treatment approach for prostate cancer (Option D): On biopsy we give Gleason score and grade based on which treatment modality is decided.

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 976

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 60-year-old male presents with increased frequency, nocturia, and weak urine stream. DRE reveals a firm nodule. A prostate biopsy is performed, and the histology image shows complex, branching papillary structures lined by pseudostratified columnar epithelium.What is the most likely diagnosis? (Q845861)

A. Benign Prostatic Hyperplasia (BPH)

B. Prostate Adenocarcinoma-Ductal Type

C. Prostatic Intraepithelial Neoplasia (PIN)

D. Chronic Prostatitis

Correct Answer: B. Prostate Adenocarcinoma-Ductal Type

Explanation: The biopsy shows complex, arborizing papillary structures with branching architecture, characteristic of prostatic ductal adenocarcinoma. The papillae are lined by tall pseudostratified columnar epithelial cells, which is a hallmark of this aggressive variant. Unlike usual acinar adenocarcinoma with small crowded glands, ductal carcinoma forms papillary and cribriform patterns. It commonly arises in the periurethral region and can present with urinary obstruction symptoms. This morphology is distinct and diagnostic. Incorrect Options: Option A) BPH : Shows large, well-formed glands with papillary infolding but never pseudostratified malignant epithelium. Option C) PIN : Can show stratified epithelium but retains the basal cell layer and lacks complex papillary architecture. Option D) Chronic Prostatitis : Shows dense inflammatory infiltrates, not complex papillary tumor structures

@Neet_pg_bot

Q5: Which of the following is a new biomarker used in Prostatic Cancer? (Q845860)

A. NMP22

B. Thymidine kinase

C. NKX 3.1

D. PLAP

Correct Answer: C. NKX 3.1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: NKX3.1 is primarily expressed in the prostate, and its expression is regulated by androgens. It is involved in the maintenance of prostate epithelial cell differentiation, growth regulation, and suppression of cellular proliferation. Therefore, NKX3.1 is elevated in prostate cancer. Tumour markers for carcinoma of prostate: Prostate specific antigen (PSA). Prostatic acid phosphatase (PAP). PCA3. NKX 3.1.

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 97

↑ *Back to this question in Part A*

@Neet_pg_bot

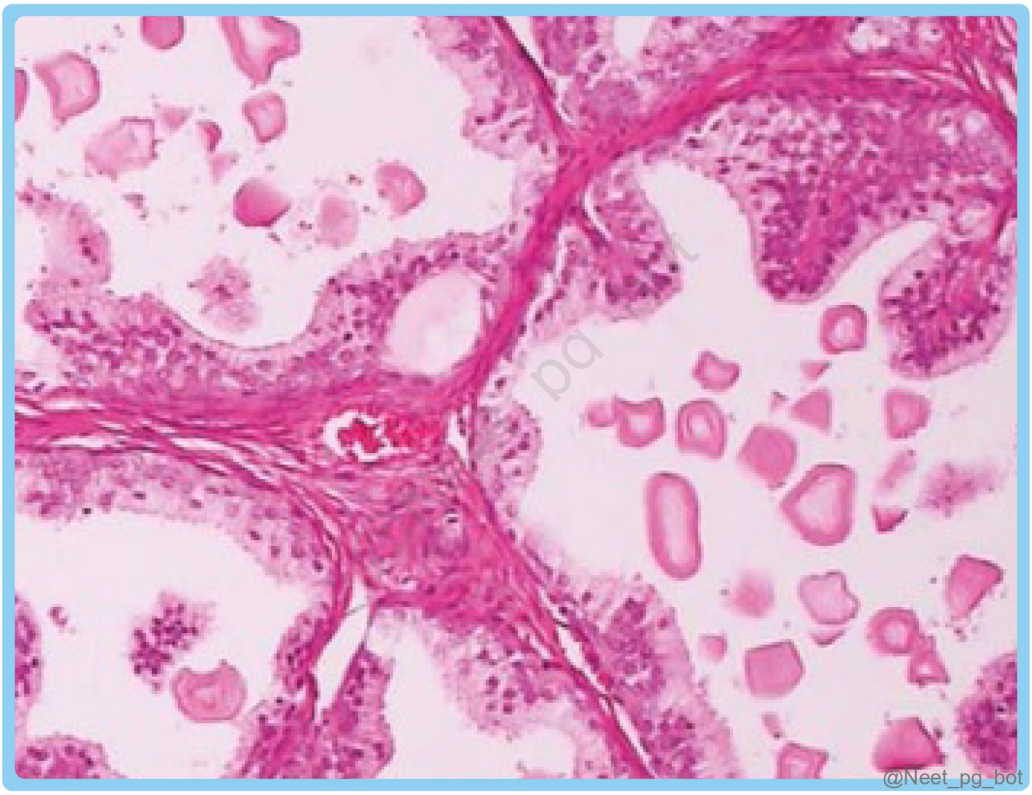
Q7: A 65-year-old man presents with complaints of increased frequency and urgency of urination, particularly at night. He also mentions a feeling of incomplete bladder emptying and a weak urine stream. The patient's PSA level is within normal limits. The histopathology image is given below. Based on the diagnosis, which of the following is true? (Q845858)

A. Infiltration of lymphocytes

B. Presence of atypical cells with high mitotic activity

C. Increased number of stromal and epithelial cells

D. Dysplastic changes in the glandular architecture



Correct Answer: C. Increased number of stromal and epithelial cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Characteristic features of the histopathology of Benign Prostatic Hyperplasia (BPH) include: Hyperplasia (increase in the number of cells) of both stromal and epithelial components of the prostate gland, forming small bulbous papillary projections. The stromal cells include fibroblasts and smooth muscle cells, while the epithelial cells line the glandular structures of the prostate. Pink secretions (corpora amylacea) are also present in the lumen. BPH occurs due to the influence of dihydrotestosterone (DHT) .

References:

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 976

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which zone of the prostate is primarily affected by benign prostatic hyperplasia (BPH), and which zone is more commonly associated with prostate cancer? (Q845857)

A. Central zone & Peripheral zone

B. Peripheral zone & Transitional zone

C. Transitional zone & Peripheral zone

D. Peripheral zone & Central zone

Correct Answer: C. Transitional zone & Peripheral zone

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Benign Prostatic Hyperplasia (BPH / Nodular Hyperplasia of prostate): The zone involved in BPH is the Transitional Zone. The transitional zone is closest to the urethra, and nodular hyperplasia compresses the urethra, which leads to early lower urinary tract symptoms (LUTS) such as frequency, urgency, nocturia, weak stream, and hesitancy. Prostate cancer: The zone involved in prostate cancer is the Peripheral Zone, which lies posteriorly. Because this zone is farther from the urethra, urethral symptoms appear late. Prostate cancer metastasizes early, commonly to bones such as the lumbar spine, pelvis, and ribs through Batson's venous plexus. Diseases Prostate zones Prostate cancer (adenocarcinoma) Peripheral Prostatic intraepithelial neoplasia Peripheral Prostatitis Central Benign prostatic hyperplasia Transitional

@Neet_pg_bot

Q9: Match the following tumour markers (Column A) with the corresponding testicular tumour types (Column B). Column A (Tumor Markers) Column B (Testicular Tumor Types) 1. Alpha-fetoprotein (AFP) A. Seminoma 2. Beta-human chorionic gonadotropin (β-hCG) B. Embryonal Carcinoma 3. CD-30 C. Yolk sac tumour 4. Placental alkaline phosphatase (PLAP) D. Choriocarcinoma 5. Cytokeratin E. Teratoma (Q845856)

A. 1-A, 2-B, 3-C, 4-D, 5-E

B. 1-C, 2-D, 3-A, 4-B, 5-E

C. 1-C, 2-D, 3-B, 4-A, 5-E

D. 1-B, 2-A, 3-D, 4-C, 5-B

Correct Answer: C. 1-C, 2-D, 3-B, 4-A, 5-E

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The various testicular tumours and their markers are given below: Testicular Tumour Corresponding Tumor Markers Seminoma Placental alkaline phosphatase (PLAP) HCG LDH Newer markers: Oct 3/4, Nanog, CD117, SALL4 Embryonal Carcinoma CD-30 Yolk sac tumour Alpha-fetoprotein (AFP) Alpha-1 antitrypsin Choriocarcinoma Beta-human chorionic gonadotropin (β-hCG) Teratoma Cytokeratin

@Neet_pg_bot

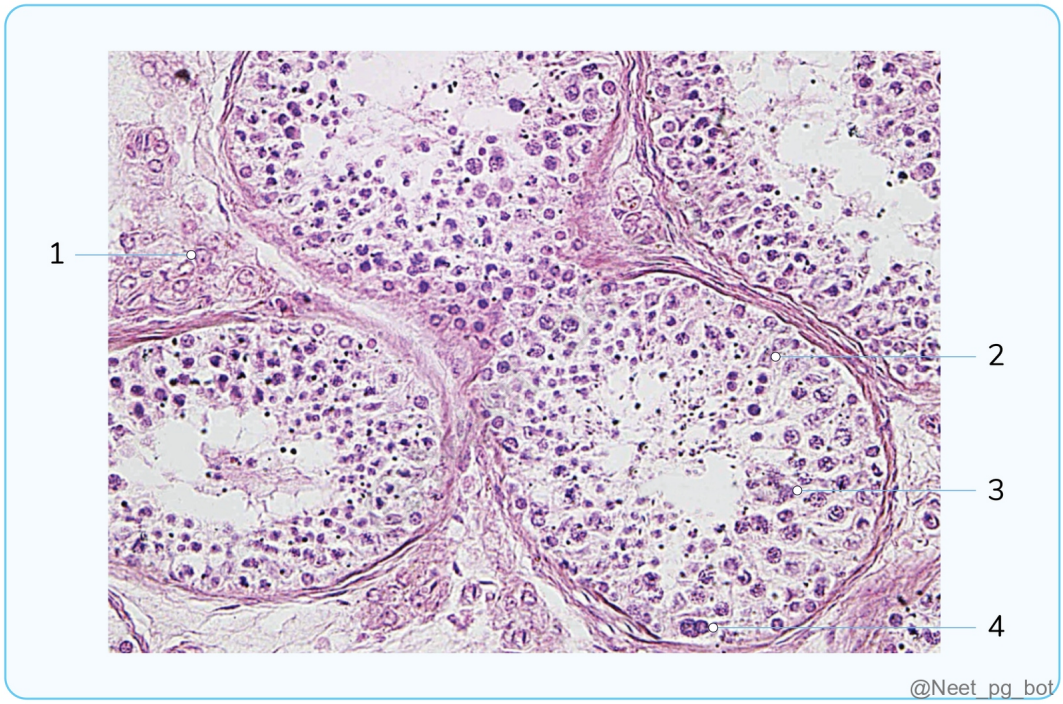
Q10: The histological examination of a normal testis is given in the image below. Which of the following callouts is responsible for maintaining the blood testis barrier? (Q845847)

A. 1

B. 2

C. 3

D. 4



Correct Answer: B. 2

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The callouts given in the illustration correspond to the following. 1- Interstitial cell of Leydig : Responsible for hormones production 2- Sertoli/sustentacular cell : Provides nutrition and makes blood-testicular barrier 3- Spermatocyte (Mature spermatogonium) 4- Spermatogonium .

Inderbir Singh Histology, 9th edition, Pages 550-552, 882.

↑ *Back to this question in Part A*

@Neet_pg_bot

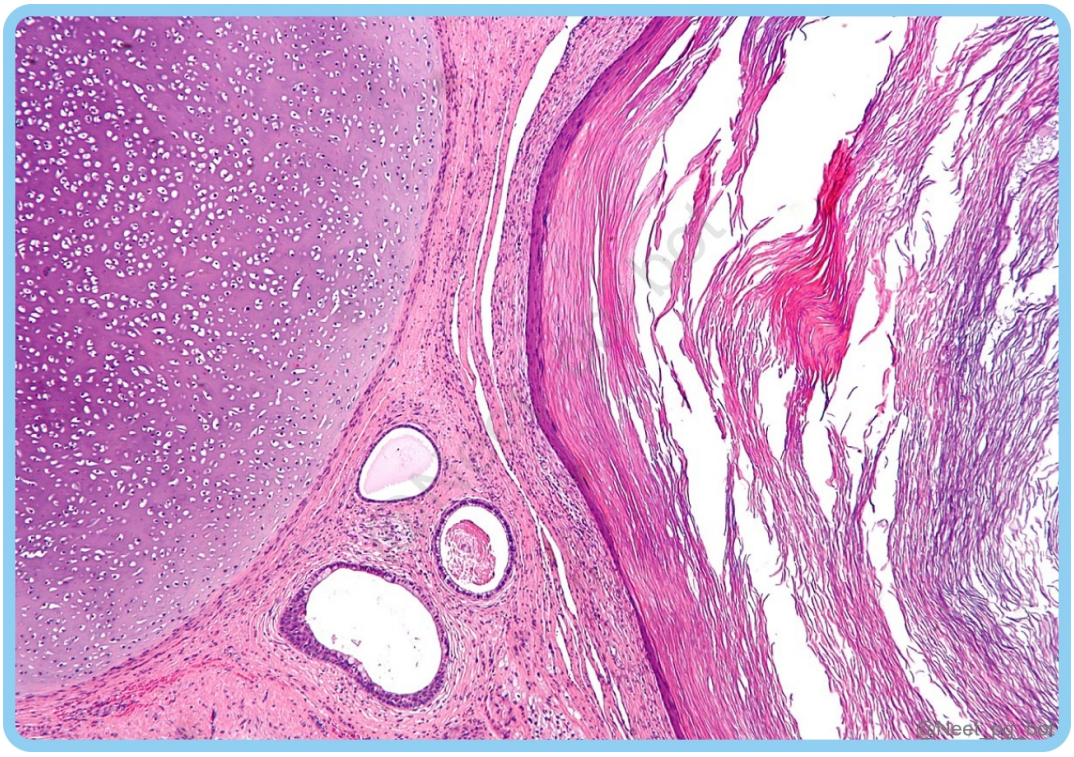
Q11: A 10-month-old boy was referred to the hospital with non-palpable right testes. The physical examination revealed no jaundice, palpable left testes, or right-sided abdominal mass. Subsequent surgical excision of the mass revealed a cystic mass with keratinous debris, and a biopsy image of the specimen was obtained. All of the following statements regarding this condition are true except? (Q845854)

A. Typically present as well-defined, encapsulated masses with cystic and solid components.

B. Often associated with areas of haemorrhage and necrosis.

C. Histologically, it contains differentiated cells or organoid structures embedded in a fibrous or myxoid stroma.

D. Demonstrate homogeneous appearance and are mostly found malignant in young children.



Correct Answer: D. Demonstrate homogeneous appearance and are mostly found malignant in young children.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Dermoid cyst/Teratoma : Germ cell tumours (GCTs) having various organoid components derived from multiple germ layers. Prepubertal teratoma: Pure teratomas are common in infants and very young children. Mostly benign, resembling normal tissue. (Option D). Can present as undescended testicular teratoma. Postpubertal adult teratomas: Malignant transformation to squamous cell carcinoma, adenocarcinoma, or sarcoma. Histopathology: Gross: Heterogeneous appearance with a well-defined encapsulated mass containing solid, cartilaginous, and cystic areas. (Option A). Associated with foci of haemorrhage and necrosis. (Option B). Microscopy: Differentiated cells or organoid structures, such as neural tissue, muscle, cartilage, epidermal-like surfaces, thyroid gland, and intestinal wall or brain substance embedded in a fibrous or myxoid stroma. (Option C) Special types include dermoid cysts containing hair, teeth, and skin.

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Pages 966-67

↑ *Back to this question in Part A*

@Neet_pg_bot

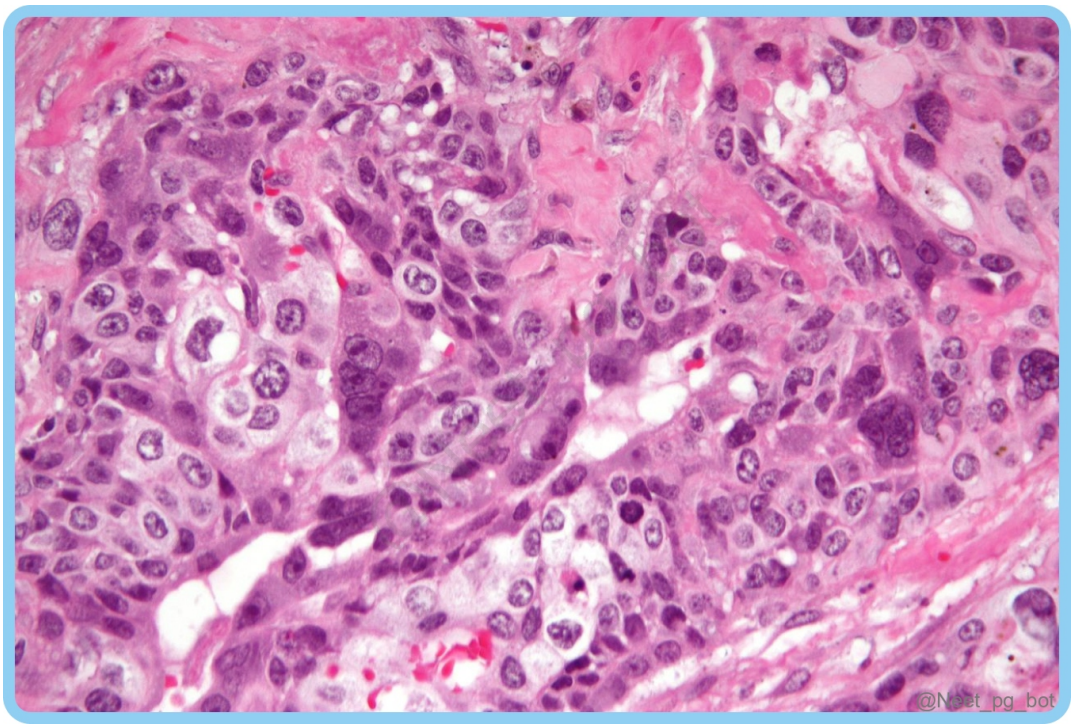
Q12: A 30-year-old male presents with a rapidly enlarging testicular mass associated with testicular pain and gynecomastia. He reports associated mild hemoptysis for the last 4 days. A biopsy of the mass is performed, and both gross and microscopic images are obtained. What is the most likely diagnosis based on the clinical presentation? (Q845853)

A. Choriocarcinoma

B. Embryonal Carcinoma

C. Seminoma

D. Yolk Sac Tumor

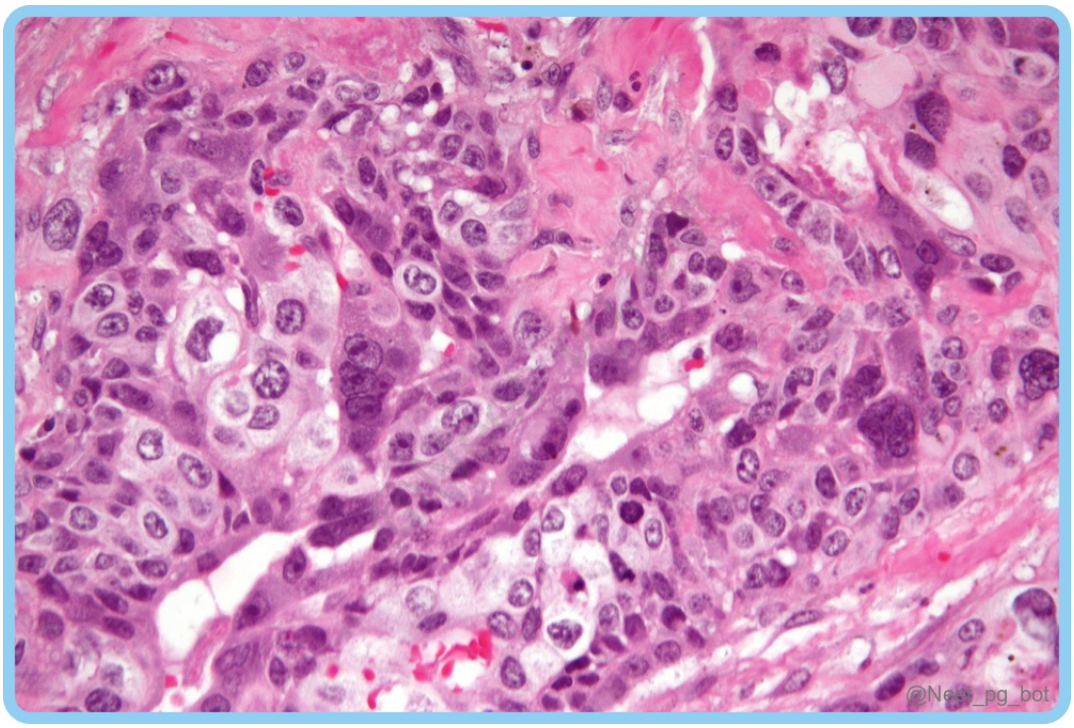


Correct Answer: A. Choriocarcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Choriocarcinoma: It is a very aggressive and highly malignant type of GCT. Tumor marker: Elevated serum beta HCG (human chorionic gonadotropin). Histopathology: Gross: Haemorrhage and necrosis at involved sites. Microscopy: Composed of two cell types- syncytiotrophoblasts and cytotrophoblasts. Syncytiotrophoblasts: Large multinucleated cells. Cytotrophoblasts: Regular, polygonal. mononuclear cells. Widespread metastasis: Hematogenous metastasis to lungs (cannonball appearance).



References:

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 972

↑ *Back to this question in Part A*

@Neet_pg_bot

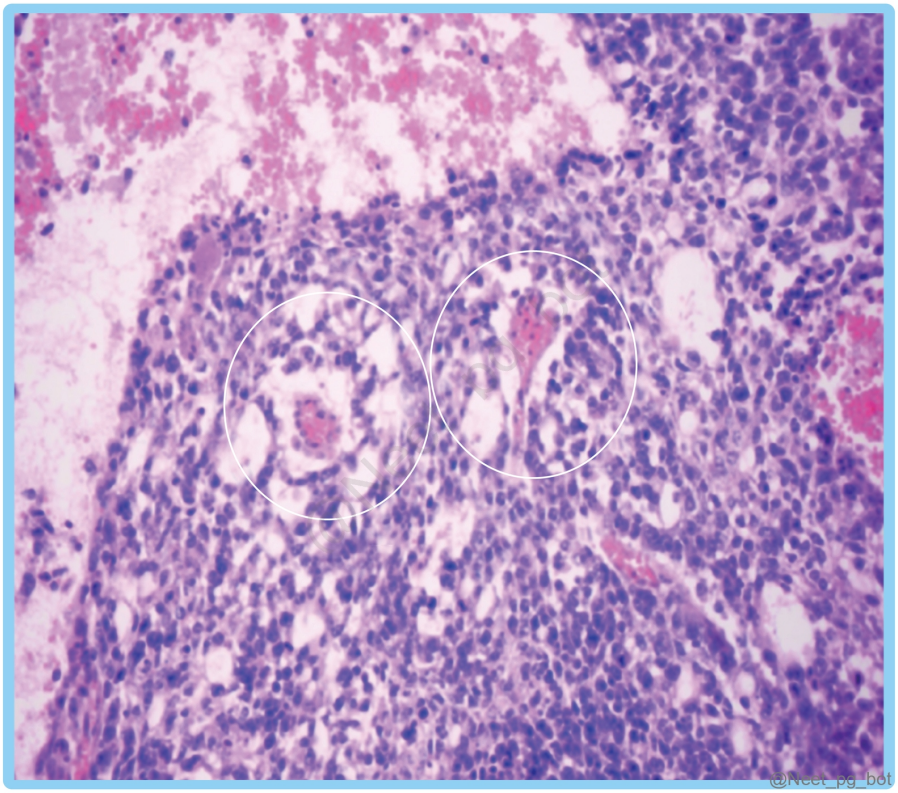
Q13: A 10-year-old male with a painless testicular mass for the past few months. On examination, the right testis was enlarged and the transillumination test was negative. A biopsy of the mass was performed and is shown below. What is the most likely diagnosis? (Q845852)

A. Hydrocoele

B. Yolk Sac tumour

C. Choriocarcinoma

D. Germ Cell tumour

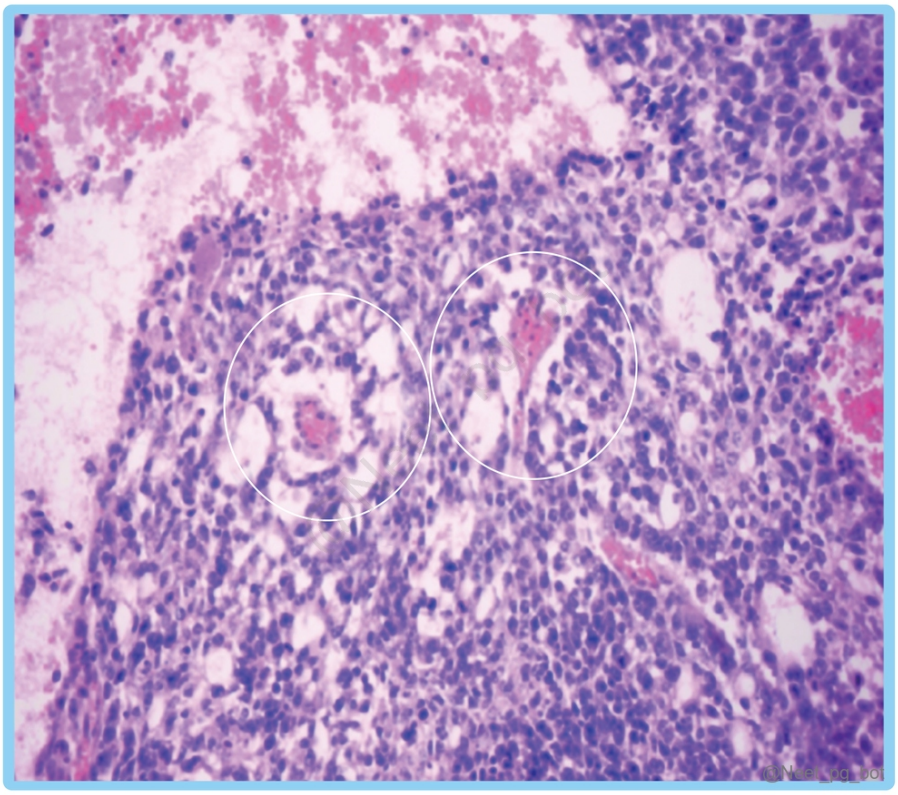


Correct Answer: B. Yolk Sac tumour

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Yolk Sac Tumour or Endodermal Sinus Tumour: Common in infants and children. Biopsy finding: Schiller-Duval or glomerular bodies: At centre, it has a reddish blood vessel which is surrounded by two rows of tumor cells, and there is space between these two rows. Because of this appearance they start looking as a gromerulus and hence the name glomerular bodies. Glomerular bodies are seen in 2 tumors: Yolk sac tumor in genitals Glioblastoma in brain.



References:

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 97

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 65-year-old male presents to the hospital with a painless scrotal mass. Ultrasound scan reveals a solid testicular mass suspicious for a spermatocytic tumour. Upon further examination, the following histological findings are identified except? (Q845851)

A. Associated with gain of function mutation

B. Presence of inflammatory infiltrates and syncytiotrophoblasts

C. Presence of three intermixed cell distinct cell populations on microscopy

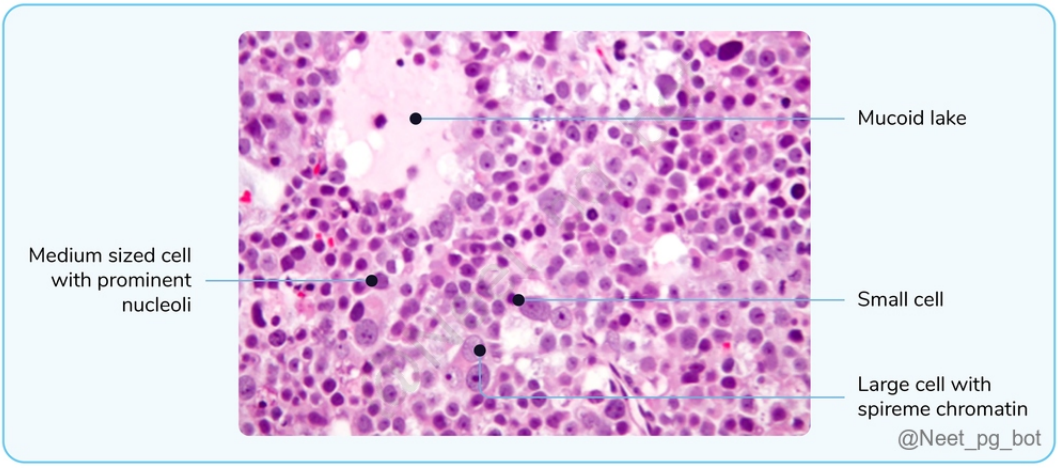
D. Low risk of metastasis following surgical resection

Correct Answer: B. Presence of inflammatory infiltrates and syncytiotrophoblasts

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Spermatocytic seminoma : Testicular germ cell neoplasm. Associated with gain of chromosome 9q (Option A). It is a slow-growing tumour and doesn't metastasise (Option D). Histopathology: Microscopy (Option C): Smaller cells with dense chromatin and a narrow eosinophilic cytoplasm rim resembling secondary spermatocytes. Medium-sized cells containing a round nucleus, spireme-type chromatin with occasional nucleoli, and eosinophilic cytoplasm. Scattered giant cells , large multinucleated cells. Presence of inflammatory infiltrates and syncytiotrophoblasts (Option B): Cytotrophoblasts and syncytiotrophoblasts indicate gestational trophoblastic diseases are seen in choriocarcinoma.



References:

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 970.

↑ *Back to this question in Part A*

@Neet_pg_bot

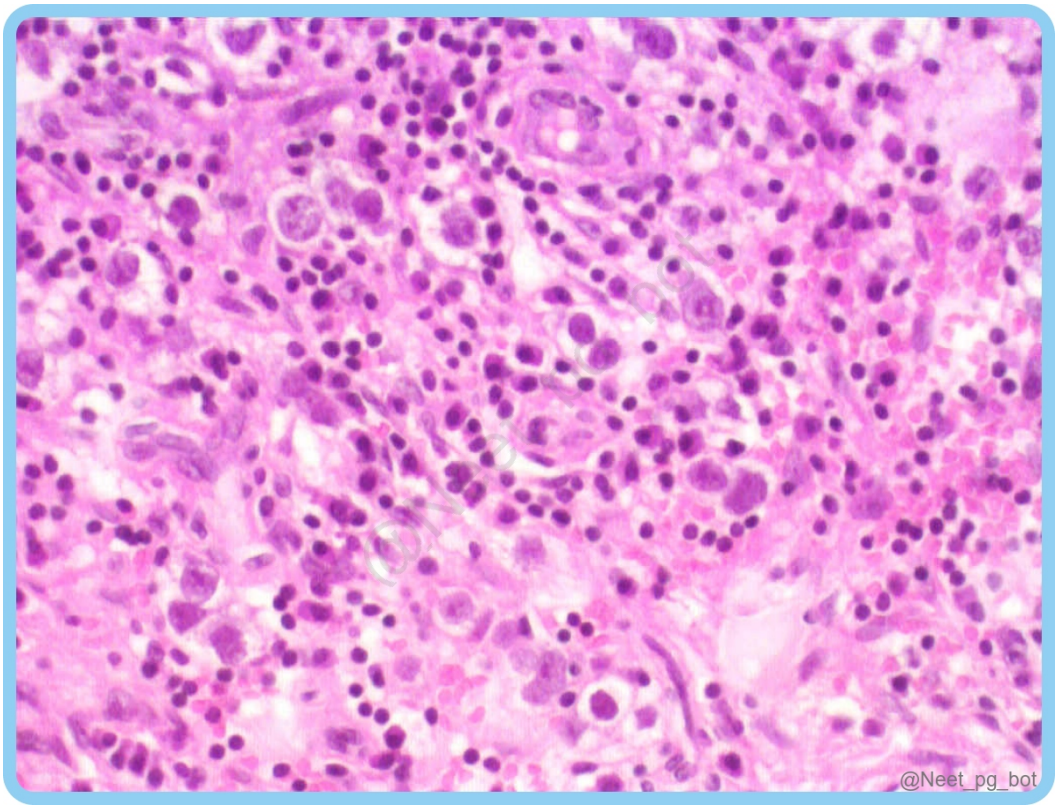
Q15: A patient underwent unilateral orchiectomy for a swelling in the right testis. The specimen is sent for histopathological examination, and its microscopic appearance is depicted in the image below. Which of the following statements is true regarding the diagnosis? (Q845850)

A. 3 different sizes of tumour cells are seen

B. Schiller-Duval bodies are present

C. Tumor cells are arranged in sheets

D. Tumor cells have a watery-clear cytoplasm

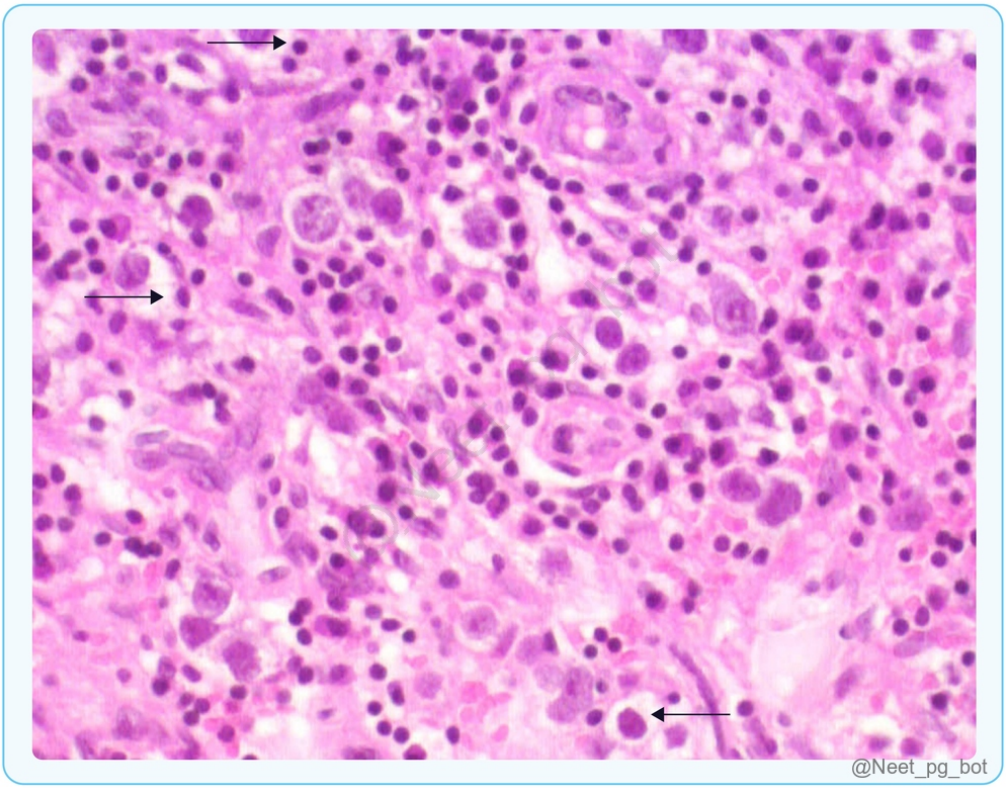


Correct Answer: D. Tumor cells have a watery-clear cytoplasm

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given histopathological image shows features suggestive of testicular seminoma. Histology of seminoma: The tumor shows cells with watery, clear cytoplasm (described as a “fried-egg” or clear cell appearance) due to glycogen accumulation, which is PAS positive. The tumor cells are arranged in nests separated by fibrous septa, and within these septa there is lymphocytic and plasma cell infiltration. This triad of clear cytoplasm, nests of tumor cells, and lymphoplasmacytic infiltrate is characteristic of seminoma . 3 different sizes of tumour cells (small, medium and giant cells) are seen in a case of spermatocytic seminoma. (Option A) Endodermal sinuses-like structures called Schiller-Duval bodies are present in the case of a yolk sac tumour. (Option B) Tumor cells arranged in sheets are typical of embryonal carcinoma, whereas in seminoma, tumor cells are arranged in nests with intervening fibrous septa. (Option C)



References:

Robbins and Cotran, Pathologic basis of disease, 10th edition, Page 970.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: Which of the following is not a germ cell tumour? (Q845849)

A. Teratoma

B. Embryonal carcinoma

C. Spermatocytic seminoma

D. Sertoli cell tumour

Correct Answer: D. Sertoli cell tumour

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The classification of testicular tumours is given in the table below. Germ cell tumours Sex cord-stromal tumours Mixed Seminomatous: Seminoma (Most common) Spermatocytic seminoma. Sertoli cell tumour. Leydig cell tumour. Pure tumours. Gonadoblastoma. Non-seminomatous: Embryonal carcinoma. Choriocarcinoma. Yolk sac tumour. Teratoma.

References:

Robbins and Cotran, Pathologic basis of disease, 10th edition. Page 969

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: A 1-year-old boy is brought to the pediatric clinic by his parents, who are concerned about the absence of his left testicle in the scrotum. On physical examination, the right testicle is palpable in the scrotum, but the left is not. All are true regarding this condition except? (Q845848)

A. It can occur in association with hypospadias.

B. The most common site of arrest of descent is the inguinal canal.

C. It is very commonly associated with a well-defined hormonal disorder.

D. The Leydig cells appear prominent.

Correct Answer: C. It is very commonly associated with a well-defined hormonal disorder.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Cryptorchidism: It is a complete or partial failure of the intra-abdominal testes to descend into the scrotal sac , associated with testicular dysfunction and an increased risk of testicular cancer. It usually occurs as an isolated anomaly but may be accompanied by other genitourinary tract malformations, such as hypospadias. (Option A) The normal descent of the testes occurs in two phases: Transabdominal phase: Mediated by Mullerian inhibiting substance. Inguinoscrotal phase: Mediated by the androgen-induced release of calcitonin-related gene peptide. Any problem in any of these descents can lead to cryptorchidism. Sites of arrest of descent: Inguinal canal (most common). (Option B) Abdomen (uncommon). When the testis fails to descend into the scrotum, it is deprived of the temperature needed for spermatogenesis. As a result, sperm production does not occur, and the seminiferous tubules contain only Sertoli cells (Sertoli cell–only syndrome). Leydig cells outside the tubules may appear prominent—not from true hypertrophy or hyperplasia, but due to the absence of germ cells—though this prominence is often mistakenly reported as Leydig cell hyperplasia . (Option D)

@Neet_pg_bot

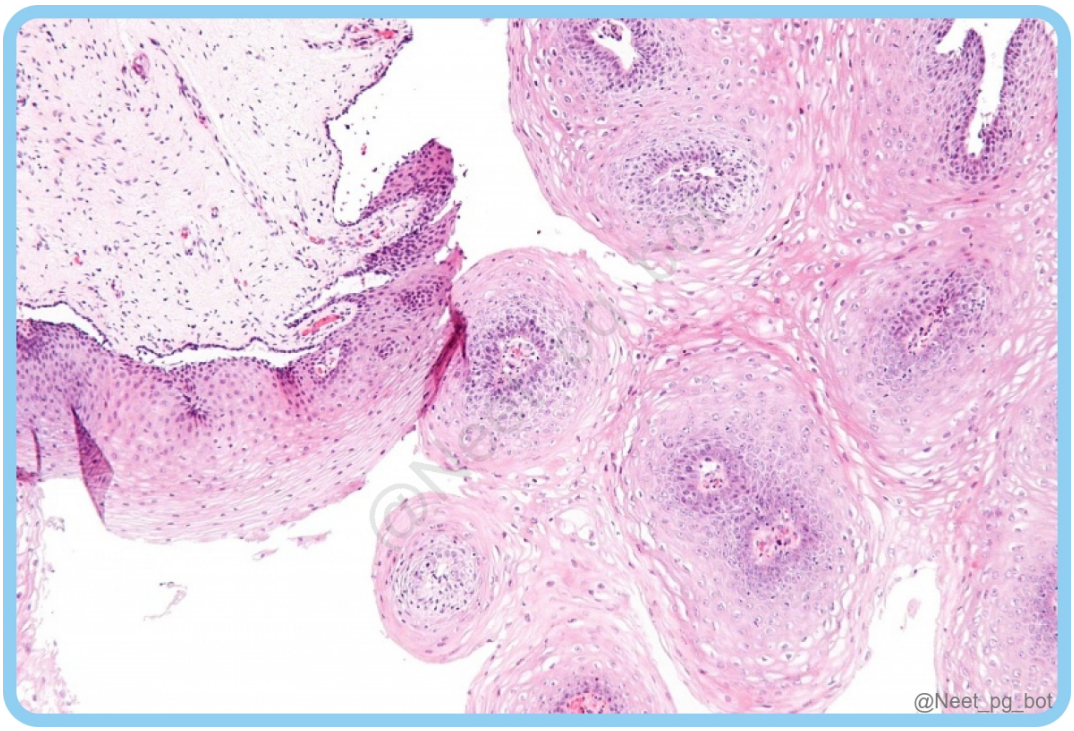
Q2: Which strain of the HPV virus is responsible for causing Condyloma acuminatum? (Q845605)

A. HPV 6 & 11

B. HPV 16 & 18

C. HPV 6 & 16

D. HPV 11 & 18

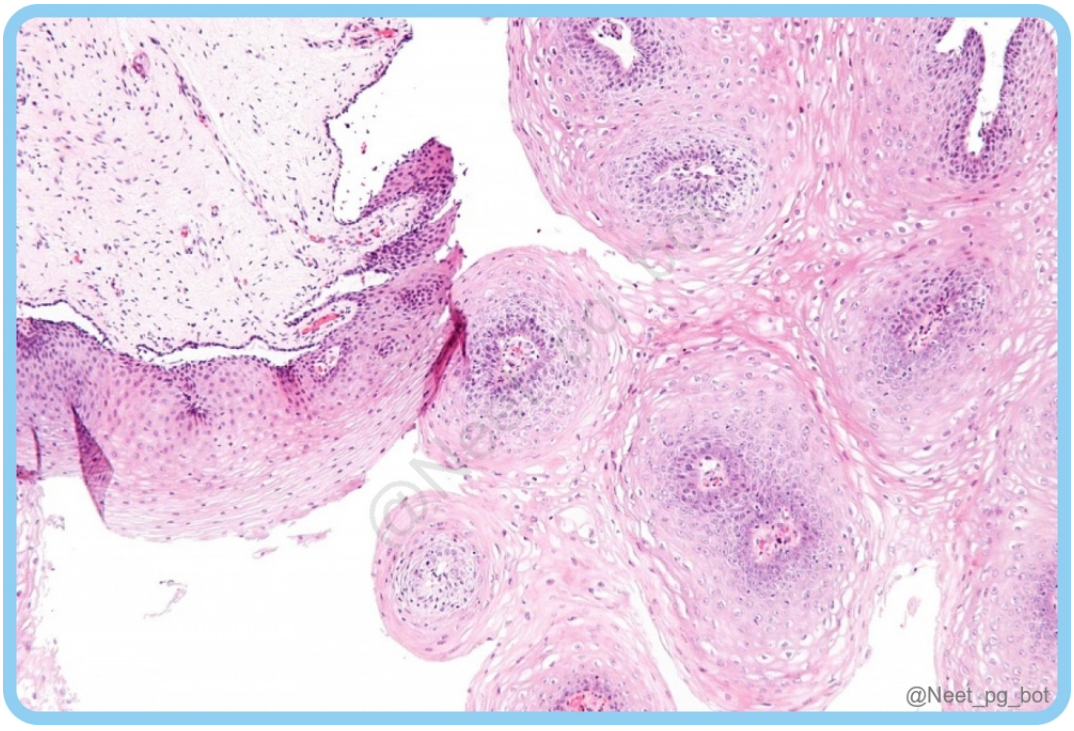


Correct Answer: A. HPV 6 & 11

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Histopathology image suggests Condylomata acuminata, which are benign genital warts caused by low-risk HPV 6 and 11, a double-stranded DNA virus that infects differentiated squamous epithelial cells. Condyloma acuminata are cauliflower-like, dry, and bulky, typically found in the squamous mucosa of the anal canal. Lots of hyperkeratosis and acanthosis are seen. {{caption_text}} HPV 16 and 18 (Option B): HPV 16 and 18 are high-risk strains responsible for cervical carcinoma, vulvar intraepithelial neoplasia (VIN) and vulvar carcinoma.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 991.

Human Papillomavirus and Cervical Cancer-PMC(NIH.gov)https://www.ncbi.nlm.nih.gov/pmc/articles/PMC145302/

↑ *Back to this question in Part A*

@Neet_pg_bot

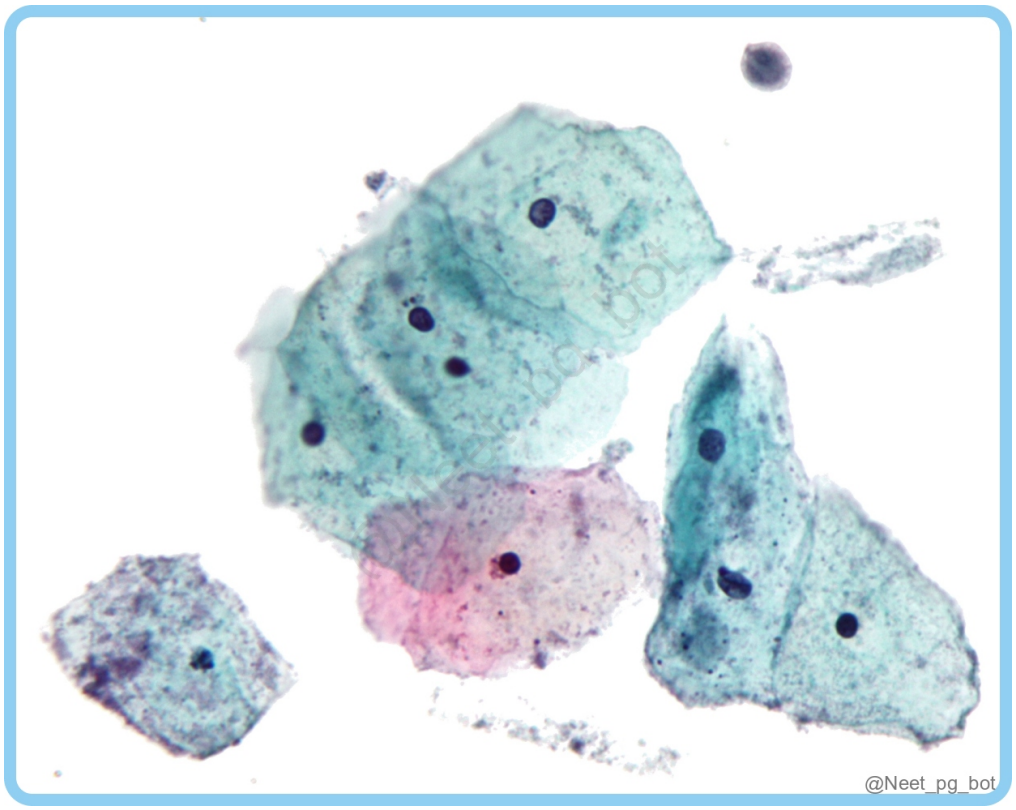
Q3: A 25-year-old sexually active female presents with foul-smelling vaginal discharge and dysuria. Upon examination of the cervix, the following appearance is noted. Wet mount microscopy reveals the findings shown in the image below. Which of the following is most likely responsible for this presentation? (Q845606)

A. Trichomonas vaginalis

B. Candida

C. Herpes simplex virus

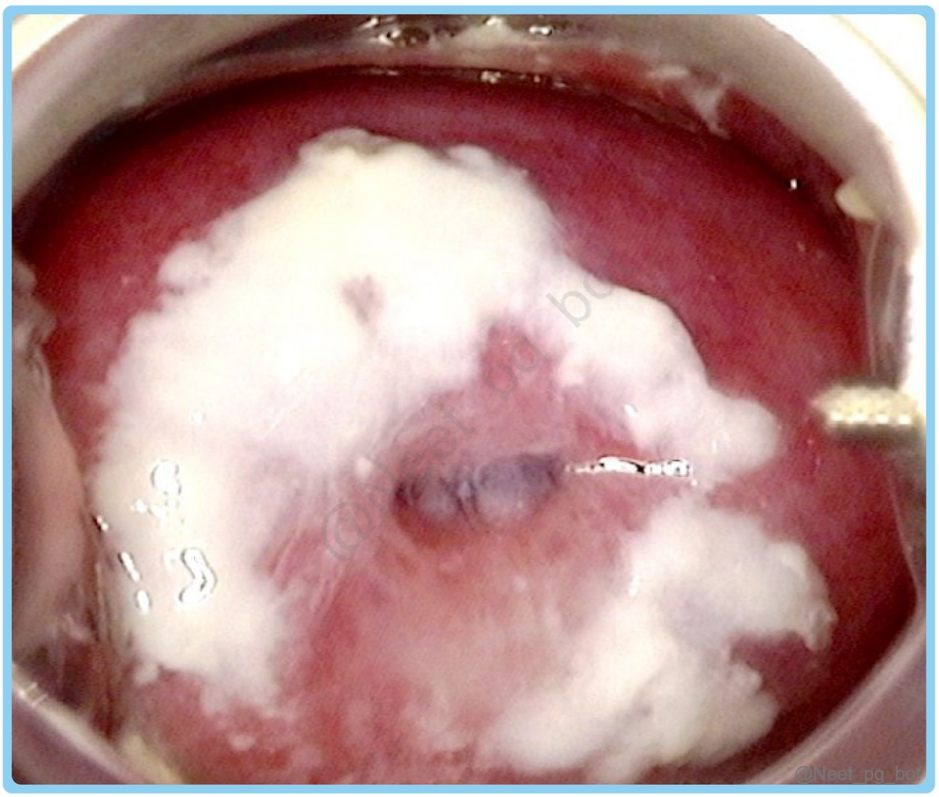
D. Human Papilloma virus



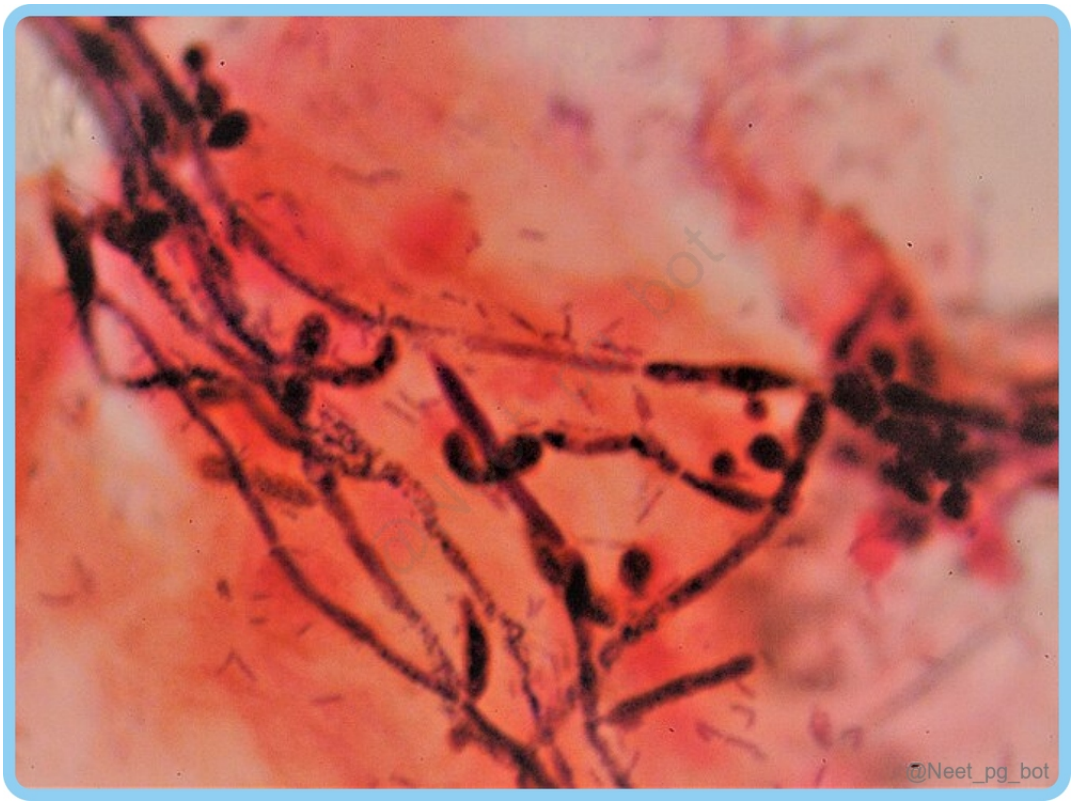
Correct Answer: A. Trichomonas vaginalis

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical presentation, examination, and microscopy findings suggest Trichomonas vaginalis infection, a large, flagellated ovoid protozoan transmitted by sexual contact. Patients may present with greenish, frothy vaginal discharge, vulvovaginal discomfort, dysuria (painful urination) dyspareunia (painful intercourse). The vaginal and cervical mucosa has a fiery-red appearance, with dilation of cervical mucosal vessels resulting in a “strawberry cervix.” Wet mount microscopy of the discharge reveals motile pear-shaped Trichomonas vaginalis with flagella. Trophozoite form of Trichomonas vaginalis Treatment: Metronidazole + Partner's treatment also. Candida (Option B): Pap smear: shish kebab effect {{caption_text}} Herpes simplex virus (Option C) Microscopy: squamous cell nuclei exhibit 3Ms : Multinucleation, molding and margination Human Papillomavirus (Option D) Microscopy: Koilocytes are seen.



@Neet_pg_bot



@Neet_pg_bot

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 988, 384, 991.

↑ *Back to this question in Part A*

@Neet_pg_bot

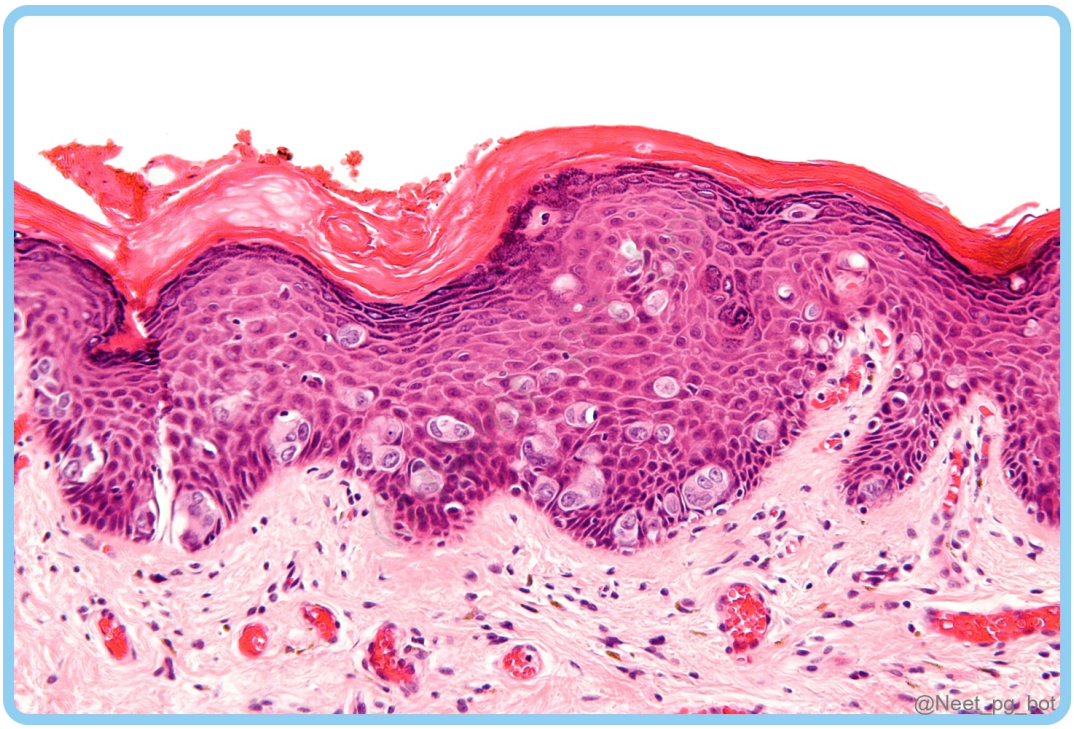
Q4: A 58-year-old woman complains of persistent itching and redness in her vulvar area. On examination, well-defined, erythematous plaques with an eczematous appearance are noted. A biopsy reveals large cells with pale cytoplasm and positive staining for mucopolysaccharides. Immunohistochemical analysis shows positive staining for cytokeratin 7. Based on these findings, what is the most likely diagnosis? (Q845607)

A. Bowen's disease of the vulva

B. Extramammary Paget's disease

C. Papillary Hidradenoma

D. Squamous cell carcinoma

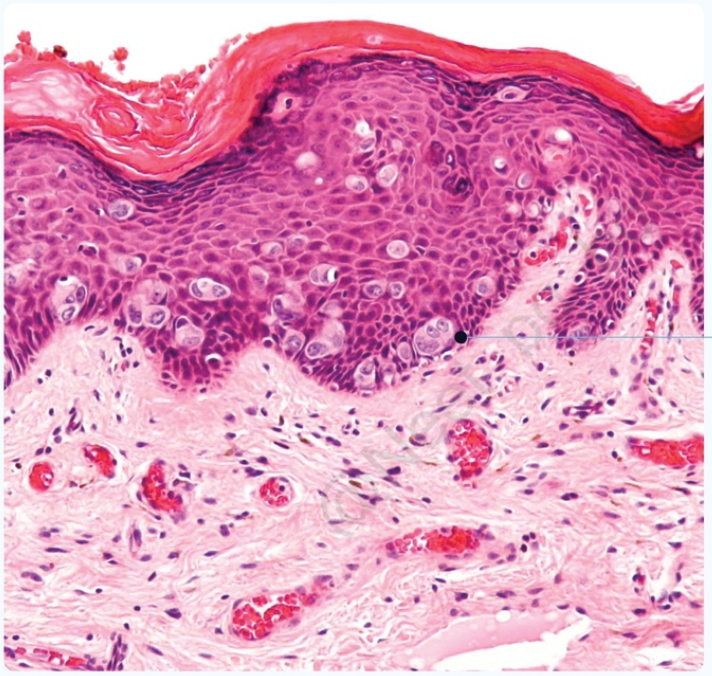


Correct Answer: B. Extramammary Paget's disease

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: 2 types of Paget's: Mammary Paget's (Paget's disease of breast): A condition with underlying cancer like ductal carcinoma in situ or ductal cancer and these cancer cells are spreading to the overlying skin, resulting in Paget cells (Clear looking cells) Extramammary Paget's (Paget's disease of vulva): It is typically not associated with underlying malignancy and is confined to the vulvar epidermis. Biopsy findings commonly reveal large, round cells, known as Paget cells, within the epidermis. These cells have pale cytoplasm containing mucopolysaccharide that stains with PAS, Alcian blue, or mucicarmine stains. Immunohistochemistry staining often shows positivity for cytokeratin (CK) 7.



Extramammary Paget's disease of vulva

@Neet_pg_bot

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 991, 993

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following has a strong association with clear cell adenocarcinoma of the vagina? (Q845608)

A. Male partner who has multiple sexual partners

B. In utero exposure to diethylstilbestrol

C. HPV infection

D. Sexual activity at a young age

Correct Answer: B. In utero exposure to diethylstilbestrol

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and biopsy findings suggest Clear cell adenocarcinoma of the vagina, characterized histologically by cells with clear cytoplasm and hobnail cells and is strongly associated with in-utero exposure to diethylstilbestrol (DES). Vaginal adenosis (precursor lesion for clear cell adenocarcinoma) refers to the presence of glandular columnar epithelium in the proximal vagina. Diethylstilbestrol is a synthetic non-steroidal estrogen that was historically widely used to prevent potential miscarriages by stimulating the synthesis of estrogen and progesterone in the placenta. Side effect of Diethylstilbestrol: Girls born to mothers who were taking this drug during pregnancy were found to have clear cell cancers of female genital tract (vagina, cervix or ovary).

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 994

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 4-year-old girl presents to the pediatric clinic with complaints of vaginal bleeding and a visible mass protruding from her vagina. On examination, a polypoid mass with a "grape-like" appearance is observed. A biopsy is taken, and immunohistochemical staining is positive for desmin. Which of the following will show as a biopsy finding? (Q845609)

A. Cells with small protrusions of cytoplasm from one end

B. Marked atypia of cells with numerous keratin pearls

C. Columnar mucinous epithelium

D. Fibrous stroma covered by mucus-secreting endocervical glands

Correct Answer: A. Cells with small protrusions of cytoplasm from one end

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical presentation and IHC findings suggest Sarcoma botryoides , a rare type of Embryonal rhabdomyosarcoma, characterised by polypoid,rounded, bulky masses that have the appearance and consistency of grapelike clusters, commonly found in infants and children younger than 5 years of age. Embryonal rhabdomyosarcoma: Embryonal: Very young children; Rhabdomyosarcoma: Skeletal muscle differentiation. Histologically characterised by cells with small and oval nuclei with small protrusions of cytoplasm resembling a tennis racket/strap (Strap cells/Tennis racket cells/ Tadpole cells) and rarely cytosolic striations (indicative of muscle differentiation) can be seen.

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 995

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following is an advantage of liquid-based cytology (LBC) over the conventional Pap smear? (Q845610)

A. Cost-effective

B. More widely available in resource-limited settings

C. Adequacy of 8,000-12,000 epithelial cells

D. Allows simultaneous HPV testing

Correct Answer: D. Allows simultaneous HPV testing

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Aspect Conventional Cervical Screening (Pap Smear) Liquid-Based Cytology (LBC) Sample Collection Cells are collected using a spatula or brush and smeared directly onto a glass slide. Cells are collected using a brush and then rinsed into a vial containing a preservative solution. Processing Time Typically longer due to manual preparation and staining. Faster automated processing and staining. Sensitivity and Specificity Lower sensitivity and specificity compared to LBC. Higher sensitivity and specificity for detecting abnormalities. Cost Generally lower cost. Higher cost due to specialized equipment and supplies. (Option A) Follow-up Testing Additional sample collection may be needed if the initial sample is inadequate. Usually provides enough samples for additional tests (e.g., HPV testing) without recollection. (Option D) Adequacy of cells 8000-12000 epithelial cells/ 10 hpf (Option C) 5000 epithelial cells/10 hpf Resource limited setting Available in resource-limited settings (Option B) Specialized equipment and infrastructure are needed

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 1000,1001

@Neet_pg_bot

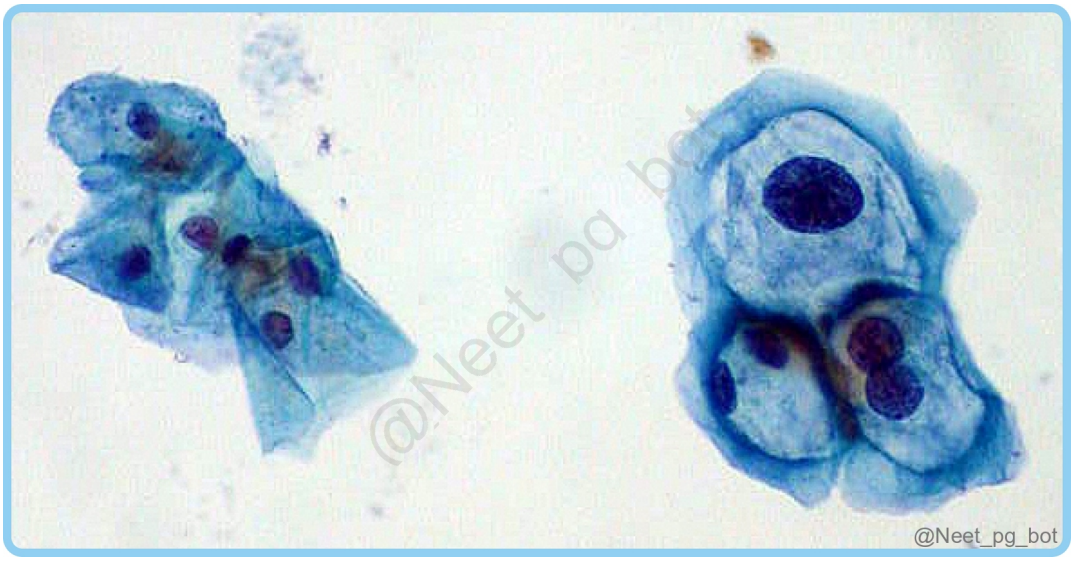
Q8: A 45-year-old woman comes to the OPD for regular Pap smear screening. The smear suggests a low-grade squamous intraepithelial lesion. Which of the following abnormal cell types was most likely seen on the smear? {{caption_text}} (Q845611)

A. Doderlein cells

B. Hobnail cells

C. Arias-Stella reaction cells

D. Koilocytes



Correct Answer: D. Koilocytes

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Koilocytes are abnormal cervical cells seen on pap smears, indicative of HPV infections of the cervix. They are squamous epithelial cells with nuclear enlargement, coarse chromatin, perinuclear cavitation, and irregular nuclear membranes. A rim of condensed cytoplasm often surrounds the perinuclear cavitation, giving the cell a "halo" appearance. Doderlein cells (Option A): Doderlein cells are large, glycogen-rich squamous epithelial cells in the vaginal epithelium, associated with Lactobacillus species. A reduction or absence of Doderlein cells can indicate pathological conditions such as bacterial vaginosis. Hobnail cells (Option B): Hobnail cells are found in clear cell carcinoma of the ovary. Arias-Stella reaction cells (Option C): Arias-Stella reaction cells are a type of glandular epithelial cell found in the endometrium during pregnancy, ectopic pregnancy, or pathological conditions like gestational trophoblastic disease.

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 996-997

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following risk factors is not typically associated with cervical cancer? (Q845612)

A. Smoking

B. Multiple sexual partners

C. Oral contraceptive pill use

D. Nulliparity

Correct Answer: D. Nulliparity

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Nulliparity is not a risk factor for cervical cancer. Multiparity is a risk factor for cervical cancer. Nulliparity is a risk factor for breast and ovarian cancer. Risk factors for cervical cancer include: Human papillomavirus (HPV) infection, particularly High-risk HPVs, is the most important factor in the development of cervical cancer Multiple sexual partners (Option B) or early sexual activity Smoking (Option A) Weak immune system Long-term use of oral contraceptives (OCP) (Option C) High parity Lack of regular cervical screening (Pap tests) Family history of cervical cancer Socioeconomic factors

↑ *Back to this question in Part A*

@Neet_pg_bot

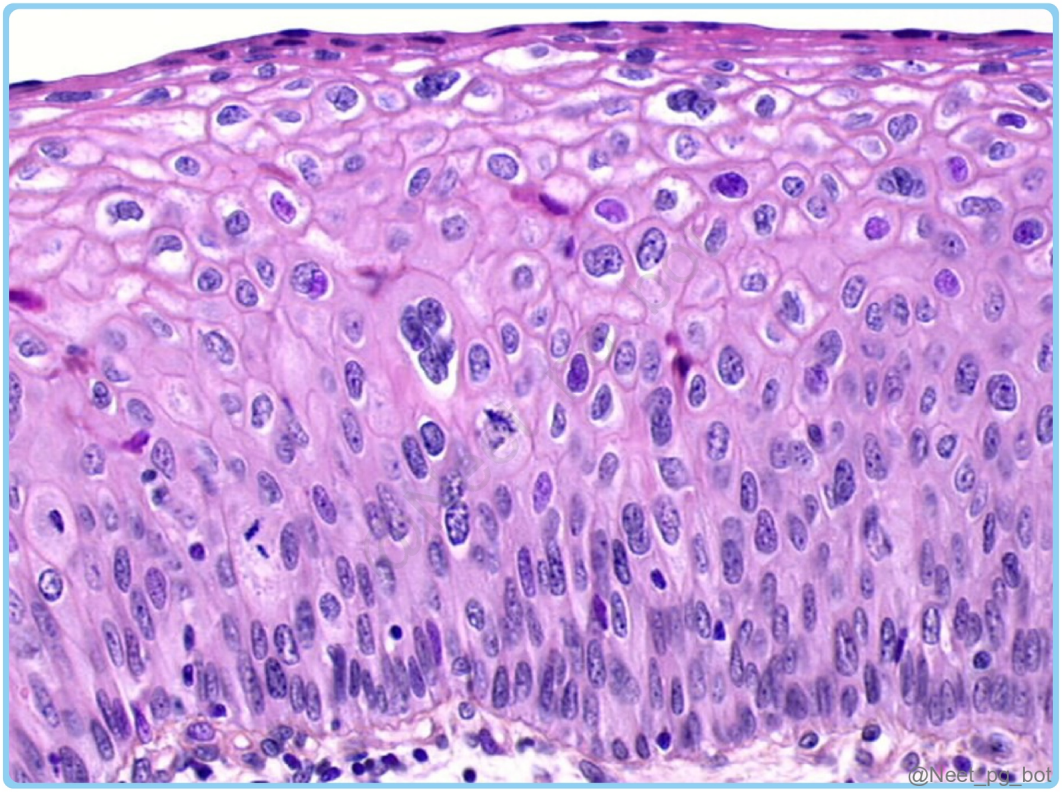
Q10: A 32-year-old woman undergoes a routine gynecological examination. Abnormalities are detected on her pap smear, and colposcopy-guided biopsy reveals dysplastic changes involving two-thirds of the cervical epithelium. What is the most likely diagnosis? {{caption_text}} (Q845613)

A. Cervical intraepithelial neoplasia 1

B. Cervical intraepithelial neoplasia 2

C. Cervical intraepithelial neoplasia 3

D. Invasive cervical carcinoma

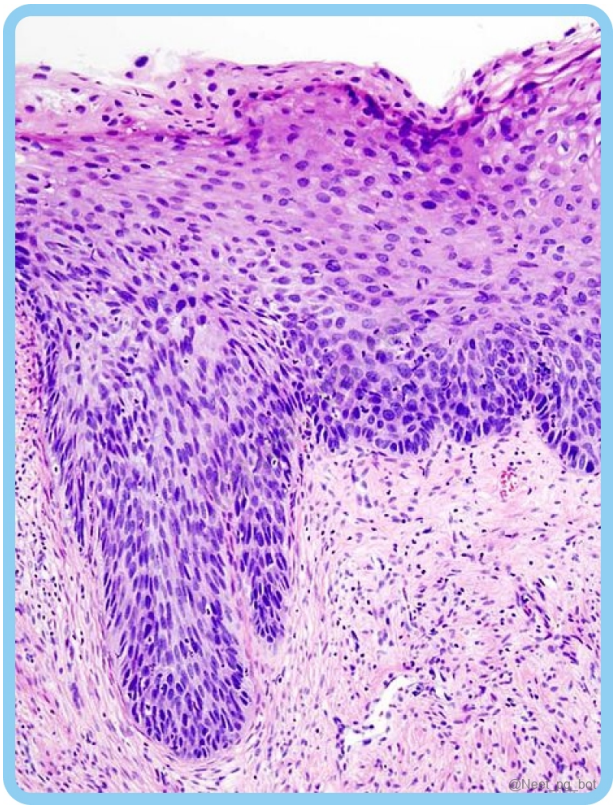


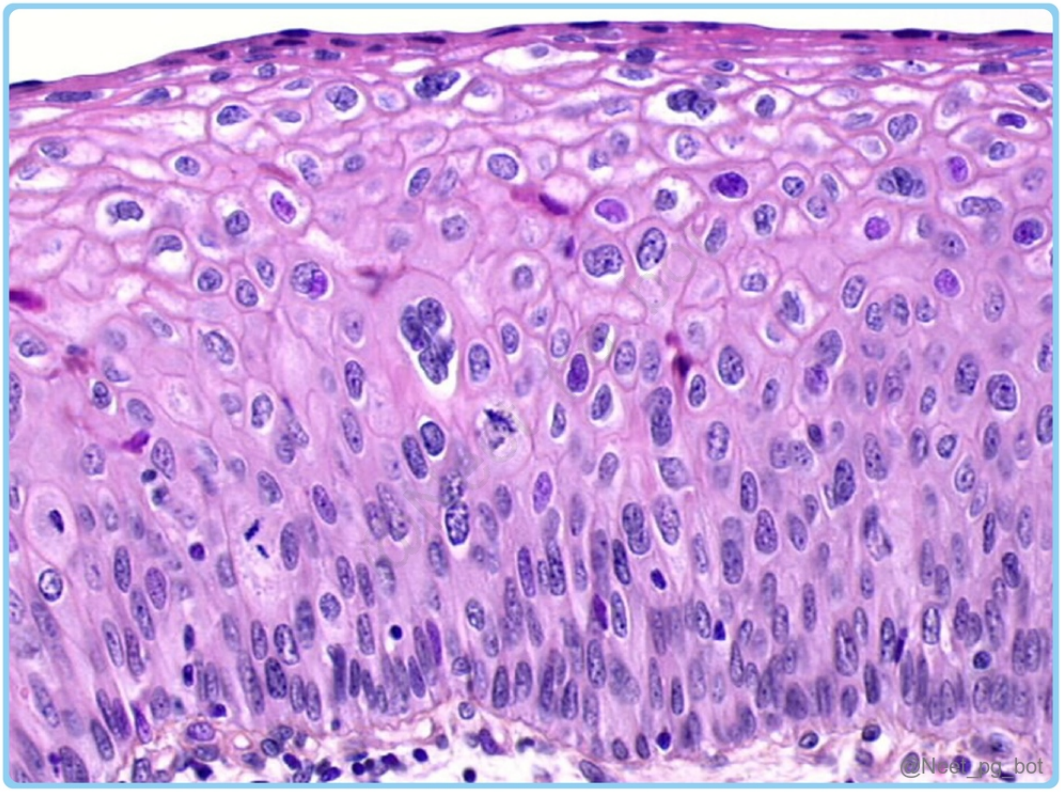
Correct Answer: B. Cervical intraepithelial neoplasia 2

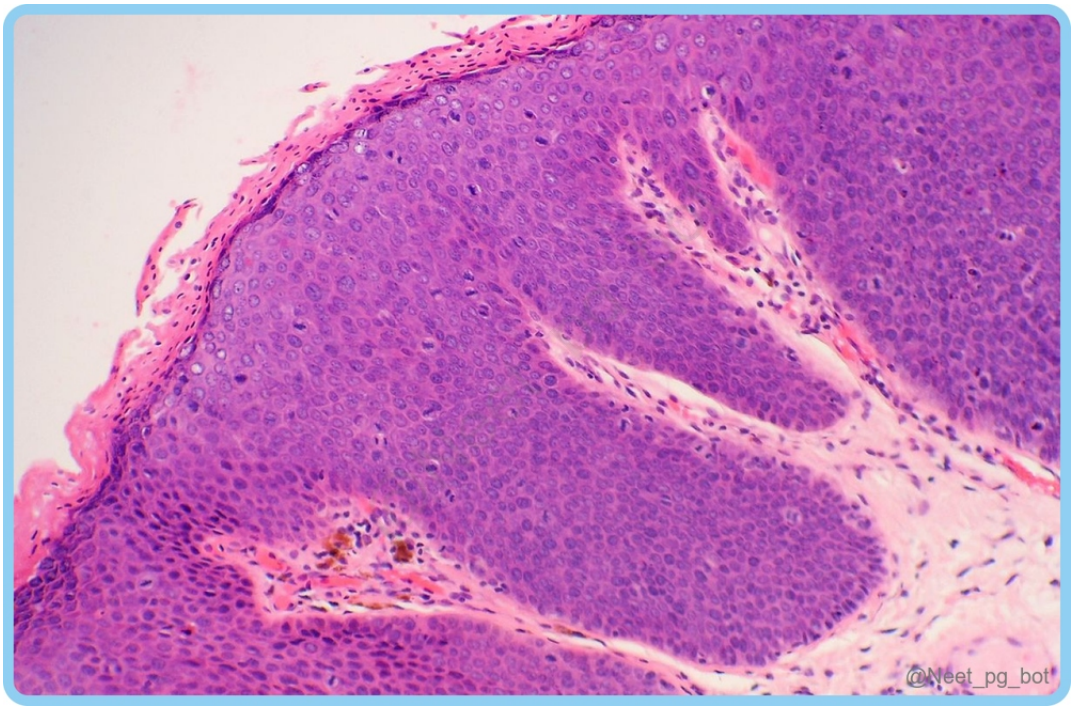
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Grade HPE Features CIN 1 Low-grade squamous intraepithelial lesion of cervical intraepithelial neoplasia with koilocytic atypia showing atypical cells in the lower 1/3rd of the epithelium . CIN 2 {{caption_text}} High-grade squamous intraepithelial lesion (HSIL) with progressive atypia and expansion of the immature basal cells in the lower 2/3rd of the epithelial thickness CIN 3 HSIL with diffuse atypia, loss of maturation, and expansion of the immature basal cells to almost the entire length of the epithelial surface. Carcinoma in situ (CIS): The entire thickness of the cervical surface lining is made up of abnormal, dysplastic cells, but these cells have not yet spread or invaded deeper tissues. Invasive cervical carcinoma (Option D): Invasive cervical carcinoma presents with invasion beyond the basement membrane of the cervical epithelium.







References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 998

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following statements is true regarding the squamous cell carcinoma of the cervix? HPV types 16 and 18 are the most common HPV types identified in invasive cervical cancer. The most common site of metastasis is the lungs. E6 protein interferes with the activity of the tumor suppressor proteins p53. Squamous cell carcinoma is the most common histologic subtype. (Q845614)

A. 1,2,3,4

B. 1,2,3

C. 1,3,4

D. Only 1

Correct Answer: A. 1,2,3,4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Cervical Carcinoma: Squamous cell carcinoma (80%) and adenocarcinoma (15%) are the main cervical cancer subtypes caused by high-risk HPVs (HPV16 and 18). HPV's E6 and E7 proteins disrupt p53 and Rb tumor suppressors, respectively. Lung metastasis is common and indicates poor prognosis. Squamous cell carcinoma is the most common histologic subtype. Squamous cell carcinoma:

@Neet_pg_bot

Q12: Which of the following is most likely associated with basaloid vulvar carcinomas? (Q846624)

A. Not associated with HPV

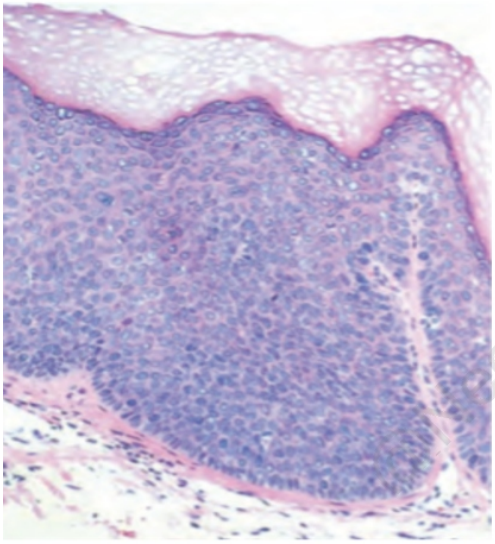
B. Arise from differentiated vulvar intraepithelial neoplasia

C. Keratinising morphology

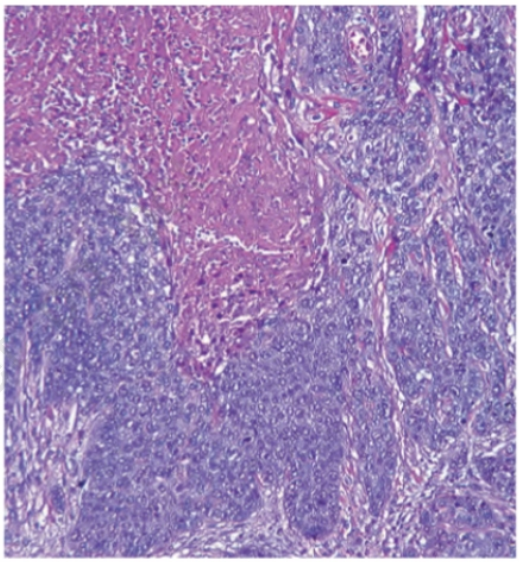
D. High-risk HPV

Correct Answer: D. High-risk HPV

Explanation: The given clinical presentation and biopsy findings suggest Basaloid or warty carcinoma of the vulva, which is highly associated with high-risk HPV, most commonly HPV-16. Types of Vulval Carcinoma: Features Basaloid or Warty carcinoma Keratinising Squamous cell carcinoma Prevalence Less common (30% of cases) More common (70% of cases) HPV association Related to high-risk HPVs, most commonly HPV-16. (Option D) Unrelated to HPV infection. (Option A) Precursor lesion Develop from classic vulvar intraepithelial neoplasia (VIN) Arise from differentiated vulvar intraepithelial neoplasia (differentiated VIN) (Option B) Histological features Basaloid and warty morphology Keratinizing morphology (Option C) Other features No association with lichen sclerosis Often associated with long-standing lichen sclerosis or squamous cell hyperplasia and TP53 mutations.



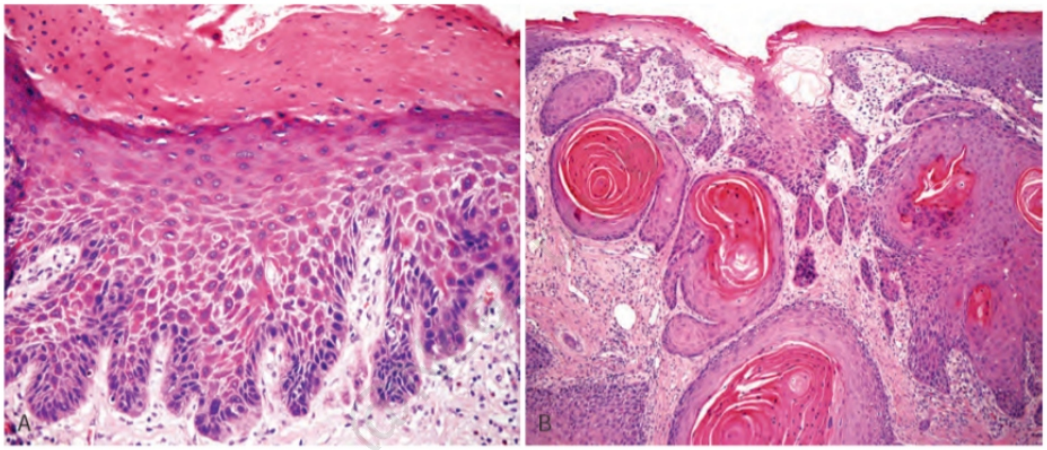
Classic vulvar intraepithelial neoplasia (HPV positive)



Basaloid vulvar carcinoma with foci of necrosis (red) (HPV positive)

@Neet_pg_bot

A



Differentiated vulvar intraepithelial neoplasia (HPV negative)

Keratinizing squamous cell carcinoma of the vulva (HPV negative)

@Neet_pg_bot

[12_Genital System] 054 Pathology Of Female Genital Tract-Ii — Quick Jump

Q1 (p. 2276) *Q2 (p. 2278)* *Q3 (p. 2279)* *Q4 (p. 2280)* *Q5 (p. 2283)* *Q6 (p. 2284)*
Q7 (p. 2286) *Q8 (p. 2287)* *Q9 (p. 2289)* *Q10 (p. 2290)* *Q11 (p. 2294)* *Q12 (p. 2296)*
Q13 (p. 2297) *Q14 (p. 2300)* *Q15 (p. 2301)* *Q16 (p. 2303)* *Q17 (p. 2305)* *Q18 (p. 2305)*
Q19 (p. 2306) *Q20 (p. 2307)*

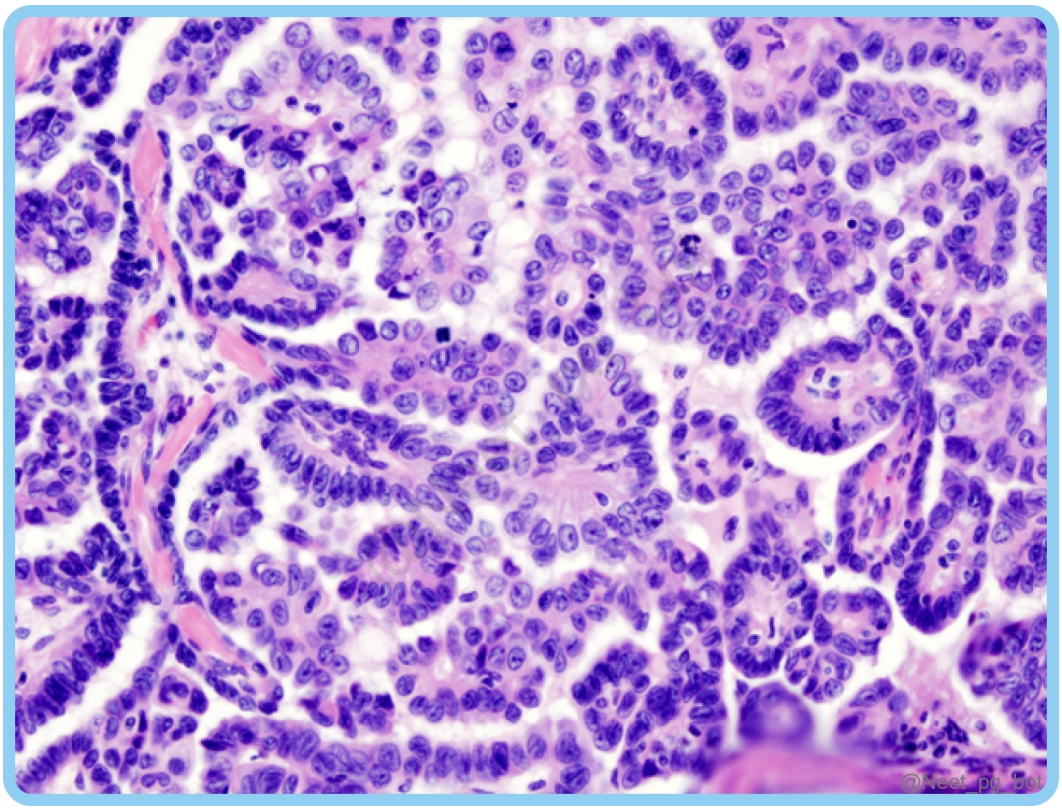
Q1: A 52-year-old woman presents with abdominal bloating, discomfort, and increased abdominal girth. Ascites and a palpable pelvic mass are noted on examination. Histopathological examination shows papillary structures with atypical epithelial cells containing psammoma bodies and elevated CA-125 levels. What is the likely diagnosis? {{caption_text}} (Q845717)

A. Mucinous cystadenocarcinoma

B. Endometrioid carcinoma

C. Serous cystadenocarcinoma

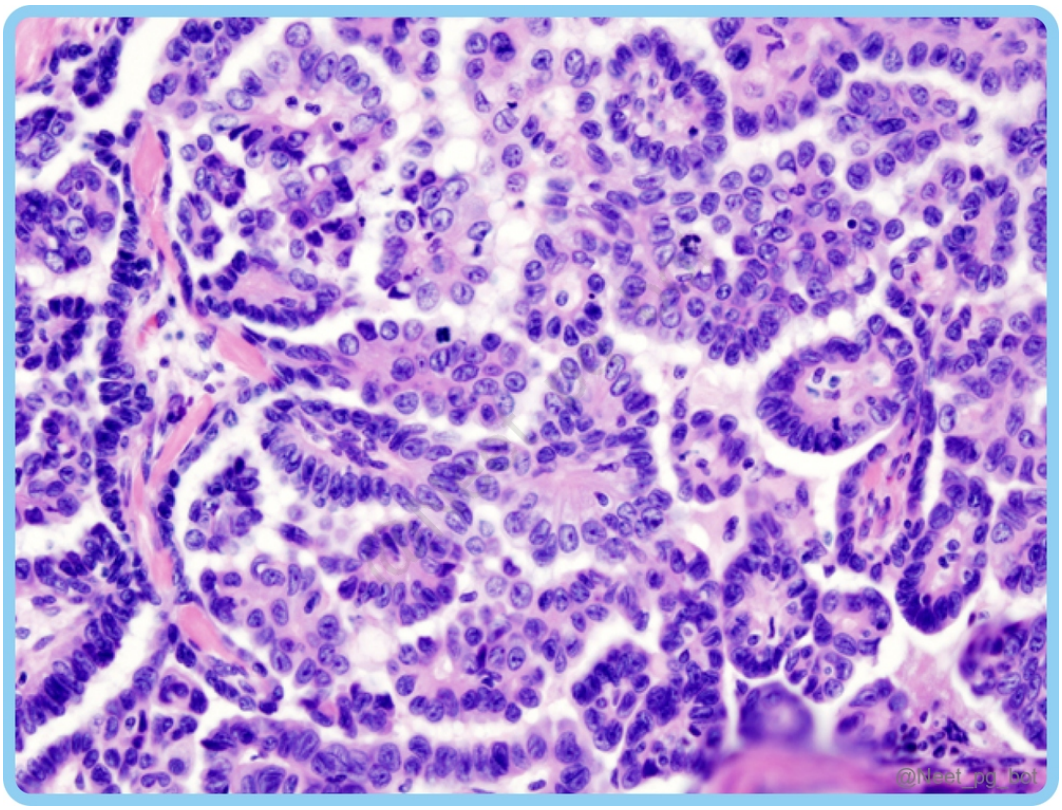
D. Clear cell carcinoma



Correct Answer: C. Serous cystadenocarcinoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The given clinical presentation and histopathological findings point towards diagnosing Serous cystadenocarcinoma of the ovary, characterised by complex papillary structures, psammoma bodies, and atypical epithelial cells with evidence of stromal invasion. Psammoma bodies in the ovaries are always suggestive of serous ovarian tumors and the tumor marker is CA-125. Serous ovarian tumors can be benign or malignant (Serous cystadenocarcinoma) Gross morphology shows larger areas of solid or papillary growth, irregularity, and capsule nodularity. {{caption_text}}



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1019

@Neet_pg_bot

Q2: What is the extent of nonsquamous growth present in Grade 2 endometrial carcinoma? (Q846626)

A. 5% or less nonsquamous solid growth pattern

B. 6 - 50% nonsquamous solid growth pattern

C. > 50% nonsquamous solid growth pattern

D. >75% nonsquamous solid growth pattern

Correct Answer: B. 6 - 50% nonsquamous solid growth pattern

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: FIGO Grading of endometrial carcinoma Grade 1 5% or less nonsquamous solid growth pattern (well-differentiated) with preserved glandular architecture (Option A) Grade 2 6 - 50% nonsquamous solid growth pattern (moderately differentiated) (Option B) Grade 3 > 50% nonsquamous solid growth pattern (poorly differentiated) (Option C)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 32-year-old woman presents with irregular vaginal bleeding and passage of grape-like clusters at ten weeks of gestation. Ultrasound reveals a heterogeneous pattern with fetal parts. On histopathology, some villi appear enlarged, and there is a presence of fetal tissue admixed with abnormal placental tissue. Which of the following is true regarding this condition? (Q846625)

A. High risk of invasive mole

B. Resulting from androgenetic fertilisation

C. Immunostaining for p57 is negative

D. High risk of malignancy

Correct Answer: A. High risk of invasive mole

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This clinical scenario strongly suggests a diagnosis of partial mole, commonly associated with a high risk of invasive mole. A partial mole has bot villi and fetal components, while a complete mole shows only molar villi with no fetal component present. The villi from a partial mole can invade into the myometrium, leading to a condition known as an invasive mole. This feature can be seen in association with a partial hydatidiform mole. Resulting from androgenetic fertilisation (Option B): A partial mole occurs when an ovum is fertilized by more than one sperm, resulting in a triploid or sometimes tetraploid conceptus, depending on the number of sperms involved. Therefore, it is not an example of androgenetic fertilization. Androgenetic fertilization, on the other hand, is seen in a complete mole. In this situation, the ovum is empty and has lost all of its DNA material, leaving it without chromosomes. When such an empty ovum is fertilized by a sperm carrying 23 chromosomes, the product cannot survive with just 23. Therefore, the sperm replicates its chromosomal material to make it diploid (46), which is the characteristic mechanism of a complete mole. Immunostaining for p57 is negative (Option C): Partial mole shows P57 Positivity. High risk of malignancy (Option D): Complete mole has a higher risk of

malignancy, not partial mole.

Robbin's Pathology, 10th edition, pg 1033, 1034

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 29-year-old woman at 11 weeks of gestation presents with vaginal bleeding and passage of grape-like clusters. Ultrasound shows a "snowstorm" appearance without fetal parts. On histopathology, most villi are enlarged with central cistern formation and the absence of fetal tissue. Which of the following is characteristic of this condition? (Q845739)

A. Presence of fetal tissue and partially developed placenta

B. Diploid karyotype, typically 46, XX or 46, XY, with no fetal tissue

C. Triploid karyotype, typically 69, XXX or 69, XXY, with some fetal tissue

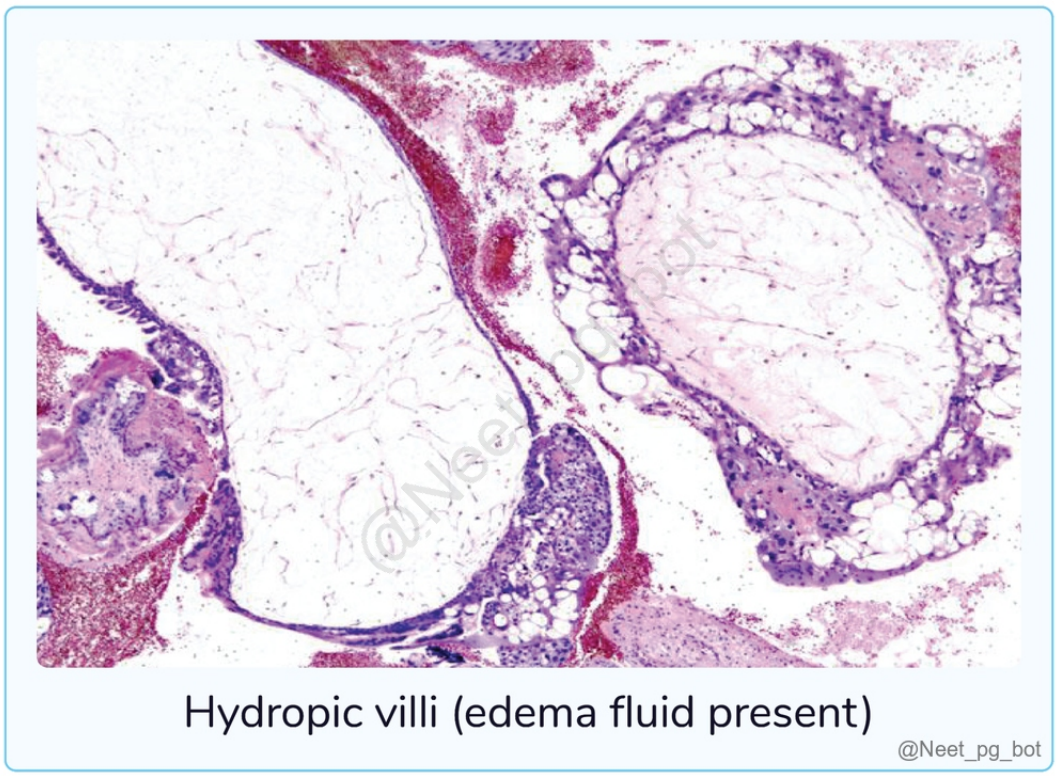
D. Normal-sized chorionic villi with no trophoblastic proliferation

Correct Answer: B. Diploid karyotype, typically 46, XX or 46, XY, with no fetal tissue

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Clinical scenario points to a diagnosis of a complete mole based on the combination of vaginal bleeding, "snowstorm" appearance on ultrasound, absence of fetal tissue, and histopathology showing diffuse trophoblastic proliferation with hydropic villi . A complete mole forms when the ovum loses all its DNA material and has no chromosomes. When such an ovum is fertilized by a sperm carrying 23 chromosomes, the sperm duplicates its genetic material to restore diploidy. As a result, the karyotype of a complete mole is diploid, with 46 chromosomes. (46, XX or 46, XY). Features of complete mole: It has a diploid karyotype . It is only going to have the villi and the mole components. It does not have any fetal part but exhibit extensive trophoblastic proliferation (Diffuse and circumferential). {{caption_text}} {{caption_text}} {{caption_text}}



Hydropic villi (edema fluid present)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 58-year-old postmenopausal woman presents with progressive abdominal distension, shortness of breath, and pelvic pain. Physical examination reveals ascites and a right-sided pleural effusion. Imaging reveals a solid ovarian mass. A biopsy of the mass shows benign ovarian fibroma. Which of the following is the most likely diagnosis? (Q845737)

A. Meigs syndrome

B. Pseudo Meigs syndrome

C. Fitz-Hugh-Curtis syndrome

D. Mayer-Rokitansky-Küster-Hauser syndrome

Correct Answer: A. Meigs syndrome

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Meigs syndrome is characterised by the triad of a benign ovarian fibroma , ascites , and pleural effusion/hydrothorax (commonly right-sided). Features of Meigs syndrome: In pelvis: Ovarian fibroma In abdomen: Ascites In chest or mediastinum: Pleural effusion or hydrothorax (commonly right-sided) Pseudo Meigs syndrome (Option B): Pseudo-Meigs syndrome is characterised by the triad of ascites, pleural effusion , and pelvic mass other than an ovarian tumor. Fitz-Hugh-Curtis syndrome (Option C): Fitz-Hugh-Curtis syndrome is a chronic manifestation of pelvic inflammatory disease (PID), characterised by inflammation of the liver capsule (perihepatitis) without the involvement of liver parenchyma. {{caption_text}} Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome (Option D): MRKH syndrome is a congenital condition characterised by the failure of the development of mullerian ducts leading to the absence of the uterus,fallopian tube and upper part of the vagina in otherwise phenotypically normal females with normal ovarian function.

@Neet_pg_bot

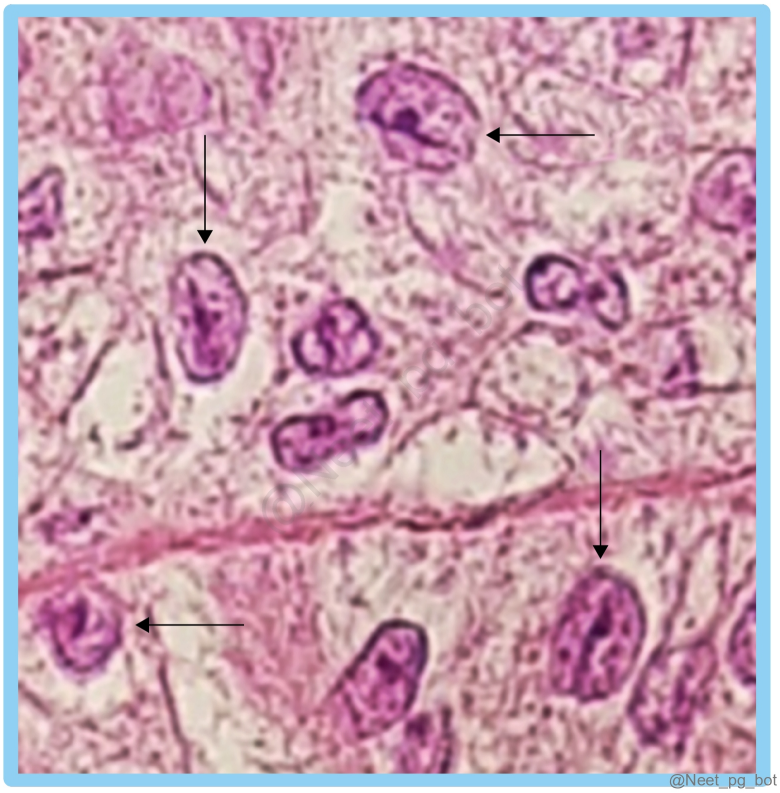
Q6: Which of the following tumours is typically NOT associated with coffee bean nuclei? {{caption_text}} (Q845736)

A. Chondroblastoma

B. Granulosa cell tumour

C. Brenner tumour

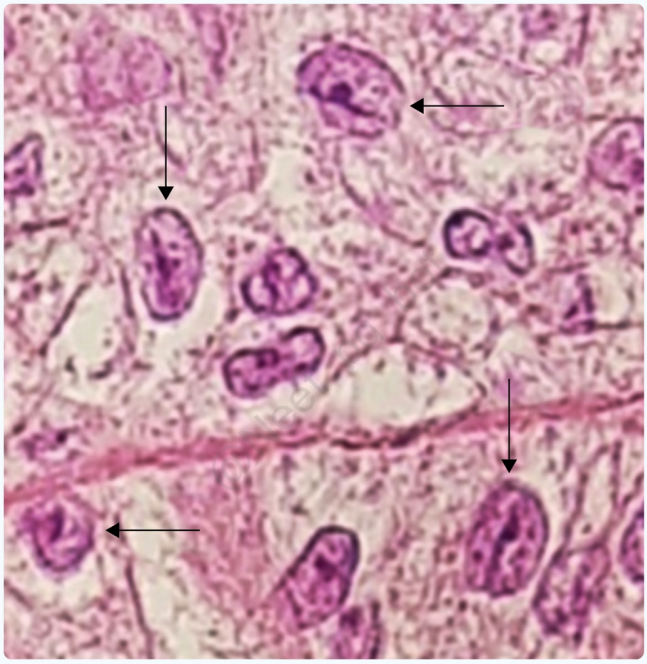
D. Yolk sac tumour



Correct Answer: D. Yolk sac tumour

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Yolk sac tumor shows Schiller-Duval bodies and not coffee bean nuclei. Coffee bean nuclei are characterised by their distinctive longitudinal groove , seen in several tumours, including: Chondroblastoma: Bone tumour (Option A) Granulosa cell tumour: Ovarian tumour (Option B) Brenner tumour: Ovarian tumour (Option C) Langerhans cell histiocytosis: Skin tumour (LCH) Papillary carcinoma thyroid {{caption_text}}



Coffee bean nuclei
(Longitudinal nuclear grooves)

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1025

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 55-year-old postmenopausal woman presents with abnormal uterine bleeding and a pelvic mass. An ultrasound reveals a solid ovarian mass. The mass is surgically removed, and the HPE shows small, follicle-like structures filled with eosinophilic material. Which histological feature is most likely associated with this ovarian tumour? (Q845732)

A. Spindle cells with lipid droplets

B. Call-Exner bodies

C. Reinke crystalloids

D. Signet ring cells

Correct Answer: B. Call-Exner bodies

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and histopathological findings are consistent with a Granulosa cell tumour , a sex cord-stromal tumour. Granulosa cell tumors are typically seen in postmenopausal women and secrete large amounts of estrogen, leading to a hyperestrogenic state. Increased estrogen levels cause endometrial hyperplasia, which leads to abnormal uterine bleeding. 2 microscopic features of Granulosa cell tumors: Call-Exner bodies: These are small, follicle-like structures filled with pinkish eosinophilic material in the lumen of the follicles. Coffee bean nuclei Tumor marker: Inhibin and CD99 positivity Spindle cells with lipid droplets (Option A): It descrives Fibrothecoma which is an ovarian tumor Reinke crystalloids (Option C): Seen in Leydig cell tumor. Signet ring cells (Option D): Seen in Krukenberg tumor. {{caption_text}}

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1026-1028

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 19-year-old woman presents with lower abdominal pain and a rapidly enlarging pelvic mass. Imaging reveals a solid and cystic ovarian tumour. A biopsy of the mass

shows immature neural elements and other embryonic-like tissues, indicating a high risk of malignancy. What is the most likely diagnosis? (Q845729)

A. Mature teratoma

B. Immature teratoma

C. Carcinoid tumour

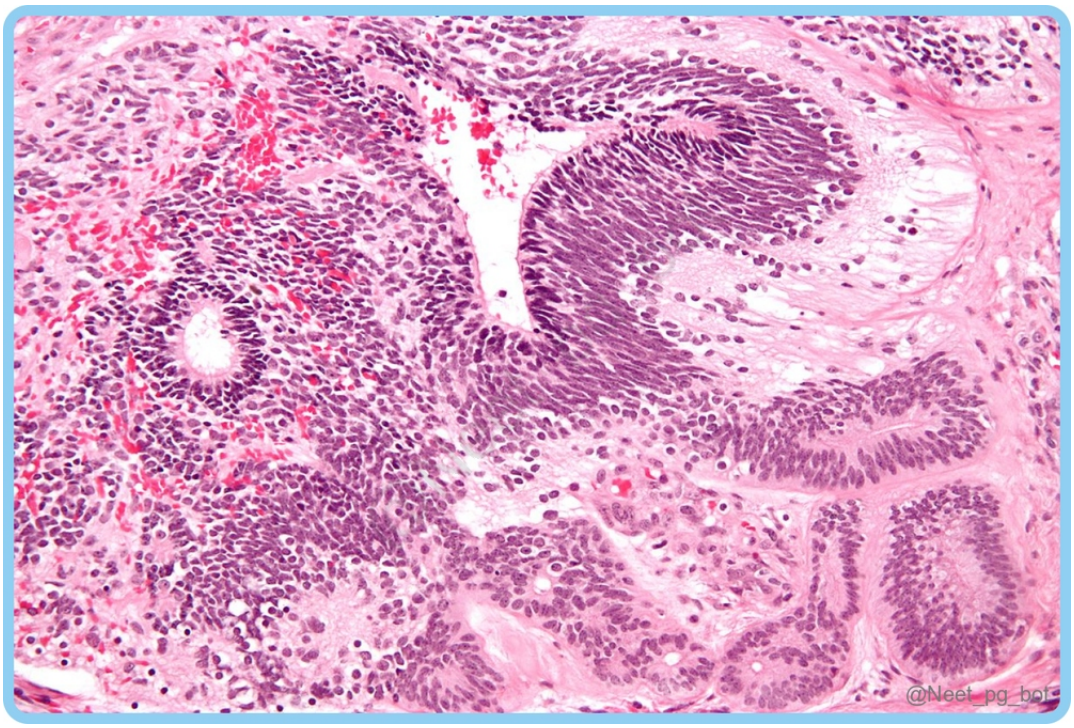
D. Monodermal teratoma

Correct Answer: B. Immature teratoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Types of Teratoma: Mature Teratoma (aka Dermoid cyst) : Benign ovarian tumour comprising tissues from all three germ layers. {{caption_text}} Immature Teratoma: Ovarian tumour with immature or embryonic-like tissues associated with an increased risk of malignancy. {{caption_text}} Monodermal Teratoma: Tumor primarily consists of a single tissue type, like thyroid tissue in struma ovarii or neuroendocrine cells in carcinoid tumours.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1025

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 28-year-old woman presents with severe vaginal bleeding and lower abdominal pain six months postpartum. USG reveals a heterogeneous uterine mass with haemorrhage and necrosis, raising suspicion of choriocarcinoma. What tumour marker is most likely elevated in her condition? (Q845724)

A. CA-125

B. LDH

C. AFP

D. HCG

Correct Answer: D. HCG

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Choriocarcinoma is a gestational trophoblastic disease. Tumor Marker Associated Tumors AFP Yolk sac tumor (Option C) β-hCG Choriocarcinoma LDH and PLAP Dysgerminoma of ovary (Counterpart of Seminoma in testes) (Option B) CA-125 Surface epithelial tumours of ovary (e.g., Serous carcinoma) (Option A)

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1024

↑ *Back to this question in Part A*

@Neet_pg_bot

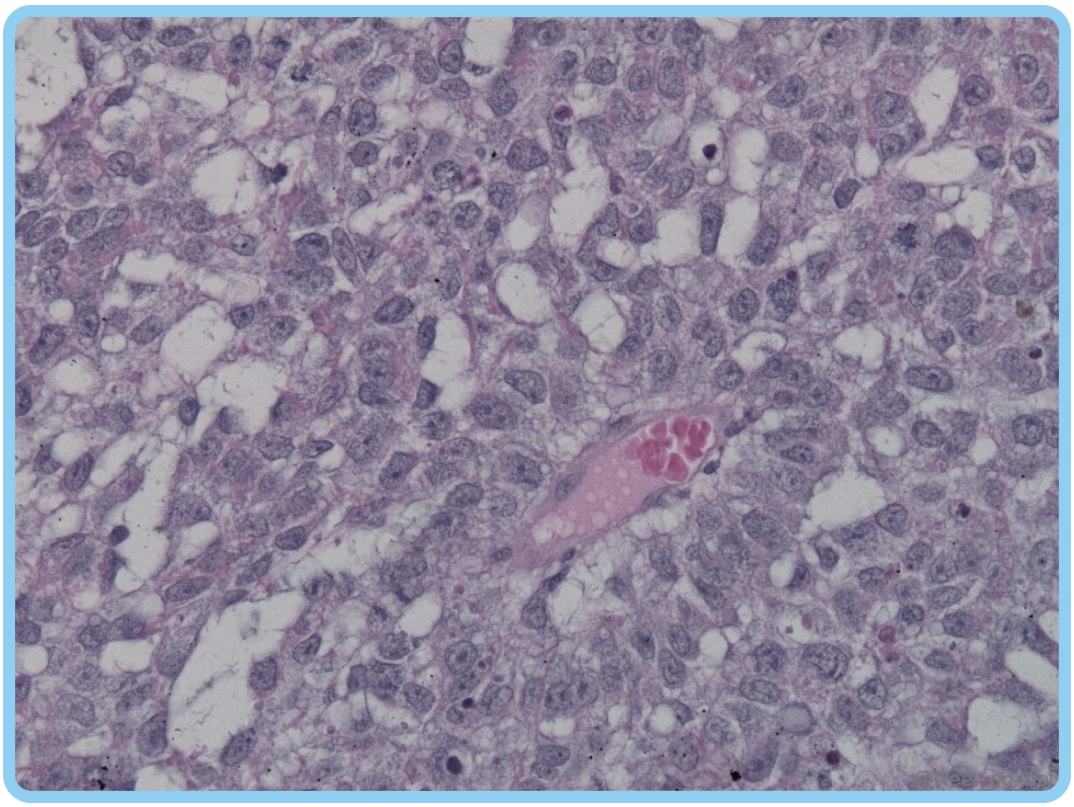
Q10: A 16-year-old female presents with abdominal pain, distension, and a large pelvic mass accompanied by ascites. Elevated serum alpha-fetoprotein levels are detected. Surgical resection of the mass reveals histopathological findings depicted in the image. What is the probable diagnosis? {{caption_text}} (Q845718)

A. Endodermal sinus tumor

B. Dysgerminoma

C. Choriocarcinoma

D. Teratoma



Correct Answer: A. Endodermal sinus tumor

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Given clinical presentation of 16 year old female with abdominal pain and ascites along with elevated serum AFP and HPE showing shiller duval bodies points towards Endodermal sinus tumor/Yolk sac tumor . Shiller duval bodies: It is characterized by a central blood vessel surrounded by a row of tumor cells, a clear space, and another outer row of tumor cells. Classification of Germ cell tumours: Tumour type Histological feature Endodermal Sinus Tumour Presence of Schiller-Duval bodies. {{caption_text}} Dysgerminoma ‘Fried egg appearance’ (large cells with clear cytoplasm and central nuclei). Lymphocytic infiltration in the fibrous septa. {{caption_text}} Choriocarcinoma Consists of cytotrophoblasts and syncytiotrophoblasts. It may show haemorrhage and necrosis. {{caption_text}} Teratoma They comprise tissues from all three germ cell layers (ectoderm, mesoderm, and endoderm), such as skin, hair,teeth, and neural tissue. {{caption_text}}

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1025

↑ *Back to this question in Part A*

Q11: A 34-year-old woman with irregular menstrual cycles and difficulty conceiving undergoes an endometrial biopsy. HPE reveals glands with tall columnar epithelial cells with subnuclear vacuoles. Which phase of the endometrial cycle is most likely being discussed here? (Q845664)

A. Proliferative phase

B. Early secretory phase

C. Late secretory phase

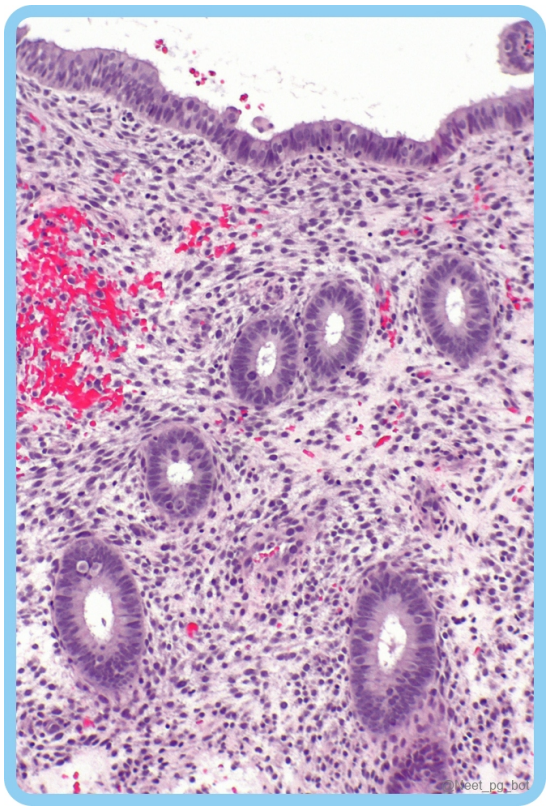
D. Menstrual phase

Correct Answer: B. Early secretory phase

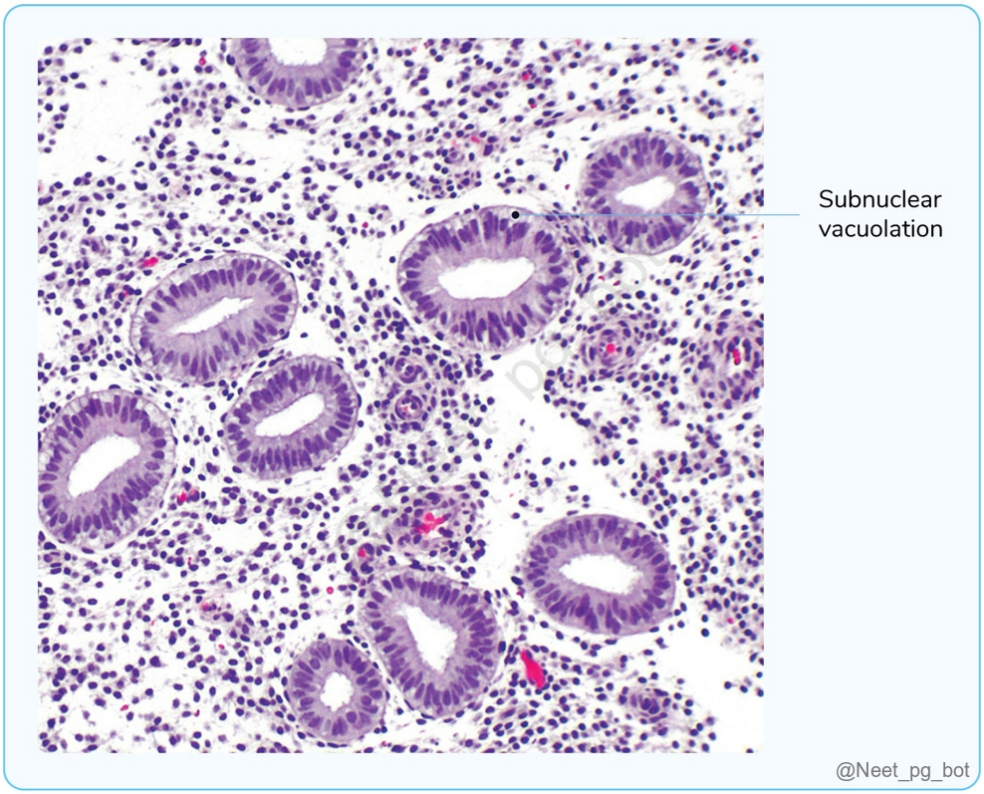
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Phase Day Morphological changes Proliferative phase (Option A) Day 5-14 The rapid growth of glands and stroma from the basalis layer and tall columnar cells with numerous mitotic figures are seen. Absence of mucus secretion or vacuolation. Stroma is composed of spindle cells with minimal cytoplasm. {{caption_text}} Ovulatory phase Day 14 Mature follicle rupture and releases oocyte. Watery mucus is produced in the cervix, which facilitates sperm passage Secretory phase Day 14-28 Early secretory phase: Presence of subnuclear vacuolation in the glandular epithelium. (Option B) {{caption_text}} Late secretory phase: Basal vacuoles gradually move to the apical surface (supranuclear vacuolation) and are shed off later. Glands become tortuous. (Serrated or Sawtooth appearance) Stromal changes include stromal cell hypertrophy infiltration of neutrophils and lymphocytes. (Option C) {{caption_text}} Menstrual phase Day 1-5 Breakdown of the corpus luteum and the subsequent drop in progesterone levels. The functional layer of the endometrium breaks down, leading to bleeding within the stroma and the start of the next menstrual cycle. (Option D)



@Neet_pg_bot



Subnuclear
vacuolation

@Neet_pg_bot

Q14: A 30-year-old pregnant woman at 20 weeks gestation presents with acute onset of severe abdominal pain. On examination, she has a tender, firm uterine mass. Ultrasound shows a fibroid with heterogeneous echotexture and increased vascularity. What type of degeneration is most likely occurring in the fibroid? (Q845698)

A. Hyaline degeneration

B. Calcific degeneration

C. Red degeneration

D. Myxoid degeneration

Correct Answer: C. Red degeneration

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient most likely has red degeneration of fibroid/leiomyoma, characterised by prominent blood vessels and haemorrhage due to inadequate blood supply to the fibroid due to its sudden, rapid growth. Red degeneration of fibroid/leiomyoma: Occurs commonly in pregnant women. Appears beefy red in colour. Symptoms: Nausea, vomiting and high-grade fever. Degenerations seen in fibroids: Hyaline degeneration (Most common) Ca;cific degeneration Red degeneration (Omly degeneration of fibroids seen in pregnancy) Myxoid degeneration

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1014 https://www.uptodate.com/contents/uterine-fibroids-leiomyomas-epidemiology-clinical-features-diagnosis-and-natural-history#H3784133710

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: A 40-year-old woman presents with heavy menstrual bleeding, pelvic discomfort, and increased urinary frequency. Examination reveals an enlarged, irregular uterus, and imaging shows well-defined, solid myometrial masses.Which of the following genetic rearrangements is seen in leiomyomas? (Q845694)

A. MED12

B. KIT

C. p53

D. BRAF

Correct Answer: A. MED12

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario points towards Leiomyoma , (aka fibroid) a benign smooth muscle tumour of the myometrium causing symptoms like heavy menstrual bleeding, pelvic discomfort, and increased urinary frequency, caused by rearrangements in the MED12 gene on chromosomes 12q and 6p. Rearrangements in the MED12 gene can cause 3 conditions in female body: Fibroid/Leiomyoma in the uterus Fibroadenoma of the breast Phyllodes tumor in the breast Leiomyoma are well-defined, whorled, firm, grey-white tumours varying in size. {{caption_text}} Microscopically, there are uniform bundles of smooth muscle cells arranged in whorls with cigar-shaped nuclei. {{caption_text}}

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 55-year-old postmenopausal woman presents with abnormal uterine bleeding and pelvic discomfort. On examination, her uterus is mildly enlarged, and an endometrial biopsy reveals hyperplasia with atypia. Further investigation suggests endometrial carcinoma.Which of the following genes is not responsible for the pathogenesis of Endometrial carcinoma? (Q845691)

A. PTEN

B. KRAS

C. CTNNB-1

D. ETV1

Correct Answer: D. ETV1

Explanation: ETV1 gene overexpression is seen in prostate carcinoma and is androgen-dependent. The clinical presentation suggests endometrial carcinoma, which arises from endometrial hyperplasia due to increased estrogen. This leads to excessive gland growth and myometrial invasion. The genes involved in the pathogenesis of endometrial carcinoma (Type I) are: PTEN (Option A) MLH1 KRAS (Option B) B-Catenin (CTNNB-1) (Option C) PIK3CA. P53 is involved in Type II endometrial carcinoma. Pathogenesis of Endometrial Carcinoma {{caption_text}} Type 2 Endometrial carcinoma {{caption_text}}

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1006-1008

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: Which of the following genetic mutations is associated with Endometrial hyperplasia? (Q845689)

A. BRCA 1 gene

B. PTEN gene

C. TP53 gene

D. BRCA 2 gene

Correct Answer: B. PTEN gene

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: PTEN gene is associated with endometrial hyperplasia. Germline mutation of PTEN, present on chromosome 10, is known as Cowden syndrome. Later on, endometrial hyperplasia can convert into endometrial carcinoma type-1. Another gene associated with endometrial hyperplasia and cancer is the ARID1A gene. BRCA1 (Option A)/BRCA2 (Option D): Breast, Ovarian, Prostate, Pancreatic, Uterine Serous Adenocarcinoma (Type 2) TP53 (Option C): Breast, Colorectal, Ovarian, Uterine Serous Adenocarcinoma (Type 2)

@Neet_pg_bot

Q19: Which of the following statements is NOT true about Adenomyosis? (Q845688)

A. It presents with abnormal uterine bleeding.

B. Ectopic endometrial tissue is found at least 2.5 cm from the endometrial junction.

C. It is seen in pre-menopausal women.

D. Biopsy shows irregular nests of endometrial stroma arranged within the myometrium.

Correct Answer: B. Ectopic endometrial tissue is found at least 2.5 cm from the endometrial junction.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Adenomyosis is the presence of endometrial tissue within the myometrium at least 2.5 mm away from the endometrial / endomyometrial junction (not 2.5 cm). It is typically seen in pre-menopausal, multiparous

women in their 30-40’s (Option C) and is associated with a history of prior uterine surgery like C-section and increased exposure to estrogen. Clinical presentation includes: Irregular and heavy menstrual bleeding (menometrorrhagia) (Option A) Crampy menstrual pain (dysmenorrhea) Pain during intercourse (dyspareunia) Pelvic discomfort, particularly before menstruation. HPE shows irregular nests of endometrial stroma arranged within the myometrium (Option D) Adenomyosis MRI : can show salt and pepper appearance. {{caption_text}}

@Neet_pg_bot

Q20: A 28-year-old woman with chronic pelvic pain worsened during menstrual periods and accompanied by heavy bleeding, was found to have a 'chocolate' brown cyst on her ovaries during a laparoscopy. What is the most commonly accepted theory for the pathogenesis of this condition? (Q845686)

A. Benign metastasis theory

B. Metaplastic theory

C. Extrauterine stem/progenitor cell theory

D. Regurgitation theory

Correct Answer: D. Regurgitation theory

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and presence of a chocolate brown cyst on the ovaries suggest Endometriosis . Endometriosis is a condition in which endometrial glands and stroma are located at sites other than the endometrium. When the endometrial glands are present in the ovary, as in this case, the ovary develops a chocolate brown color , which occurs because the endometrial tissue within the ovary undergoes menstruation every month, leading to the accumulation of old, altered blood that gives the ovary its characteristic appearance.. The Regurgitation theory (Sampson's theory) proposes that endometriosis is caused by the backward flow of menstrual blood through the fallopian tubes into the pelvic cavity. In this theory, endometrial cells carried in the menstrual blood implant on pelvic surfaces, such as the ovaries, and then proliferate to form endometriotic lesions. Other theories for the pathogenesis of endometriosis: Benign metastasis theory (Halban's theory) (Option A) Metaplastic theory (Meyer and Ivanoff's theory) (Option B) Extrauterine stem/progenitor cell theory (Option C)

« Back to Folder Directory

[12_Genital System] 055 Previous Year Questions — Quick Jump

Q1 (p. 2309) *Q2 (p. 2310)* *Q3 (p. 2311)* *Q4 (p. 2313)* *Q5 (p. 2314)* *Q6 (p. 2315)*
Q7 (p. 2319) *Q8 (p. 2319)* *Q9 (p. 2323)* *Q10 (p. 2326)* *Q11 (p. 2330)* *Q12 (p. 2331)*
Q13 (p. 2332)

Q1: A patient presents with ascites and omental caking. Imaging reveals solid components in an adnexal mass, and there is a long-standing history of symptoms. CA-125 is positive. What is the most probable diagnosis? (Q865380)

A. Serous ovarian tumor

B. Mucinous ovarian tumor

C. Endometroid tumor

D. Granulosa cell tumor

Correct Answer: A. Serous ovarian tumor

Explanation: The presence of ascites, omental caking, a solid adnexal mass, elevated CA-125, and chronic vague symptoms strongly points to serous ovarian tumor. Types of Epithelial Ovarian Tumor: Type of Epithelial Ovarian Tumor Characteristics Clinical Presentation Serous Tumors Serous Cystadenoma: Benign, unilateral, cystic spaces with serous epithelium. Large cystic mass, unilateral. Serous Cystadenocarcinoma: Malignant, often bilateral, cystic and solid components. Bilateral involvement in 30%, elevated CA-125. Mucinous Tumors Mucinous Cystadenoma: Benign, unilateral, filled with mucinous fluid. Large, unilateral mass. Mucinous Cystadenocarcinoma: Malignant, unilateral, mucinous epithelial lining. May rupture and spread to the peritoneum. Endometrioid Tumors (Option C ruled out) Endometrioid Carcinoma: Arises from endometrial-like tissue, solid and cystic. Solid and cystic components, associated with endometriosis. Clear Cell Tumors Clear Cell Carcinoma: Clear cytoplasm due to glycogen accumulation. Advanced stage, associated with endometriosis. Brenner Tumors (Transitional Cell) Brenner Tumor: Transitional epithelial cells resembling urinary tract epithelium. Rare, usually benign. Mucinous ovarian tumor (Option B) typically presents as a large, unilateral, multiloculated cystic mass and is less commonly associated with peritoneal spread or omental caking. CA-125 elevation is not as prominent unless the disease is advanced, and it lacks the classic imaging and spread pattern seen in serous carcinoma. Granulosa cell tumors (Option D) are sex cord-stromal tumors that secrete estrogen and often cause hormonal symptoms like abnormal uterine bleeding; they rarely cause ascites or omental caking, and CA-125 is typically not elevated.

Shaw’s Textbook of Gynaecology, 17th Edition, Page 442.

↑ *Back to this question in Part A*

@Neet_pg_bot

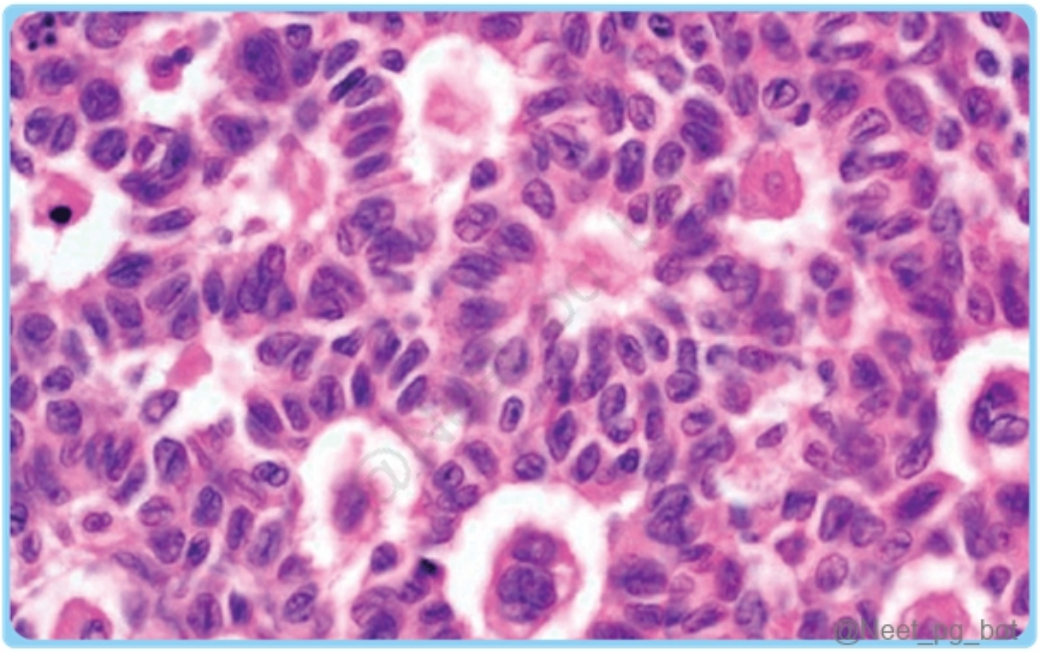
Q2: A histopathological image of an ovarian mass in a lady is shown below. Which of the following statements are true regarding this condition? Sex cord stromal tumor Call-Exner bodies are seen CA125 is high Inhibin is a marker (Q865416)

A. 1, 2, 3

B. 1, 2, 4

C. 2, 4

D. 1, 4



Correct Answer: B. 1, 2, 4

Explanation: The ovarian tumor showing Call-Exner bodies on histopathology is most consistent with a Granulosa Cell Tumor, a type of Sex Cord-Stromal Tumors , for which inhibin serves as an important diagnostic marker. Feature Sertoli-Leydig tumour, Pure Leydig tumour (or Hilus cell tumour) Fibroma, Thecoma, Fibrothecoma Granulosa Cell Tumor Derived from Sertoli or Leydig cells Ovarian stroma Granulosa cells of ovarian follicle Age of Occurrence Second and third decades Any age Postmenopausal (adult type), any age (juvenile type) Associated symptoms Abnormal sexual development or Virilization Associated with Meigs syndrome and basal nevus syndrome Precocious sexual development in juveniles or abnormal uterine bleeding, endometrial hyperplasia (carcinoma) in adults Histological features Reinke crystalloids (in pure Leydig cell tumours) Well-differentiated

fibroblasts (fibroma), plump spindle cells with lipid droplets (thecomas) Call-Exner bodies, Coffee bean nuclei (Statement 2) Mutations & Markers Mutations in DICER1 (which encodes endonuclease) Vimentin +, Thecoma: Oil Red O +ve Fibroma: Oil Red O -ve Elevated inhibin levels, CD99+, and FOXL2 mutations (in adult cases) (Statement 4) Prognosis Low recurrence or metastasis rate (<5%) Benign; Rarely malignant (fibrosarcomas) Potentially malignant with unpredictable behaviour; 10-year survival rate 85%

↑ *Back to this question in Part A*

@Neet_pg_bot

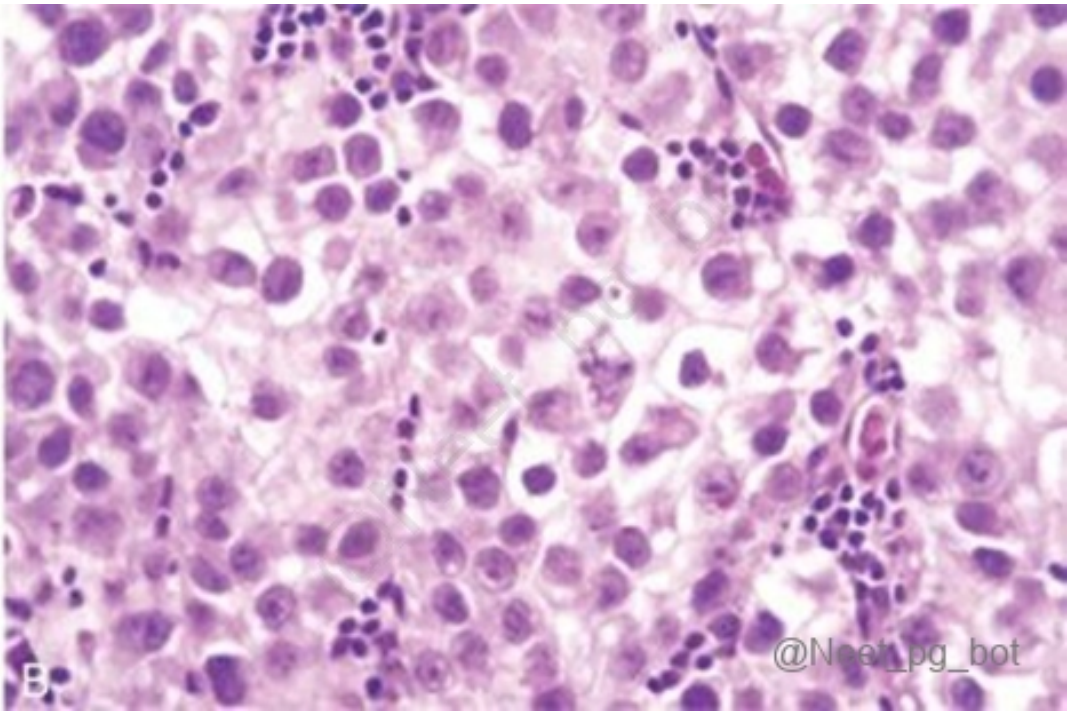
Q3: A 30-year-old man presents with a painless testicular mass. An ultrasound shows a well-circumscribed, homogeneous, non-hemorrhagic testicular tumour. Which of the following is the most likely diagnosis? (Q866364)

A. Yolk sac tumour

B. Choriocarcinoma

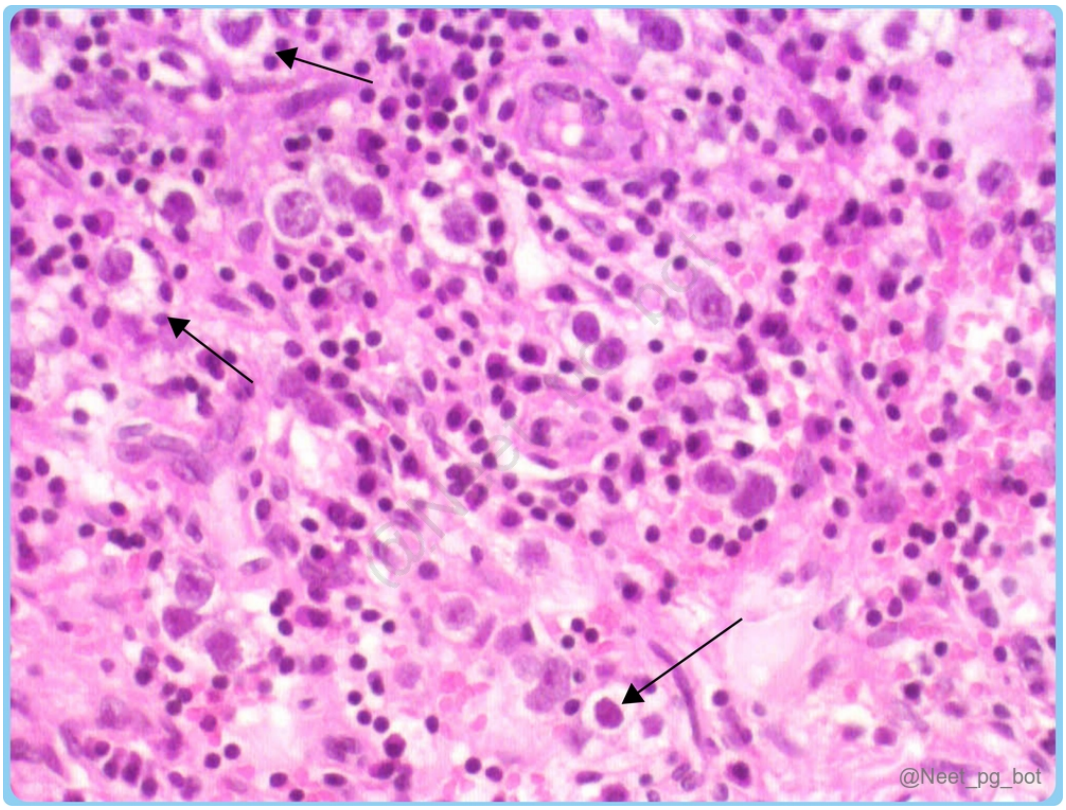
C. Teratoma

D. Seminoma



Correct Answer: D. Seminoma

Explanation: The given histopathological image shows features suggestive of testicular seminoma. Histology of seminoma: Sheets of monomorphic cells. The sheets are divided into poorly demarcated lobules by the septa of the fibrous tissue. The septa show lymphocytic infiltration (T lymphocytes). The classic seminoma cell is large and round to polyhedral with a distinct cell membrane and a large, central nucleus with one or two prominent nucleoli. The cytoplasm is clear or watery appearing and contains glycogen . The arrows in the image below show seminomatous tumour cells. Seminoma: It is the most common germ cell tumour of the testis. A similar presentation in the ovary is called dysgerminoma , and germinoma is present in the pineal gland . Incidence: Peak incidence in the fourth decade. Genetics: Seminomas contain isochromosome 12p and express OCT3/4 & NANOG. Gross: Seminoma has a homogeneous, grey-white, lobulated cut surface, usually devoid of haemorrhage or necrosis . Generally, the tunica albuginea is not penetrated, but extension to the epididymis, spermatic cord, or scrotal sac occasionally occurs.



References:

@Neet_pg_bot

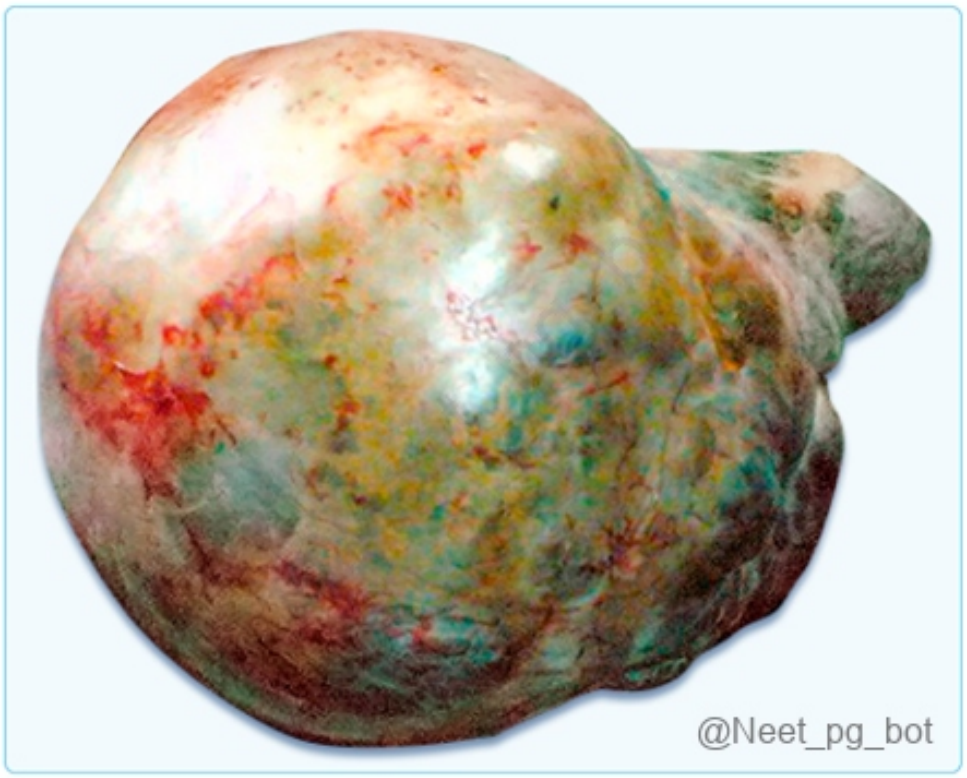
Q4: A patient presents with an ovarian mass that is multiloculated and has a serum CA-125 level >1000 U/mL. What is the most likely diagnosis? (Q866385)

A. Serous cystadenoma

B. Mature teratoma

C. Granulosa cell tumor

D. Serous cystadenocarcinoma



Correct Answer: D. Serous cystadenocarcinoma

Explanation: Serous cystadenocarcinoma is the most common malignant epithelial ovarian tumour , often bilateral, and tends to be multiloculated with papillary projections. CA-125 is a tumour marker for epithelial ovarian cancers, especially serous and endometrioid types . A very high CA-125 (>1000 U/mL) is far more suggestive of malignancy than benign lesions. Patients often present with abdominal distension, ascites, and an adnexal mass. Incorrect Options: Serous cystadenoma (Benign epithelial tumour) (Option A): Usually unilocular or mildly multilocular, with thin walls and clear serous fluid. CA-125 levels may be normal or only mildly elevated, not usually >1000. There is no invasive growth, and it occurs in younger women compared to cystadenocarcinoma Mature teratoma (Dermoid cyst) (Option B): Benign germ cell tumour containing ectodermal derivatives like hair, teeth, and sebaceous material. It usually occurs in younger women (teens to early adulthood). CA-125 is not a typical marker; instead, you might find elevated AFP or β-hCG in other germ cell tumours (not teratomas). On imaging, it often has fat-fluid levels or calcifications, not a multiloculated cystic appearance. Granulosa cell tumour (Sex cord–stromal tumour) (Option C): Often estrogen-producing may cause precocious puberty in children or postmenopausal bleeding in older women. Serum marker: Inhibin (not CA-125). Usually, a solid or cystic-solid mass, not a multiloculated cyst with such high CA-125.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: What is the role of inhibin? (Q860564)

A. Stimulates the release of FSH

B. Inhibits the secretion of FSH

C. Inhibition of PRL

D. Stimulation of PRL

Correct Answer: B. Inhibits the secretion of FSH

Explanation: Inhibin from the granulosa cells inhibits FSH secretion. It is a hormone primarily produced by the ovaries (in females) and testes (in males). It regulates the reproductive system by inhibiting the secretion of FSH (Follicle-Stimulating Hormone) from the anterior pituitary gland. Inhibin suppresses the FSH Inhibin B: Before ovulation Inhibin A: After ovulation Stimulates the secretion of FSH (Option A): Inhibin does not stimulate FSH release; instead, it inhibits it. FSH is involved in the growth and maturation of reproductive cells, but inhibin reduces its secretion once the follicle or sperm production reaches sufficient levels. Inhibition of PRL (Option C) and Stimulation of PRL (Option D): Inhibin does not directly regulate prolactin (PRL), a hormone involved in milk production. PRL levels are primarily controlled by dopamine from the hypothalamus and other factors, not by inhibin. Therefore, inhibin neither inhibits nor stimulates PRL production.

@Neet_pg_bot

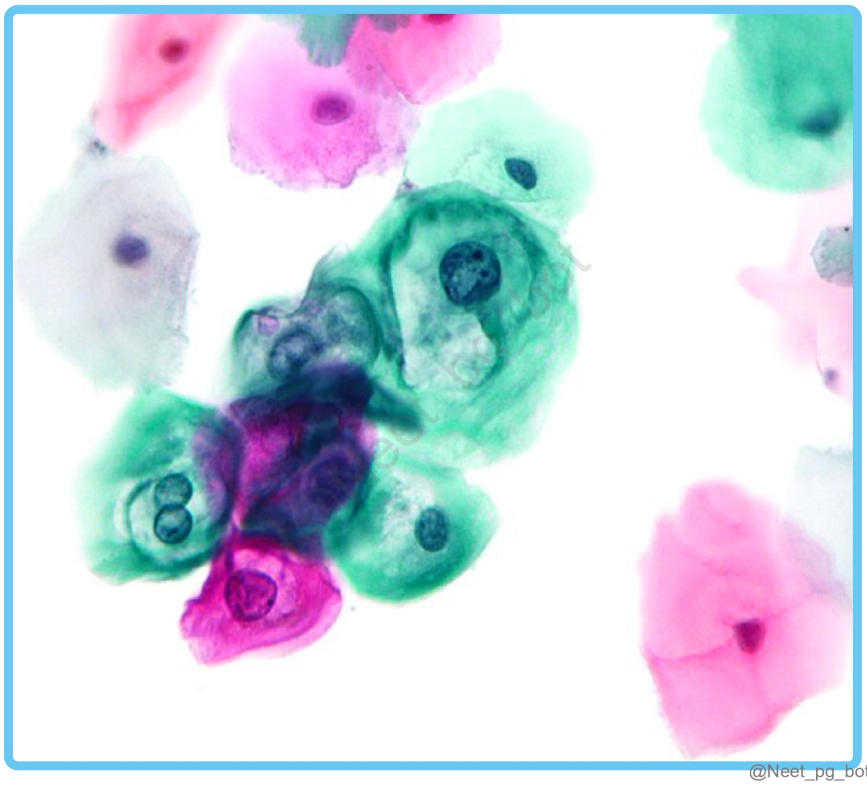
Q6: In the cervical smear below, which of the following stains are used (Q857417)

A. Papanicolaou stain

B. H & E stain

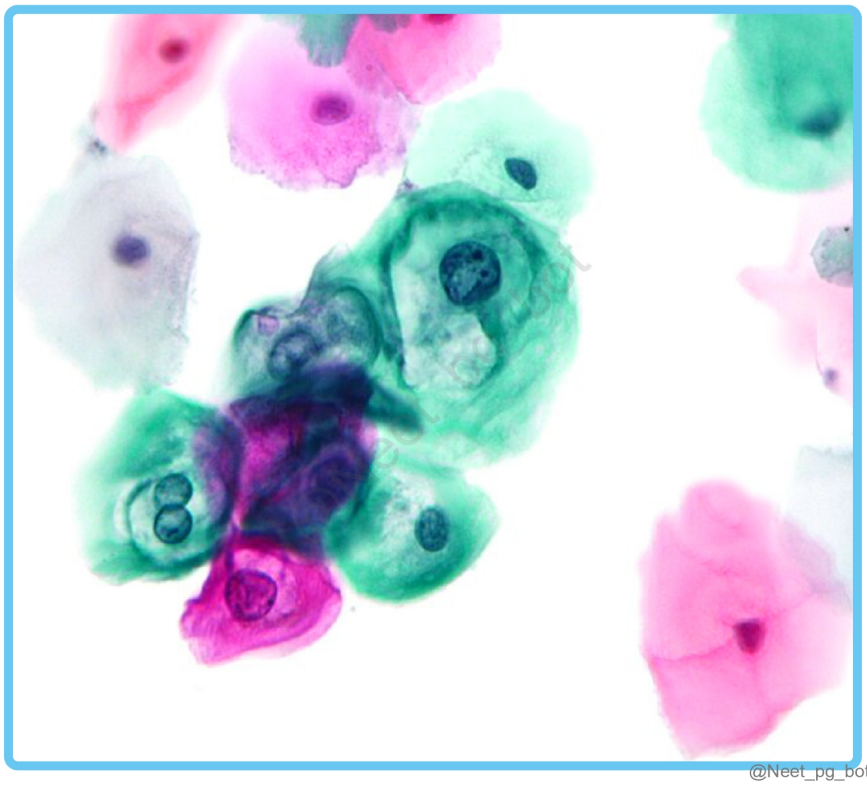
C. Giemsa stain

D. Toluidine blue



Correct Answer: A. Papanicolaou stain

Explanation: Papanicolaou stain is the standard stain used in cervical smears to detect cellular abnormalities. {{caption_text}} The Pap stain results in: Well-stained nuclear chromatin Differential polychromatic counterstaining of the cytoplasm Cytoplasmic transparency H & E stain (Option B) (hematoxylin and eosin) staining procedure uses two dyes to stain tissue samples, making it easier to see cell structure under a microscope; this is commonly used for histopathological tissue sections , not for cervical smears. {{caption_text}} Giemsa stain (Option C) is used to stain blood and bone marrow smears, as well as some parasites, but it is not used in cervical cytology. {{caption_text}} Toluidine blue (Option D) is a basic metachromatic dye primarily used to stain acidic components of tissues, such as nucleic acids and mast cell granules. It is not used for routine cervical cytology. {{caption_text}}



@Neet_pg_bot

Q7: Which of the following tumour markers are positive for seminoma? PLAP OCT3/4 NANOG HCG (Q854709)

A. 1 only

B. 1 and 2

C. 1, 2 and 3

D. 1, 2, 3 and 4

Correct Answer: D. 1, 2, 3 and 4

Explanation: Seminomas are characterized by specific tumour markers like PLAP (Placental alkaline phosphatase) HCG LDH Newer markers: OCT ¾ NANOG CD117 SALL4 Seminoma is the most common germ cell tumour of the testis. A similar presentation in the ovary is called dysgerminoma , and germinoma is present in the pineal gland . Incidence: Peak incidence in the fourth decade. Gross: Seminoma has a homogeneous, grey-white, lobulated cut surface, usually devoid of haemorrhage or necrosis .

@Neet_pg_bot

Q8: Which of the following conditions is NOT caused by high-risk strains of human papillomavirus (HPV)? (Q855950)

A. Cervical cancer

B. Anal cancer

C. Oropharyngeal cancer

D. Laryngeal papillomatosis

Correct Answer: D. Laryngeal papillomatosis

Explanation: Laryngeal papillomas are benign lesions primarily associated with HPV serotypes 6 and 11 . These serotypes are known to cause condyloma acuminatum and are commonly associated with laryngeal lesions, particularly in children and young adults Types of HPV Cutaneous involvement HPV 1, 2, 3 (low risk) Filiform wart Verruca Plantaris HPV 5, 8 (high risk) Epidermodysplasia Verruciformis Mucosal involvement HPV 6, 11

(low risk) Condyloma Acuminatum Recurrent laryngeal papillomas HPV 16, 18, 31, 33, 35 (high risk) Squamous cell carcinoma HPV 16 (High risk) LSIL, HSIL, Carcinoma cervix Vulval carcinoma Oropharyngeal SCC HPV 18 (High risk) LSIL, HSIL, Carcinoma cervix Anogenital carcinoma Cutaneous involvement Benign Warts Common Skin Warts (Verruca Vulgaris) : Small, hard, rough growths on the skin; commonly seen in children (associated with serotypes 2, 4, 27, 57). Flat Warts (Verruca Plana) : Also prevalent among children. Plantar Warts (Verruca Plantaris) : Benign lesions commonly found in adolescents (linked to serotype 1). {{caption_text}} {{caption_text}} Epidermodysplasia Verruciformis Rare autosomal recessive conditions may progress to squamous cell carcinoma, especially in sun-exposed areas. Associated with serotypes 5, 8 , 9, 12, 17, 20, 36, and 47. {{caption_text}} Mucosal involvement Anogenital Warts It is also known as Condyloma Acuminatum. A sexually transmitted infection in adults, associated with HPV serotypes 6 and 11. {{caption_text}} Head and Neck Lesions Benign : Recurrent laryngeal papillomas , especially in children (serotypes 6, 11). Malignant : Laryngeal and esophageal carcinomas (serotypes 16, 18) {{caption_text}} Carcinoma Cervix Mainly squamous cell carcinoma , linked to high-risk serotypes like 16, 18, 31, 33, and others . Serotype 16 alone accounts for ~50% of cases, while serotypes 16 & 18 together cause ~70% of cervical cancers.

@Neet_pg_bot

Q9: What is the most probable tumour that a 22-year-old woman with a sizable growth in her right ovary, which has been determined to originate from all three germ layers based on histopathology, is experiencing? (Q857106)

A. Dysgerminoma

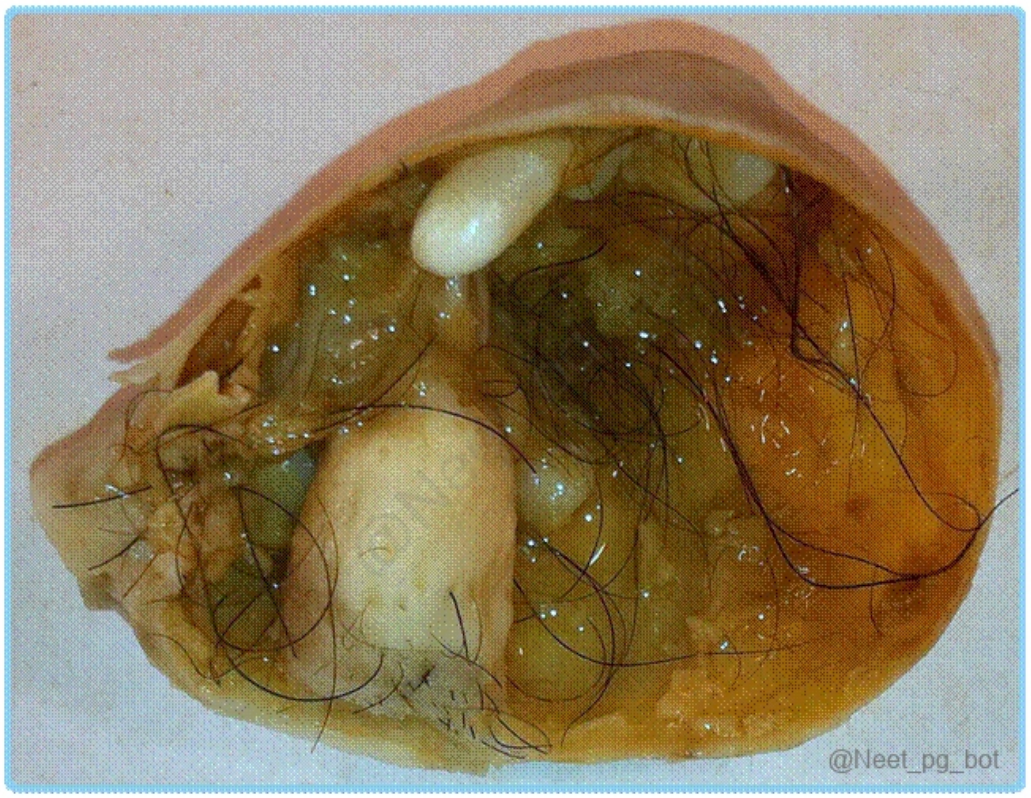
B. Teratoma

C. Thecoma

D. Theca lutein cyst

Correct Answer: B. Teratoma

Explanation: Teratomas are tumours that originate from all three germ layers (ectoderm, mesoderm, and endoderm) and are commonly found in the ovaries. They are often seen in young women and can contain a variety of tissue types, such as hair, teeth, and muscle, which reflects their origin from all three germ layers. {{caption_text}} Immature teratoma: Bulky, solid ovarian tumours that contain immature neuroepithelium, cartilage, bone, and muscle, with areas of necrosis and haemorrhage. They grow rapidly, often spreading beyond the ovary. They are seen in young females and have a high risk of malignancy. They have small, round blue cells (Immature neural components). {{caption_text}} Mature teratoma Mature teratomas, or dermoid cysts , are common benign ovarian tumours found in young women. They are bilateral in 10-15% of cases. They contain tissues from all three germ layers, including skin, hair, and teeth, and can rarely undergo malignant transformation to squamous cell carcinoma. Grossly, they are unilocular cysts with a thin wall and hair; microscopically, they have stratified squamous epithelium and sebaceous glands. Monodermal teratoma: Monodermal teratomas consist predominantly of a single type of tissue, such as thyroid tissue in struma ovarii or neuroendocrine cells in carcinoid tumours. They lack immature or embryonic-like tissues and typically do not have a high risk of malignancy. Dysgerminoma (Option A) is also a type of germ cell tumour (GCT) that typically secretes beta hCG. {{caption_text}} Thecoma (Option C) is a rare benign tumour originating from the ovarian stroma, accounting for less than 1% of all ovarian tumours. It is most commonly found in perimenopausal and postmenopausal women. {{caption_text}} Theca lutein cysts (Option D) are rare benign cystic lesions caused by hypertrophy of the theca interna layer due to excessive stimulation by hCG. {{caption_text}}



@Neet_pg_bot

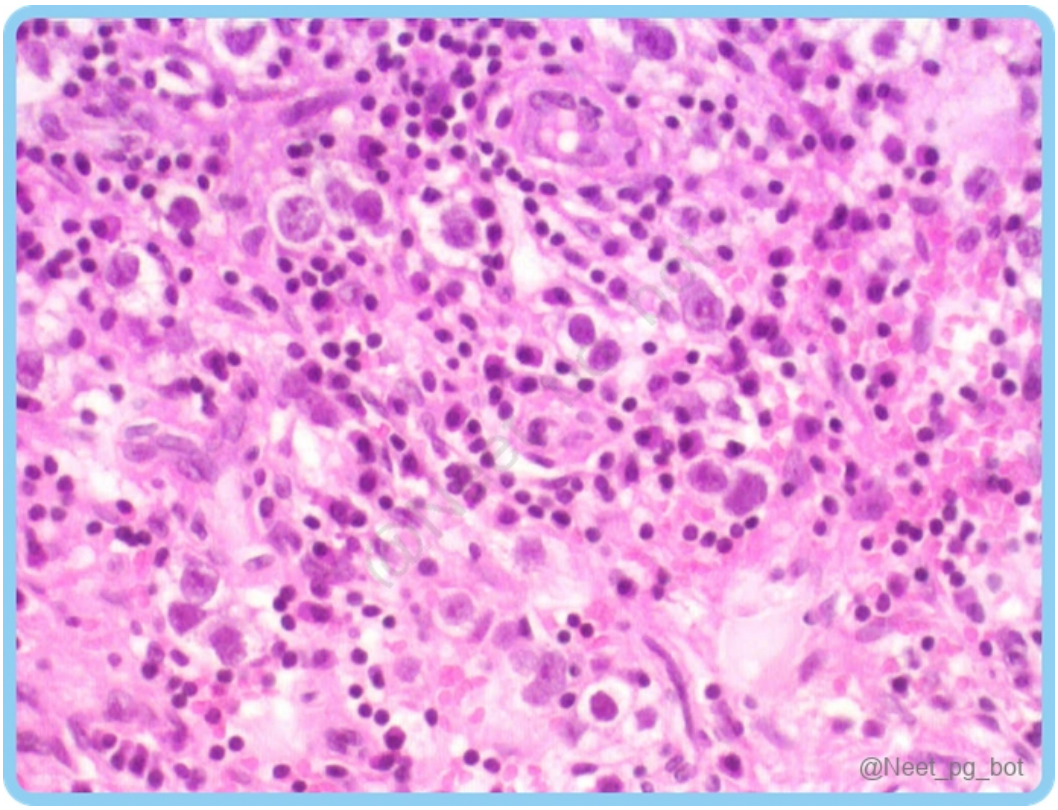
Q10: What is the most likely diagnosis for a 48-year-old patient who came with scrotal swelling, had elevated LDH levels but normal AFP levels on tests for testicular tumours, and exhibited a specific histological picture after orchidectomy? (Q857111)

A. Yolk sac tumor

B. Teratoma

C. Seminoma

D. Embryonal carcinoma



Correct Answer: C. Seminoma

Explanation: The clinical presentation and histopathological findings suggest testicular seminoma. Seminomas elevate LDH levels, while AFP remains normal. Histology shows large, uniform cells with clear cytoplasm and prominent nucleoli. Seminoma: It is the most common germ cell tumour of the testis. A similar presentation in the ovary is called dysgerminoma , and germinoma is present in the pineal gland . Incidence: Peak incidence in the fourth decade. Genetics: Seminomas contain isochromosome 12p and express OCT3/4 & NANOG. Morphology: Seminoma has a homogeneous, grey-white, lobulated cut surface, usually devoid of haemorrhage or necrosis . Histology of seminoma: Sheets of monomorphic cells. The sheets are divided into poorly demarcated lobules by the septa of the fibrous tissue. The septa show lymphocytic infiltration (T lymphocytes). The classic seminoma cell is large and round to polyhedral with a distinct cell membrane and a large, central nucleus with one or two prominent nucleoli. The cytoplasm is clear or watery appearing and contains glycogen . The arrows in the image below show seminomatous tumour cells. {{caption_text}} Source: Testicular Tumour Corresponding Tumor Markers Seminoma Placental alkaline phosphatase (PLAP) HCG LDH Newer markers: Oct 3/4, Nanog, CD117, SALL4 Embryonal Carcinoma {{caption_text}} CD-30 Yolk sac tumour {{caption_text}} Alpha-fetoprotein (AFP) Alpha-1 antitrypsin Choriocarcinoma Beta-human chorionic gonadotropin (β-hCG) Teratoma {{caption_text}} Cytokeratin

Q11: Which of the following is not a component of Meigs syndrome? (Q857125)

A. Ascites

B. Right-sided hydrothorax

C. Fibromas of ovary

D. Dysgerminoma of ovary

Correct Answer: D. Dysgerminoma of ovary

Explanation: Dysgerminoma is a type of germ cell tumour and is not part of Meigs syndrome. Meigs Syndrome: Meigs syndrome is a condition characterised by a triad of: Ovarian fibroma (fibrothecoma) Ascites Hydrothorax (pleural effusion) {{caption_text}} {{caption_text}}

@Neet_pg_bot

Q12: Which of the following statements is accurate concerning liquid-based cytology? (Q856890)

A. Urine specimen is used

B. Sanger sequencing is used

C. Study of fluid in the tumor microenvironment

D. DNA is collected in microvessels

Correct Answer: A. Urine specimen is used

Explanation: Liquid-based cytology is often used to collect specimens, including urine, and study cells for various diagnostic purposes. Liquid-based cytology: It is a technique to collect and prepare cell samples for microscopic

analysis. It involves gathering cells from various body fluids, such as cervical or vaginal fluids, respiratory secretions, or urine, depending on the diagnostic goal. This method is commonly used for cervical cancer screening. Cells collected from the cervix with a brush or spatula are suspended in a preservative solution. This suspension is used to prepare slides for cytological examination to detect abnormalities or disease. Advantages of Liquid-Based Cytology (LBC): Improved slide preparation: LBC creates a thin-layer or monolayer slide preparation, providing better quality and clarity than conventional Papanicolaou (Pap) smears. Enhanced cell preservation: The collection fluid used in LBC fixes, homogenizes, and rinses the cells, ensuring better preservation for microscopic examination. Reduced sample contamination: The homogenization process minimizes the presence of non-representative material, such as blood or mucus, leading to a more accurate analysis of the collected cells. Increased diagnostic accuracy: With improved sample quality, LBC enhances the sensitivity and specificity of cervical cancer screening, allowing for more reliable detection of abnormalities. Disadvantage: Although cervical cytological screening has proven effective in reducing the incidence and mortality of cervical cancer, the conventional Pap test is less sensitive than commonly thought. The false-negative rate of the conventional Pap test has been reported to reach as high as 50%.

@Neet_pg_bot

Q13: Which of the following is not a constituent of the Papanicolaou stain? (Q856892)

A. Light green SF

B. Orange G

C. Eosin B

D. Hematoxylin

Correct Answer: C. Eosin B

Explanation: Eosin B is not a constituent of the Papanicolaou stain. Eosin is a different type of stain typically used for general histology to highlight cytoplasm in tissues, but it is not used in the Papanicolaou (Pap) stain. The Papanicolaou (Pap) stain is a widely used technique for examining cells from the cervix to screen for cervical cancer and other abnormalities. It uses a combination of multiple dyes to differentiate cellular components: Hematoxylin - Stains the cell nuclei, allowing for clear visualization of nuclear structure. Orange G - Stains keratinized cells orange, highlighting squamous cells. Eosin A - Second counterstain & a polychrome mixture of Eosin Y and Light Green (stains cytoplasm and helps differentiate between various cell types). {{caption_text}}

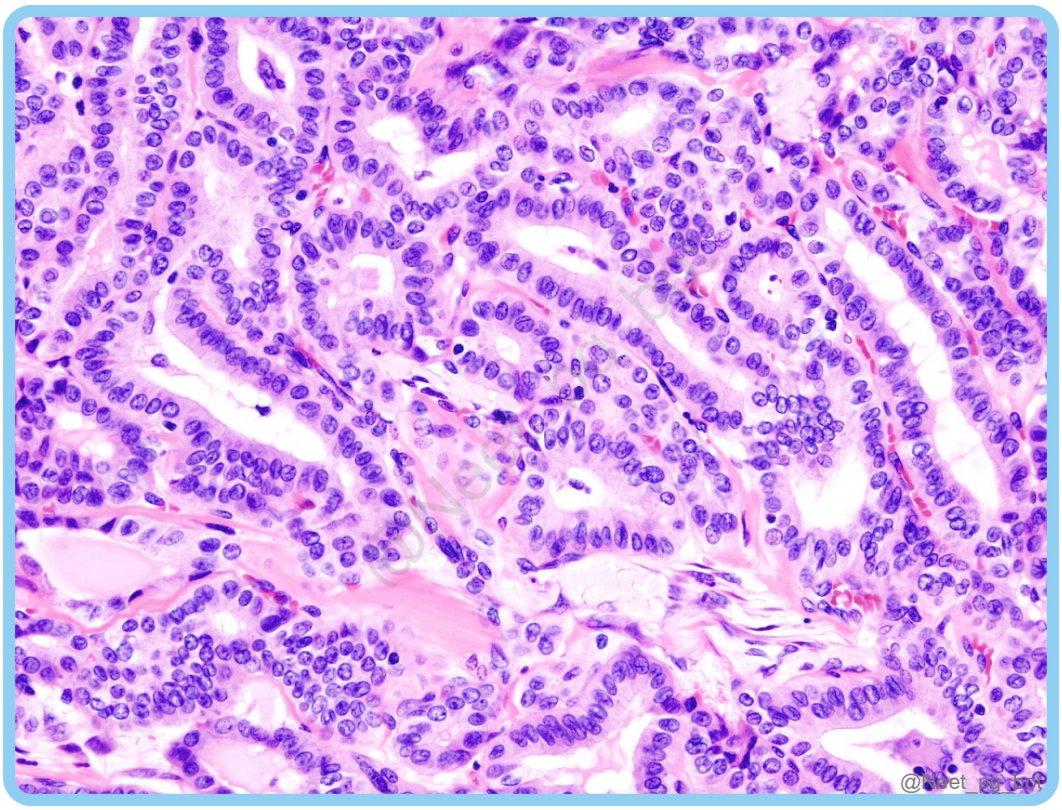
Q1: A 40-year-old patient presents with a nodule in the anterior neck and lymphadenopathy. The tumour is found to have spread to the lymphatics. Histopathological examination shows characteristic findings. What is the most likely diagnosis? (Q845553)

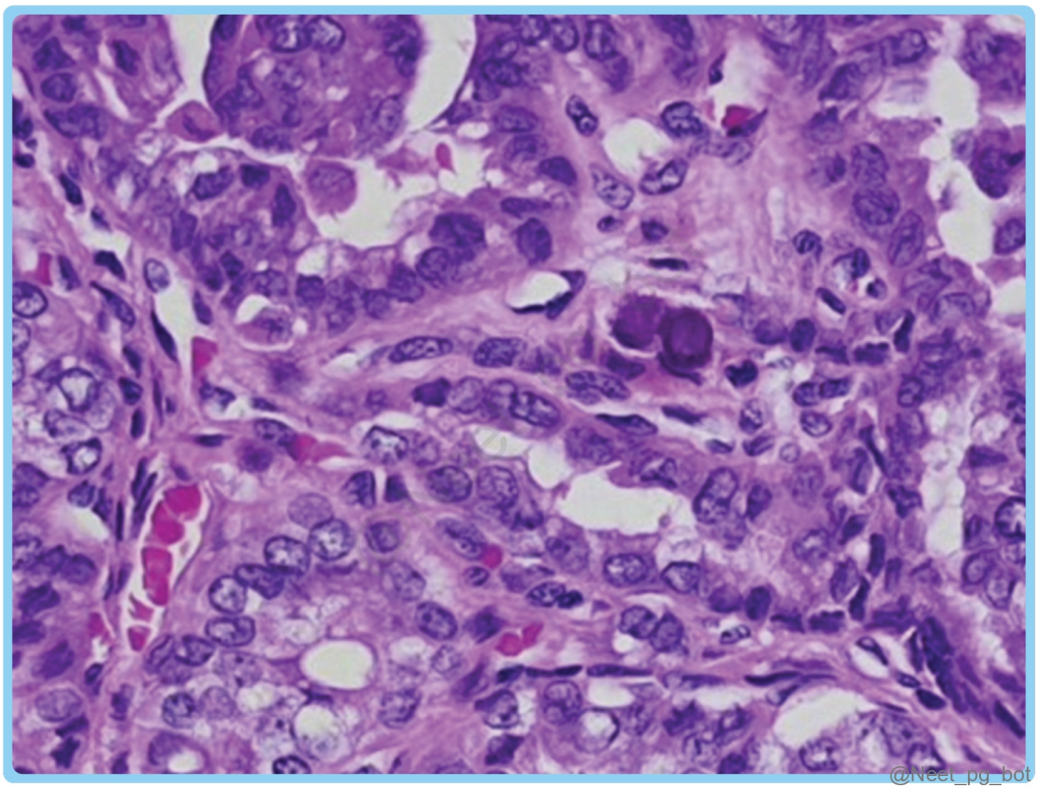
A. Follicular thyroid carcinoma

B. Medullary thyroid carcinoma

C. Papillary thyroid carcinoma

D. Anaplastic thyroid carcinoma



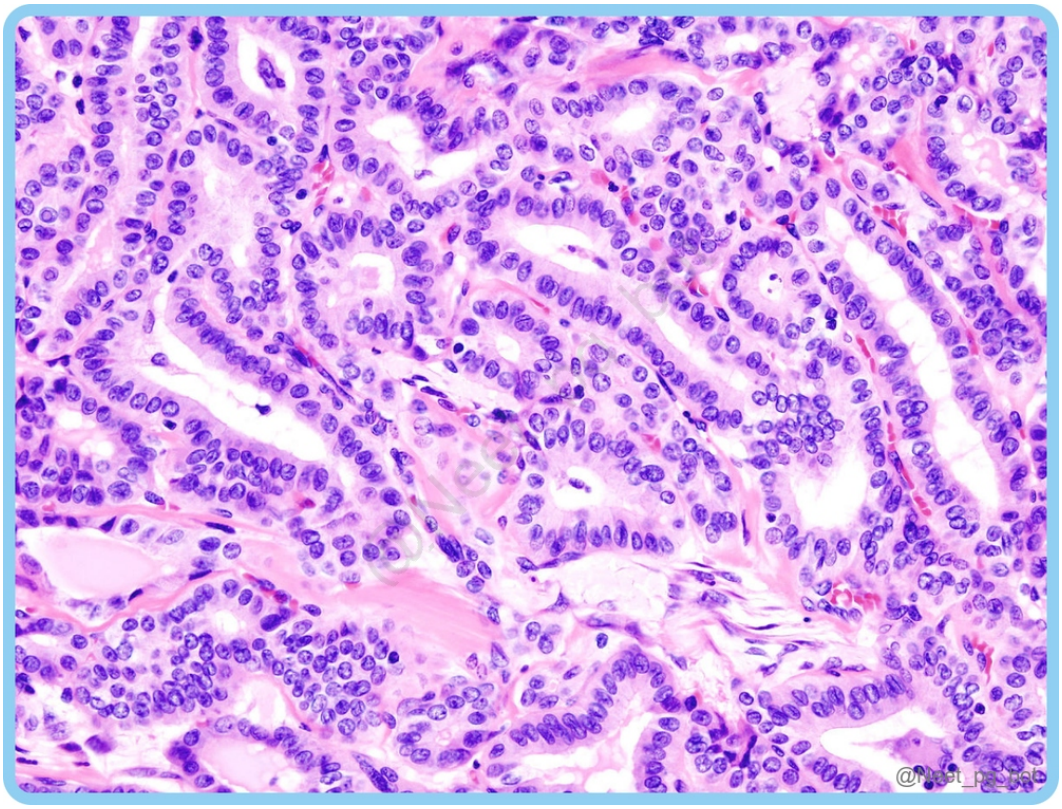


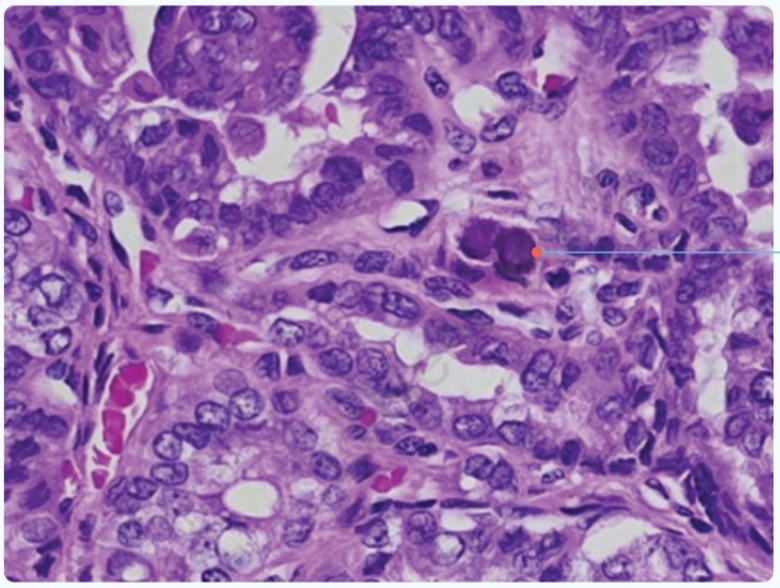
Correct Answer: C. Papillary thyroid carcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above features and HPE showing psammoma bodies, nuclear grooves, and " Orphan Annie eye" nucle i are indicative of papillary thyroid carcinoma. This is the most common type of thyroid cancer and is characterised by lymphatic spread. Clinical features: Thyroid nodule + Lymphadenopathy Microscopy (Biopsy): True papilla Fibrovascular core Fingerlike projections with central core of fibrovascular tissue. (Image 1) Psammoma bodies (Dystrophic calcification) Blue colour bodies (Image 2) Orphan Annie eye nucleus Optically clear nucleus Formalin artifact Seen on biopsy Not seen on FNAC INCI - Intranuclear cytoplasmic inclusion Nuclear groove/Coffee bran nucleus Microscopy (FNAC): Chewing gum colloid





@Neet_pg_bot

Q2: A 35-year-old patient is diagnosed with papillary thyroid carcinoma. Which of the following statements about papillary thyroid carcinoma is true? (Q890473)

A. Not associated with radiation exposure

B. Hot nodule on scintigraphy

C. Accounts for 85% of thyroid cancers

D. Has a poor prognosis

Correct Answer: C. Accounts for 85% of thyroid cancers

Explanation: Papillary thyroid carcinoma (PTC) is the most common thyroid cancer , representing approximately 85% of cases . Papillary Thyroid Carcinoma (PTC): Most common thyroid cancer (~85%) Age: 25-50 years Strongly associated with prior ionising radiation (Option A) Morphology: Gross: Solitary/multifocal, cystic, may calcify Microscopic: Branching papillae, Orphan Annie nuclei , nuclear grooves, pseudoinclusions, psammoma bodies , lymphatic invasion common Clinical features: Usually asymptomatic nodule or cervical lymphadenopathy Advanced: hoarseness, dysphagia, cough, dyspnea Diagnosis: FNA cytology reliable Cold nodule on scintigraphy (Option B) Molecular testing for indeterminate cytology Prognosis/Management: 10-year survival >95% (Option D) Lobectomy for low-risk; total thyroidectomy + radioactive iodine for high-risk Recurrence 5-20%; distant metastases 10-15% Poor prognosis: age >55, extrathyroidal extension, metastases

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 989, 990

↑ *Back to this question in Part A*

@Neet_pg_bot

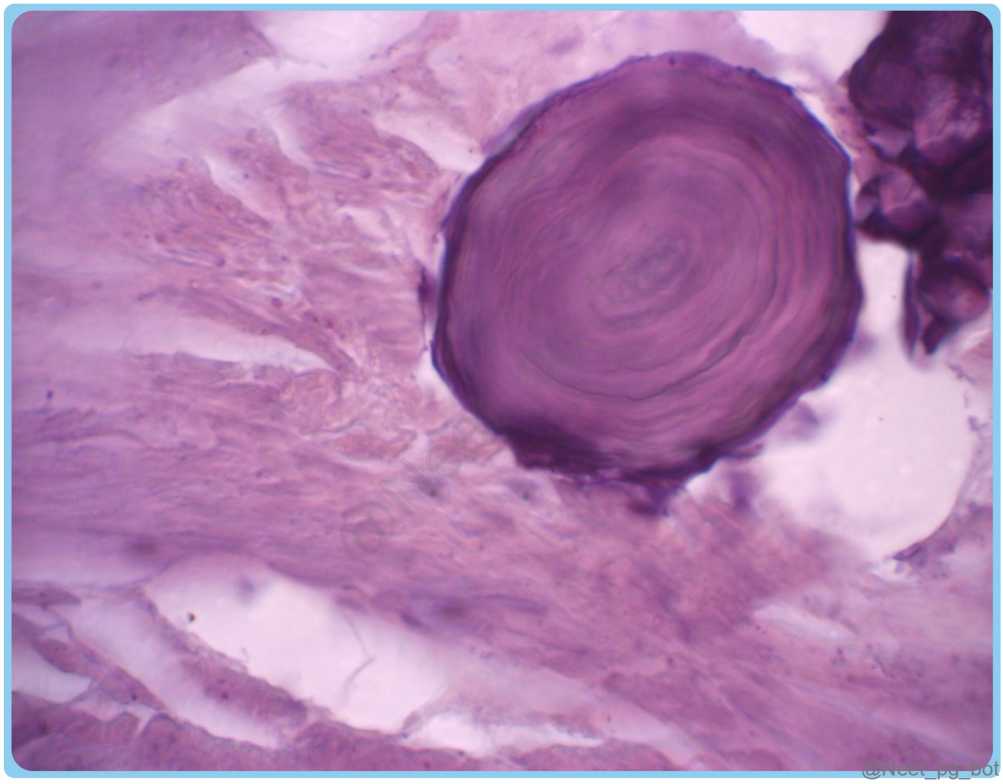
Q3: A 32-year-old woman presents with a midline neck swelling that moves with deglutition and tongue protrusion. The swelling has been present since childhood but has recently increased in size. Surgical excision is performed. Histopathological examination reveals the following findings. What is the most likely diagnosis? (Q890469)

A. Follicular carcinoma

B. Papillary carcinoma

C. Medullary carcinoma

D. Anaplastic carcinoma



Correct Answer: B. Papillary carcinoma

Explanation: The image shows a psammoma body , characterised by concentric lamellated calcification . Psammoma bodies are a characteristic feature of papillary thyroid carcinoma (PTC) and are commonly found within papillary structures or adjacent stroma. The clinical presentation of a midline neck swelling that moves with tongue protrusion suggests a thyroglossal cyst , which may contain ectopic thyroid tissue . Papillary carcinoma can arise in this ectopic thyroid tissue Papillary Thyroid Carcinoma (PTC): Most common thyroid cancer (~85%) Age: 25-50 years Strongly associated with prior ionising radiation Microscopic features: Branching papillae with fibrovascular cores Orphan Annie eye nuclei (clear nuclei with finely dispersed chromatin) Nuclear grooves and intranuclear pseudoinclusions Psammoma bodies (concentric calcifications) Lymphatic invasion is common, vascular invasion is uncommon Clinical features: Usually asymptomatic thyroid nodule May present with an enlarged cervical lymph node Advanced disease: hoarseness, dysphagia, dyspnea Follicular carcinoma (Option A): Characterised by follicular architecture with capsular and vascular invasion; lacks the nuclear features of papillary carcinoma. Medullary carcinoma (Option C): Arises from parafollicular (C) cells and produces calcitonin; does not show papillary structures or characteristic nuclear features. Anaplastic carcinoma (Option D): Highly aggressive, undifferentiated tumour in elderly patients; shows marked pleomorphism without papillary architecture or nuclear features.

@Neet_pg_bot

Q4: Which of the following correctly represents the most common and least common thyroid carcinomas, respectively? (Q890467)

A. Papillary carcinoma - Anaplastic carcinoma

B. Follicular carcinoma - Medullary carcinoma

C. Medullary carcinoma - Papillary carcinoma

D. Anaplastic carcinoma - Papillary carcinoma

Correct Answer: A. Papillary carcinoma - Anaplastic carcinoma

Explanation: Papillary thyroid carcinoma (~85%) is the most common , whereas anaplastic carcinoma (<1%) is the least common and most aggressive thyroid cancer. Thyroid Carcinomas: Major Subtypes & Frequency: Papillary thyroid carcinoma (PTC) (~85% of cases) Follicular or oncocytic thyroid carcinoma (~5-15% of cases) High-grade

differentiated and poorly differentiated carcinoma (~5% of cases) Anaplastic (undifferentiated) carcinoma (~1% of cases) Medullary thyroid carcinoma (a neoplasm of C cells) (<5% of cases)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following is the correct statement regarding a solitary thyroid nodule? (Q890465)

A. Most often malignant

B. Incidence decreases with age

C. Rare in the general population

D. Higher risk of malignancy than multiple nodules

Correct Answer: D. Higher risk of malignancy than multiple nodules

Explanation: A solitary thyroid nodule is more likely to be neoplastic and has a higher risk of malignancy compared with multinodular goitre. However, most nodules are still benign , and the incidence increases with age and they are relatively common . Solitary Thyroid Nodule: A solitary thyroid nodule (STN) is a clinically palpable, discrete swelling in the thyroid gland, although many such nodules are actually part of multinodular disease on ultrasonography . Present in up to 50% (autopsy studies) (Option C) Incidence increases with age (Option B) Clinical significance: Primary concern: malignancy Most nodules are benign (Option A) (multinodular goitre, cysts, thyroiditis, follicular adenoma) Risk factors for malignancy: Male sex Extremes of age (<20 or >60 years) History of head & neck radiation Rapid growth, hard nodule, cervical lymphadenopathy

@Neet_pg_bot

Q6: A 45-year-old woman presents with painful enlargement of the thyroid following an upper respiratory infection. Laboratory tests show ↑ T3/T4, ↓ TSH, and low radioactive iodine uptake. What is the most likely diagnosis? (Q890464)

A. Hashimoto thyroiditis

B. Graves disease

C. Subacute granulomatous thyroiditis

D. Riedel thyroiditis

Correct Answer: C. Subacute granulomatous thyroiditis

Explanation: The most likely diagnosis is subacute granulomatous thyroiditis , suggested by a painful thyroid enlargement following a viral upper respiratory infection , with transient thyrotoxicosis (↑T3/T4, ↓TSH) and low radioactive iodine uptake , due to release of preformed thyroid hormones from damaged follicles. Subacute Granulomatous Thyroiditis (de Quervain): Age: 40-50 years F:M = 4:1 Etiology: Post-viral (URTI) Viruses: Coxsackie, SARS-CoV-2, mumps, measles, adenovirus Pathology: Granulomatous inflammation Multinucleated giant cells around colloid Damaged/collapsed follicles Later fibrosis Clinical features: The most common cause of painful thyroid Transient thyrotoxicosis (2-6 weeks) ↑T3/T4, ↓TSH Low radioactive iodine uptake May have a temporary hypothyroid phase Recovery in 6-8 weeks Hashimoto thyroiditis (Option A) : Painless autoimmune hypothyroidism with lymphocytic infiltration and Hürthle cells. Graves disease (Option B) : Hyperthyroidism with diffuse goiter and increased radioactive iodine uptake . Riedel thyroiditis (Option D) : Extensive fibrosis producing a hard, fixed thyroid mass that may mimic carcinoma.

@Neet_pg_bot

Q7: Which of the following is the most common cause of hypothyroidism in iodine-sufficient areas? (Q890463)

A. Hashimoto thyroiditis

B. Wolff-Chaikoff effect

C. Pituitary failure

D. Thyroid agenesis

Correct Answer: A. Hashimoto thyroiditis

Explanation: Hashimoto thyroiditis is the most common cause of hypothyroidism in iodine-sufficient regions. It is an autoimmune disease characterised by destruction of thyroid follicles and the presence of anti-thyroid peroxidase and anti-thyroglobulin antibodies . Hypothyroidism: ↓ thyroid hormone production due to dysfunction of the

thyroid, pituitary, or hypothalamus 10× more common in females Primary Hypothyroidism (Most common): Due to intrinsic thyroid disease Causes: Hashimoto thyroiditis - most common in iodine-sufficient areas Iodine deficiency Post-ablative (thyroid surgery, radioiodine, irradiation) Drugs: lithium, amiodarone, thionamides Congenital defects Thyroid agenesis/hypoplasia Dyshormonogenesis Secondary (Central) Hypothyroidism: Due to pituitary failure → ↓ TSH Tertiary Hypothyroidism: Due to hypothalamic disease → ↓ TRH Wolff-Chaikoff effect (Option B): The Wolff-Chaikoff effect refers to a temporary inhibition of thyroid hormone synthesis following exposure to large amounts of iodine. Although it may cause transient hypothyroidism in certain situations, it is not the most common cause of hypothyroidism. Pituitary failure (Option C): Pituitary failure leads to secondary (central) hypothyroidism due to decreased secretion of thyroid-stimulating hormone (TSH). However, central hypothyroidism is much less common than primary hypothyroidism caused by thyroid gland disorders. Thyroid agenesis (Option D): Thyroid agenesis is a congenital absence of the thyroid gland and is an important cause of congenital hypothyroidism , but it is rare and not the most common cause of hypothyroidism in the general population.

@Neet_pg_bot

Q8: Which of the following histopathological features is not typically seen in Hashimoto thyroiditis? (Q890447)

A. Lymphoid follicles with germinal centres

B. Hürthle (oncocytic) cell change

C. Fibrosis extending beyond the thyroid capsule

D. Dense mononuclear inflammatory infiltrate

Correct Answer: C. Fibrosis extending beyond the thyroid capsule

Explanation: Fibrosis extending beyond the thyroid capsule is characteristic of Riedel thyroiditis and is not seen in Hashimoto thyroiditis. In Hashimoto thyroiditis, fibrosis may be present but remains confined within the gland. Hashimoto Thyroiditis - Morphology: Thyroid gland: Diffusely enlarged, well-demarcated Cut surface: Pale, yellow-tan, firm, slightly nodular Microscopy: Dense mononuclear inflammatory infiltrate (Option D) Lymphocytes Plasma cells Lymphoid follicles with germinal centres (Option A) Atrophic thyroid follicles Hürthle (Oncocytic) Cell Change: (Option B) Follicular epithelial cells with abundant eosinophilic granular cytoplasm Represents metaplastic response to chronic injury On FNAC: oncocytes + mixed lymphocytes → characteristic Fibrosis: Increased interstitial connective tissue Does not extend beyond the thyroid capsule (unlike Riedel thyroiditis)

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 982

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following statements regarding hyperthyroidism is correct? (Q890446)

A. Graves' disease is the most common cause of hyperthyroidism.

B. Serum TSH levels are increased in primary hyperthyroidism.

C. Osteoporosis is not a complication

D. Constipation is a typical feature of hyperthyroidism.

Correct Answer: A. Graves' disease is the most common cause of hyperthyroidism.

Explanation: Graves' disease accounts for approximately 85% of cases of hyperthyroidism and is the most common cause. It results from autoantibodies that stimulate the TSH receptor, leading to increased thyroid

hormone production. Hyperthyroidism: Hyperthyroidism: thyrotoxicosis due to thyroid gland hyperfunction Common causes: Graves' disease (~85%) Toxic multinodular goitre Toxic adenoma Rare: TSH-secreting pituitary tumor Other Causes (without ↑ hormone production): Subacute thyroiditis Painless thyroiditis Struma ovarii Factitious thyrotoxicosis Clinical features: Weight loss despite ↑ appetite Heat intolerance, sweating Warm, flushed skin Tachycardia, palpitations, atrial fibrillation Tremor, anxiety, insomnia Hyperdefecation (Option D) Lid lag, staring gaze Proptosis (Graves disease) Complications: Osteoporosis (Option C) Thyroid storm (life-threatening) Apathetic hyperthyroidism in the elderly Lab findings: Primary: ↓ TSH, ↑ T4 (Option B) T3 toxicosis: ↑ T3 only Secondary: normal/↑ TSH

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 979, 980

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 45-year-old patient presents with a painless lump on the front of the neck, bone pain, fatigue, and episodes of flushed skin. Genetic studies reveal a mutation in the RET gene. Which type of amyloid is typically deposited in this condition? (Q845555)

A. A-β

B. A-CAL

C. A-L

D. A-TTR

Correct Answer: B. A-CAL

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given scenario and mutation are associated with medullary thyroid carcinoma, which has amyloid deposition derived from calcitonin, known as A-CAL. Medullary carcinoma of the thyroid is a neuroendocrine tumour arising from parafollicular C cells. In this condition, excess calcitonin is secreted (a hormone that regulates calcium levels), leading to facial flushing and bone pain. When calcitonin is converted into amyloid, it is known as A-CAL type of amyloid. Types and mutation: Familial syndrome Sporadic: RET gene TEN (On chromosome 10) MED - Medullary carcinoma thyroid MEN (II a& II b) Tumor marker: ↑ Calcitonin → ACaL Microscopic examination: Pink extracellular ACaL Congo red stain: Apple green birefringence on polarizing microscopy Markers: Neuroendocrine markers + Medullary thyroid carcinoma with amyloid deposition:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Pages 261, 1091.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following is not a common feature of follicular carcinoma of thyroid? (Q845554)

A. Second most common thyroid malignancy

B. Has a Hurthle cell variant

C. Commonly spreads by lymphatic route

D. FNAC is not helpful in diagnosis

Correct Answer: C. Commonly spreads by lymphatic route

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Spread by lymphatic route is not a common feature of follicular carcinoma as they commonly spread by hematogenous route. It spreads through the hematogenous route, affecting bones and producing lytic lesions in the skull as well as other parts of the body. Follicular carcinoma of thyroid is the second common malignancy of thyroid following papillary carcinoma. Both follicular adenoma and carcinoma has a huethle cell variant. They are commonly associated with K-RAS mutation Capsular and vascular invasion on biopsy is a diagnostic feature of follicular carcinoma. FNAC is not helpful in diagnosis of follicular carcinomas because we cannot see capsular and vascular invasions by it. Capsular invasion: Vascular Invasion:

@Neet_pg_bot

Q12: Which system is widely used for reporting thyroid cytopathology? (Q845542)

A. TIRADS

B. Gleason System

C. Bethesda System

D. Duke Classification

Correct Answer: C. Bethesda System

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The Bethesda System for Reporting Thyroid Cytopathology (TBSRTC) is a standardised reporting system designed to classify thyroid Fine-Needle Aspiration Cytology (FNAC) biopsy results. The Bethesda system

is used to report: Thyroid FNAC Cervical cytology (pap smears or cervical smears) Breast FNAC Adequacy criteria of FNAC: ≥ 6 cell clusters ≥ 10 follicular cells /cluster Exception: Cancer cells Colloid cysts (↑↑ colloid) Inflammatory disorder (Hashimoto's thyroiditis) Bethesda system categories: Bethesda Category Diagnostic Category Risk of Malignancy (Approx.) Usual Management I Nondiagnostic / Unsatisfactory 5–10% Repeat FNA with ultrasound guidance II Benign 0–3% Clinical follow-up (Ultrasound) III AUS / FLUS (Atypia/Follicular Lesion of Undetermined Significance) 10–30% Repeat FNA, molecular testing, or lobectomy IV Follicular Neoplasm (or Suspicious for FN) 25–40% Surgical lobectomy V Suspicious for Malignancy 50–75% Near-total thyroidectomy or lobectomy VI Malignant 97–99% Thyroidectomy TIRADS (Thyroid Imaging Reporting and Data System) (Option A) is a classification system for reporting thyroid ultrasound findings, not cytopathology. Guides which nodules need FNA , but doesn't interpret cytology results Uses nodule features (composition, echogenicity, margins, calcifications, shape) to assign TR1-TR5 scores The Point System: Points are awarded for 5 features: Composition (solid vs. cystic), Echogenicity (darkness), Shape (taller than wide), Margins (irregular), and Echogenic Foci (calcifications). Categories: TR1/TR2: Benign/Not suspicious; no biopsy needed. TR3: Mildly suspicious; biopsy if ≥ 2.5 cm. TR4: Moderately suspicious; biopsy if ≥ 1.5 cm. TR5: Highly suspicious; biopsy if ≥ 1.0 cm. Gleason’s System (Option B) is used to grade prostate cancer based on histological patterns. Unlike Bethesda (which uses categories), Gleason uses a "Score" based on architectural patterns: A pathologist looks for the most common pattern (Primary) and the second most common (Secondary). Each is graded 1 to 5. The Score: Expressed as a sum (e.g., 3 + 4 = 7). Grade 1-2: Glands look nearly normal. Grade 3: Well-formed, discrete glands. Grade 4: Fused, "cribriform," or ill-defined glands. Grade 5: No glands; sheets or nests of cells. Duke Classification (Option D) is a system for staging colorectal cancer. Duke A: Limited to the bowel wall (mucosa/submucosa). Duke B: Through the muscle layer of the bowel, but no lymph nodes. Duke C: Any depth of invasion with lymph node involvement. Duke D: Distant metastasis (e.g., to the liver or lungs).

@Neet_pg_bot

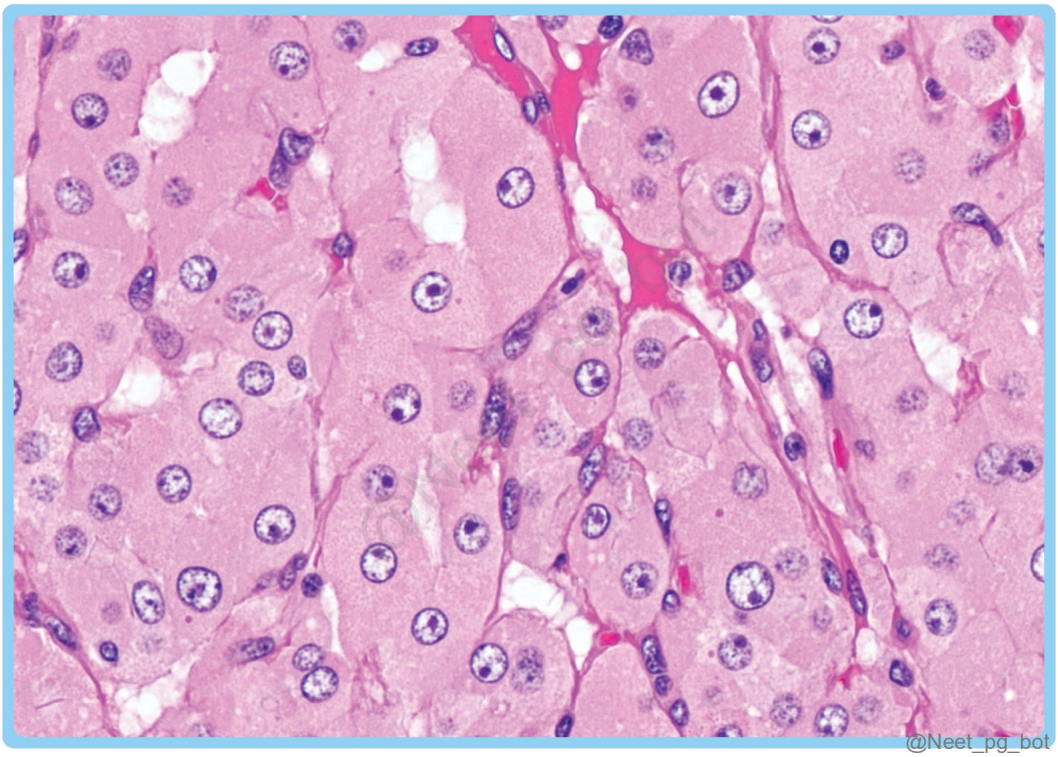
Q14: A 55-year-old patient presents with a solitary thyroid nodule. The patient also reports difficulty swallowing, with no complaints of weight loss, fatigue, or heat intolerance. An excisional biopsy reveals >75% of the following characteristic cells. Which genetic mutation is most commonly associated with this type of thyroid tumour? {{caption_text}} (Q845551)

A. BRAF

B. GNAS

C. RAS

D. PTEN



Correct Answer: C. RAS

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above image shows cells with abundant pinkish eosinophilic cytoplasm and small regular nuclei, suggesting Hurthle cells. The presence of >75% of these cells indicates a Hurthle cell adenoma , a rare thyroid neoplasm of follicular cell origin associated with RAS mutation. Hurthle cell adenomas are variants of follicular adenoma, and the presence of more than 75% of Hurthle cells is a key diagnostic feature. {{caption_text}} Thyroid Malignancy Mutations/Genetic Alterations Follicular Thyroid Adenoma (Benign Condition) RAS Papillary Thyroid Carcinoma (PTC) BRAF V600E RET/PTC rearrangements Follicular Thyroid Carcinoma (FTC) RAS PAX8-PPARγ rearrangements PIK3CA Medullary Thyroid Carcinoma (MTC) RET Anaplastic Thyroid Carcinoma (ATC) TP53

@Neet_pg_bot

Q15: What is the finding in the histopathological examination of a biopsy specimen from a patient with De Quervain Thyroiditis? (Q845550)

A. Extensive stromal fibrosis extending beyond the thyroid capsule

B. Follicular hyperplasia with scalloping colloid

C. Mononuclear infiltration with well-developed germinal centres

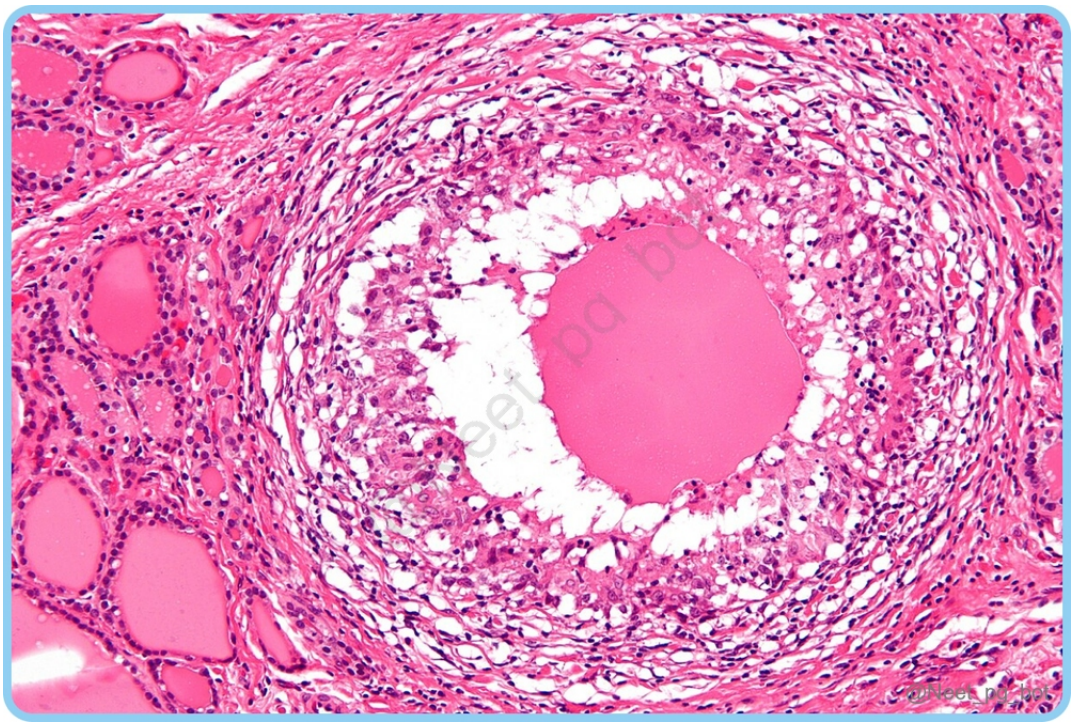
D. Mixed cellular infiltration with occasional multinucleated giant cells

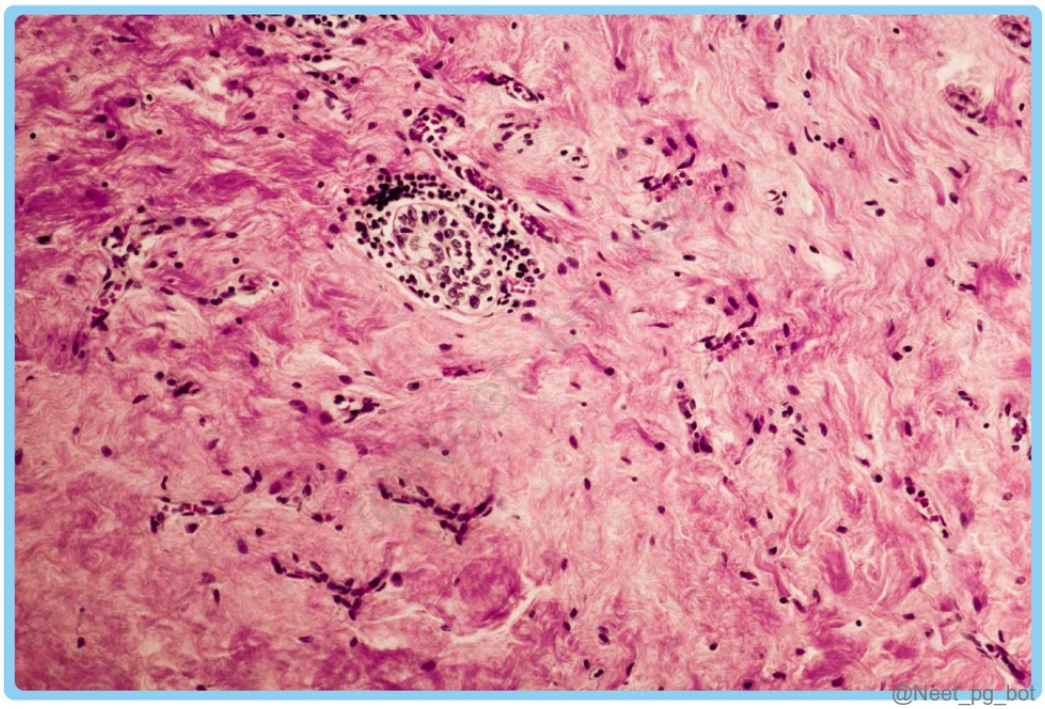
Correct Answer: D. Mixed cellular infiltration with occasional multinucleated giant cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Painful enlargement of the thyroid gland following a viral infection such as mumps or adenovirus infection is suggestive of De Quervain thyroiditis/Granulomatouus thyroiditis.. The microscopic findings include: Large multinucleated giant cells Giant cells with engulfed colloid Mixed cellular infiltration Extensive stromal fibrosis extending beyond the thyroid capsule (Option A): Seen in Riedel thyroiditis Follicular hyperplasia with scalloping colloid (Option B) is a feature of hyperthyroidism seen in Grave's disease. Mononuclear infiltration with well-developed germinal centres (Option C): Seen in lymphocytic or hashimotos's thyroiditis.





@Neet_pg_bot

Q16: Which of the following is not a feature of subacute lymphocytic thyroiditis? (Q845549)

A. Also called postpartum thyroiditis

B. Usually presents as a painful enlargement of the thyroid

C. Self-limiting condition

D. Lymphocytic inflammation in the thyroid

Correct Answer: B. Usually presents as a painful enlargement of the thyroid

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Subacute lymphocytic thyroiditis is also know as Postpartum thyroiditis because it is seen in postpartum women. (Option A) It is a self-limiting condition does not usually require treatment (Option C) It is characterised by lymphocytic inflammation in the thyroid. (Option D) Subacute lymphocytic thyroiditis is typically a painless enlargement of the thyroid. The only painful thyroiditis is De Quervain thyroiditis or granulomatous thyroiditis, ■■■■■■which is usually seen following a viral infection. hyroiditis: 4 types: Hashimoto's Thyroiditis / Chronic Lymphocytic Thyroiditis: Autoimmune M/c cause of hypothyroidism in iodine sufficient areas Associated with HLA-DR3, DR5, PTPN22, CTLA Antibodies: Anti-TG antibody (antithyroglobulin antibody), Anti-TSH antibody Investigations: ↓T3, ↓T4, ↑TSH RAIU - radioactive iodine uptake: < 5% Feature - Painless diffuse enlargement of thyroid Microscopy: Hurthle cell/Askanazy cell/Oncocytic cell/Oxyphilic cell De Quervain’s Thyroiditis / Granulomatous Thyroiditis / Subacute Thyroiditis: Cause - HLA B5 mutation, post-viral Painful enlargement of the thyroid M/c cause of thyroid pain High ESR and low iodine uptake Subacute Lymphocytic Thyroiditis / Silent Thyroiditis / Painless Thyroiditis : ■■■■■■■ Painless Seen in postpartum females Self-limiting Transient thyrotoxicosis followed by hypothyroidism Riedel's Thyroiditis /

Invasive Fibrous Thyroiditis : ■■■■■■■ Stony/woody hard thyroid - Due to fibrosis Mimics cancer

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1080

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: Which of the following best describes the gross morphology of Riedel's thyroiditis? (Q845548)

A. Localised nodule within the gland

B. Diffusely enlarged thyroid gland

C. Mobile and well-circumcised mass

D. Stony and hard consistency

Correct Answer: D. Stony and hard consistency

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Riedel's Thyroiditis belongs to an IgG4-related disease that causes extensive fibrosis. Fibrosis causes the thyroid to become stony and hard. It also attaches the thyroid to the adjacent tissues, muscles, and vessels implying the mass is fixed and does not move with deglutition. So it behaves like/mimics a cancer. IgG4-related diseases: Disease Fibrosis Mikulicz syndrome Salivary gland and lacrimal gland Kuttner syndrome Submandibular gland Ormond disease Retroperitoneal Riedel's thyroiditis Thyroid Thyroiditis: 4 types: Hashimoto's Thyroiditis / Chronic Lymphocytic Thyroiditis: Autoimmune M/c cause of hypothyroidism in iodine sufficient areas Associated with HLA-DR3, DR5, PTPN22, CTLA Antibodies: Anti-TG antibody (antithyroglobulin antibody), Anti-TSH antibody Investigations: ↓T3, ↓T4, ↑TSH RAIU - radioactive iodine uptake: < 5% Feature - Painless diffuse enlargement of thyroid Microscopy: Hurthle cell/Askanazy cell/Oncocytic cell/Oxyphilic cell De Quervain's Thyroiditis / Granulomatous Thyroiditis / Subacute Thyroiditis: Cause - HLA B5 mutation, post-viral Painful enlargement of the thyroid M/c cause of thyroid pain High ESR and low iodine uptake Subacute Lymphocytic Thyroiditis / Silent Thyroiditis / Painless Thyroiditis : ■■■■■■■■■■■■■■■ Painless Seen in postpartum females Self-limiting Transient thyrotoxicosis followed by hypothyroidism Riedel's Thyroiditis / Invasive Fibrous Thyroiditis : ■■■■■■■ Stony/woody hard thyroid - Due to fibrosis Mimics cancer

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1081

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 28-year-old woman comes to the office due to progressively worsening eye irritation and double vision over the last two months. She also reports unintentional weight loss, mood swings, diarrhoea, and palpitations. Physical examination shows tachycardia and bilateral proptosis. What is the pathophysiology causing proptosis? (Q845547)

A. Increased activity of orbital fibroblasts

B. Increased breakdown of hyaluronic acid

C. Increased synthesis of thyroid hormones

D. Increase in sympathetic activity

Correct Answer: A. Increased activity of orbital fibroblasts

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This patient with hyperthyroidism (weight loss, palpitations, tachycardia) and significant ophthalmopathy (proptosis, diplopia) has Graves disease with ophthalmopathy, which is due to increased activity of orbital fibroblasts. Triad in Graves: Hyperthyroidism Pretibial myxoedema: infiltrative dermopathy due to thickening of the dermis due to deposition of glycosaminoglycans and lymphocyte infiltration. Proptosis: Increased activity of orbital fibroblasts leads to bulging of the eyeballs (proptosois).

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Pages 1081-1082

↑ *Back to this question in Part A*

@Neet_pg_bot

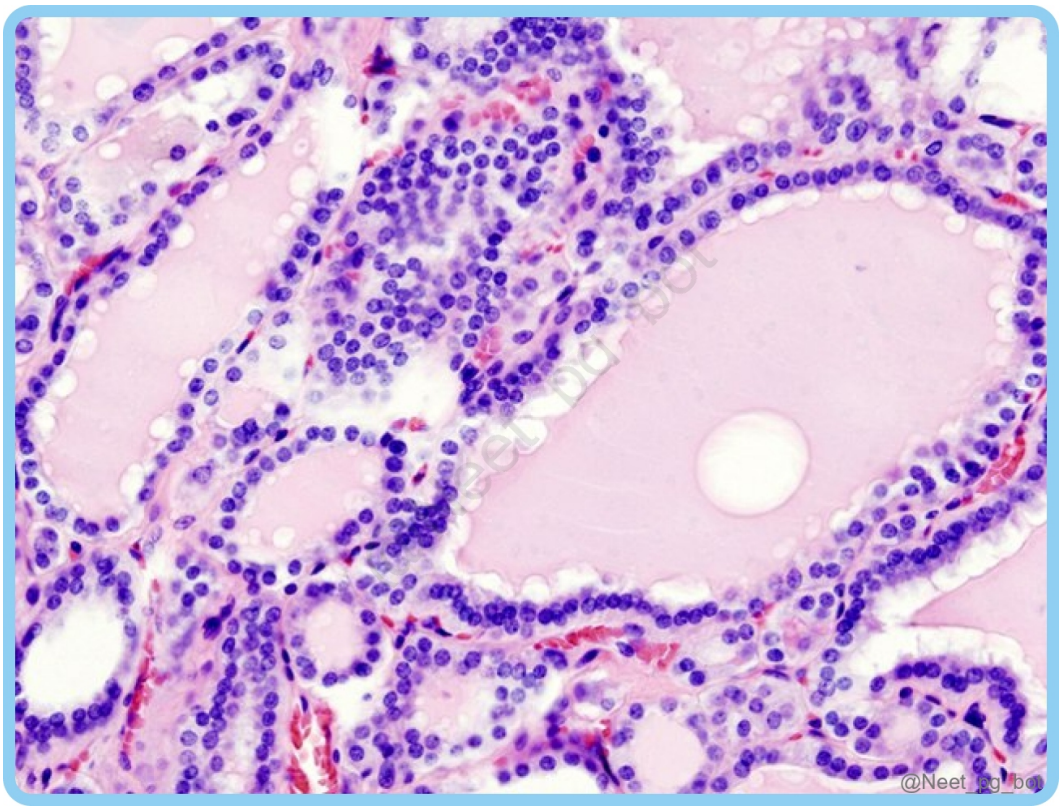
Q19: A 29-year-old lady has been experiencing loss of appetite, profuse sweating, and palpitations for the past three months. Laboratory tests conclude increased T3 and T4 levels with decreased TSH levels. A representative HPE of this condition is shown below. The most common antibodies in this condition target which of the following? {{caption_text}} (Q845546)

A. TSH receptor

B. Thyroid peroxidase

C. Thyroglobulin

D. Dermal fibroblasts

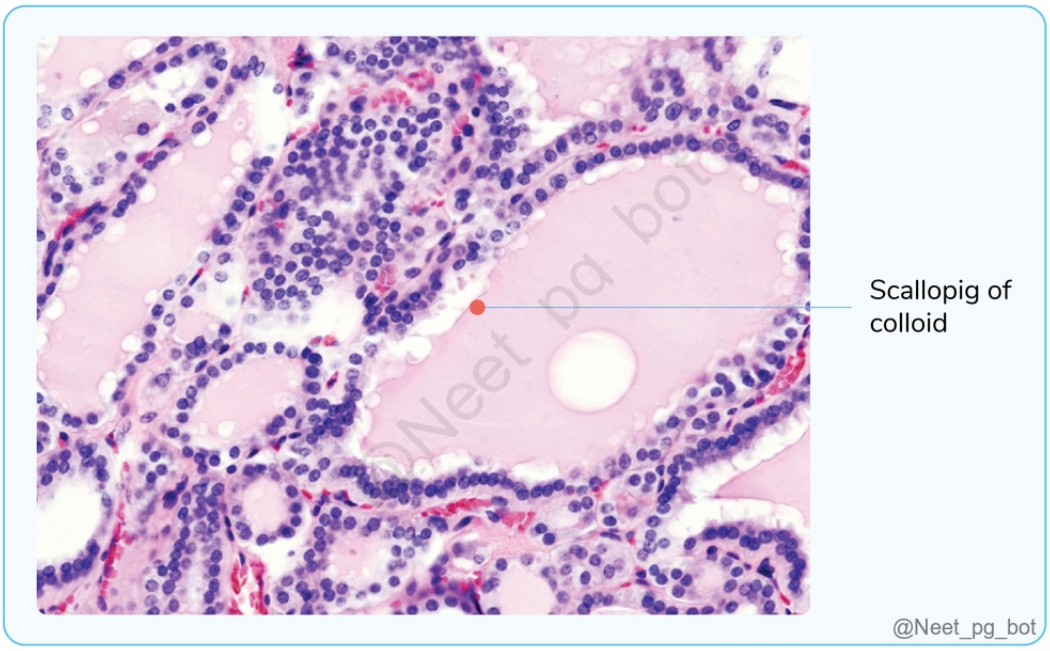


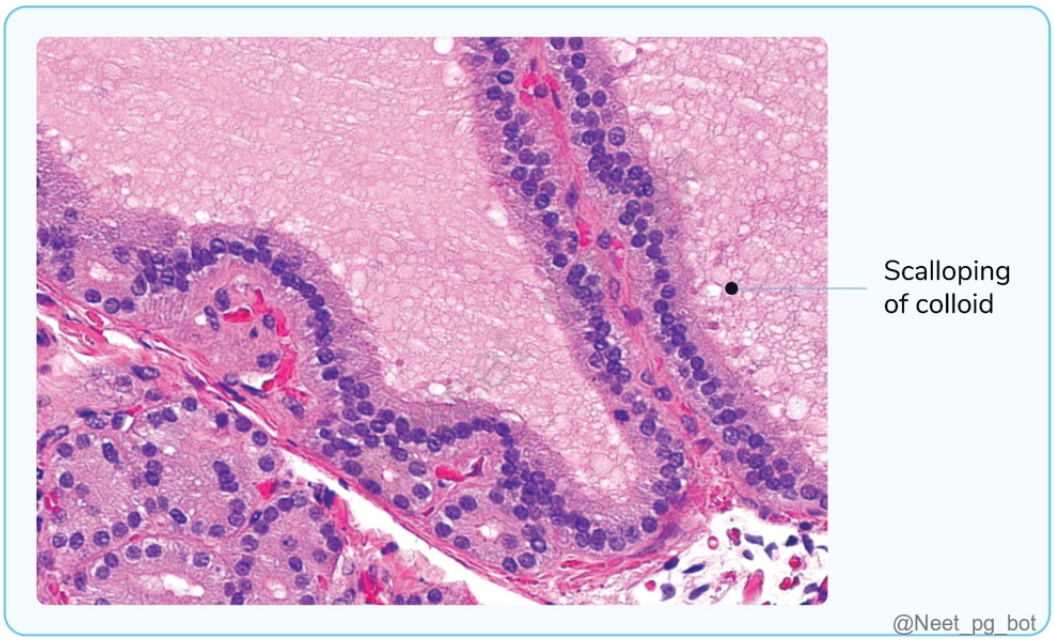
Correct Answer: A. TSH receptor

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The HPE image demonstrates features of Grave’s disease, most commonly due to long-acting thyroid stimulator antibodies that bind to and activate the TSH receptor. Antibodies in Graves disease: TSI - Thyroid-stimulating immunoglobulin■■■: When these antibodies bind to the TSH receptor, they stimulate production of T3 and T4, leading to hyperthyroidism. The classical finding of Graves' disease on HPE is scalloping of colloids.





References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1081

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: Which of the following antibodies are elevated in a patient of Hashimoto's thyroiditis? (Q845545)

A. Thyroid-stimulating immunoglobulins (TSI)

B. Anti-thyroid peroxidase antibodies (Anti-TPO)

C. Anti-thyroid stimulating hormone receptor antibodies (Anti-TSHR)

D. Anti-thyroid hormone antibodies (Anti-T3/T4)

Correct Answer: B. Anti-thyroid peroxidase antibodies (Anti-TPO)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hashimoto's thyroiditis is an autoimmune disorder in which autoantibodies target the thyroid gland, leading to reduced production of T3 and T4 and resulting in hypothyroidism. The autoantibodies responsible for Hashimoto's thyroiditis include: Anti-Thyroid Peroxidase (TPO) Antibodies Anti-Thyroglobulin(Tg) Antibodies In Graves' disease, thyroid-stimulating immunoglobulins (TSI) are found, which cause hyperthyroidism. (Option A)

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Pages 1077 , 1078 , 1079

Harrison’s principle of internal medicine, 21st Edition, Page 2934

↑ *Back to this question in Part A*

@Neet_pg_bot

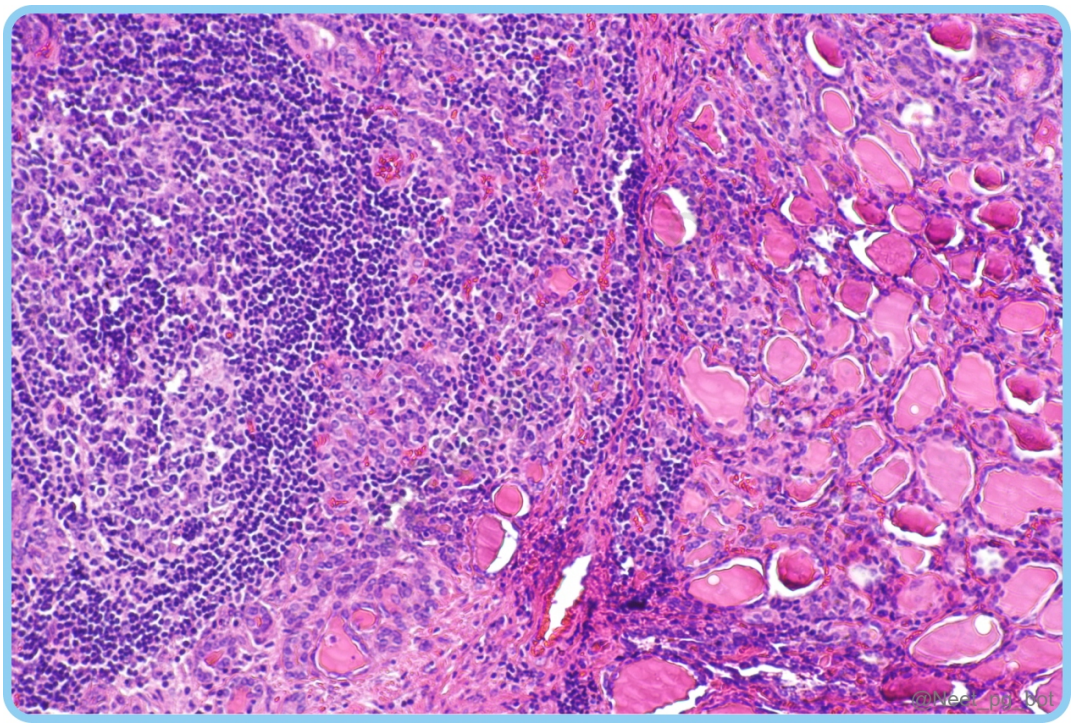
Q21: A 35-year-old female presents with fatigue, weight gain, and cold intolerance. On physical examination, she has diffuse goitre and dry skin. Histopathological examination shows lymphoid infiltration, atrophic thyroid follicles lined in many areas by epithelial cells with abundant eosinophilic, granular cytoplasm as shown below. What is the likely diagnosis? {{caption_text}} (Q845544)

A. Grave’s disease

B. Thyroid nodule

C. Papillary carcinoma

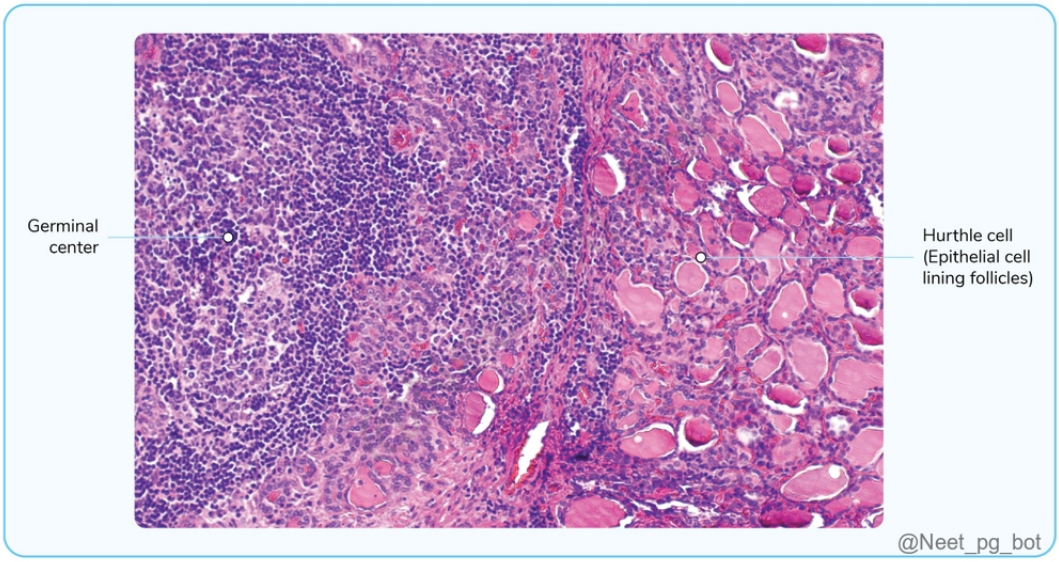
D. Hashimoto thyroiditis



Correct Answer: D. Hashimoto thyroiditis

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The above scenario and HPE findings suggest a diagnosis of Hashimoto's thyroiditis/Lymphocytic thyroiditis.. It is the most common cause of hypothyroidism in iodine-sufficient areas. In histopathology, there is extensive lymphocytic infiltration with well-developed germinal centres. The thyroid follicles are atrophic and are lined in many areas by epithelial cells with abundant eosinophilic, granular cytoplasm, termed Hürthle cells (hallmark feature of Hashimoto's thyroiditis) . It is an autoimmune condition, so on hematological testing we see autoantibodies like Anti-TSH receptor antibody, antithyroglobulin antibody, and anti-TPO antibodies. Genetic cause of Hashimoto's thyroiditis is HLA-DR3 and HLA-DR5 polymorphisms. Long standing Hashimoto's thyroiditis can give rise to some cancers like: Papillary carcinoma thyroid Maltoma (a marginal zone lymphoma) {{caption_text}}



References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1079

↑ *Back to this question in Part A*

@Neet_pg_bot

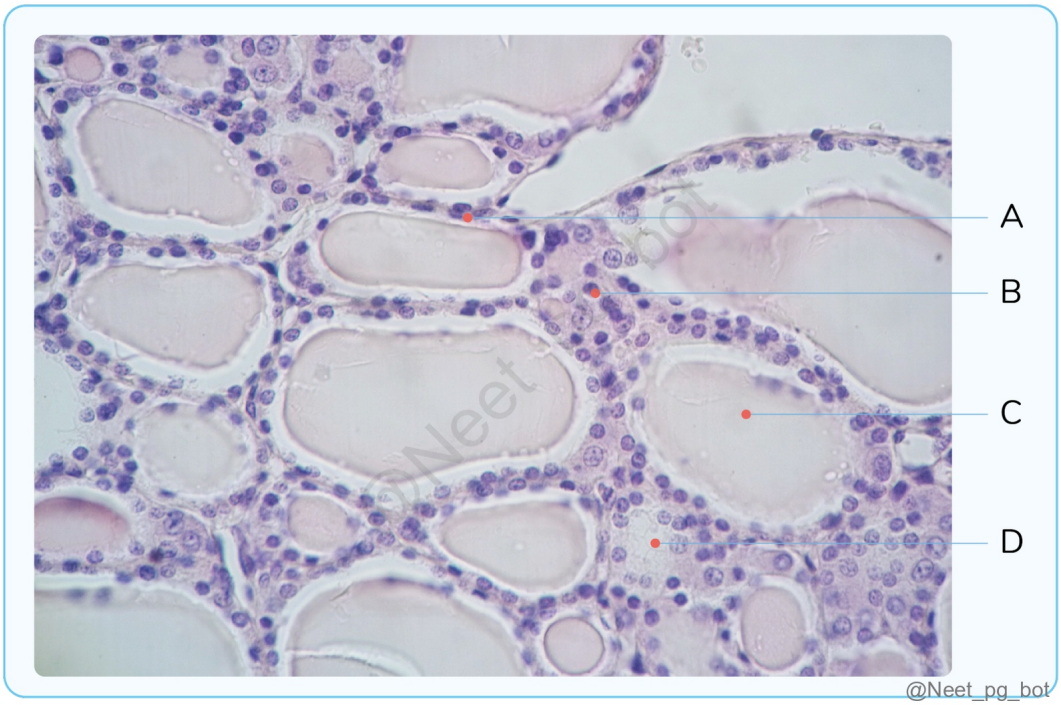
Q22: You are examining a high-resolution microscopic image of thyroid tissue. Which of the following depicts cells responsible for the secretion of calcitonin? {{caption_text}} (Q845543)

A. A

B. B

C. C

D. D



Correct Answer: B. B

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Parafollicular C-cells responsible for calcitonin secretion are indicated by ‘B’ in the given image. Parafollicular C-cells, located between the thyroid follicles, secrete the hormone calcitonin (Hypocalcemic Hormone). Follicular Cells (Option A) have a round nucleus and basophilic cytoplasm. Their function is to synthesize thyroid hormones. Colloid (Option C) is a gel-like substance that appears pinkish and homogeneous in the follicles and serves as a reservoir for thyroid hormones. Stromal Cells (Option D) fill up spaces between the follicles and connective tissue, capillaries, and stroma.

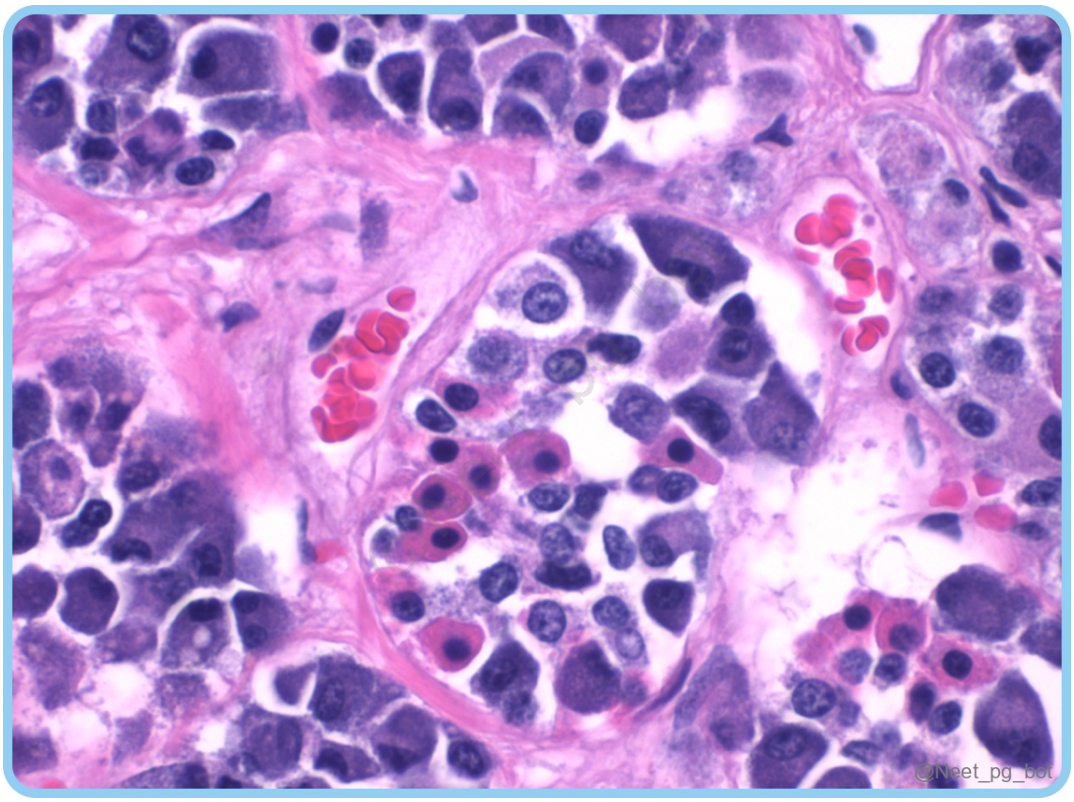
Q1: Which of the following cell types are typically found in the anterior lobe of the pituitary gland, and which are stained pink and purple, respectively? (Q845580)

A. Sommatotrophs and lactotrophs

B. Lactotrophs and thyrotrophs

C. Corticotrophs and gonadotrophs

D. Gonadotrophs and somatotrophs



Correct Answer: B. Lactotrophs and thyrotrophs

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The scenario suggests acidophils and basophils seen in the anterior pituitary. Lactotrophs and thyrotrophs are examples of cells found respectively with these staining. The pituitary consists of 2 lobes. The Anterior pituitary/ Adenohypophysis c ontains many hormone-producing cells. These cells can be acidophilic, basophilic or poorly staining based on the staining pattern. Acidophils- Eosinophilic/pink colored- Sommatotrophs and lactotrophs Basophils- Basophilic/blue colored- Corticotrophs, thyrotrophs, and gonadotrophs Chromophobe cells- poorly staining cytoplasm

Robbins and Cotran Pathologic basis of disease, 10th edition, Page 1068

↑ *Back to this question in Part A*

@Neet_pg_bot

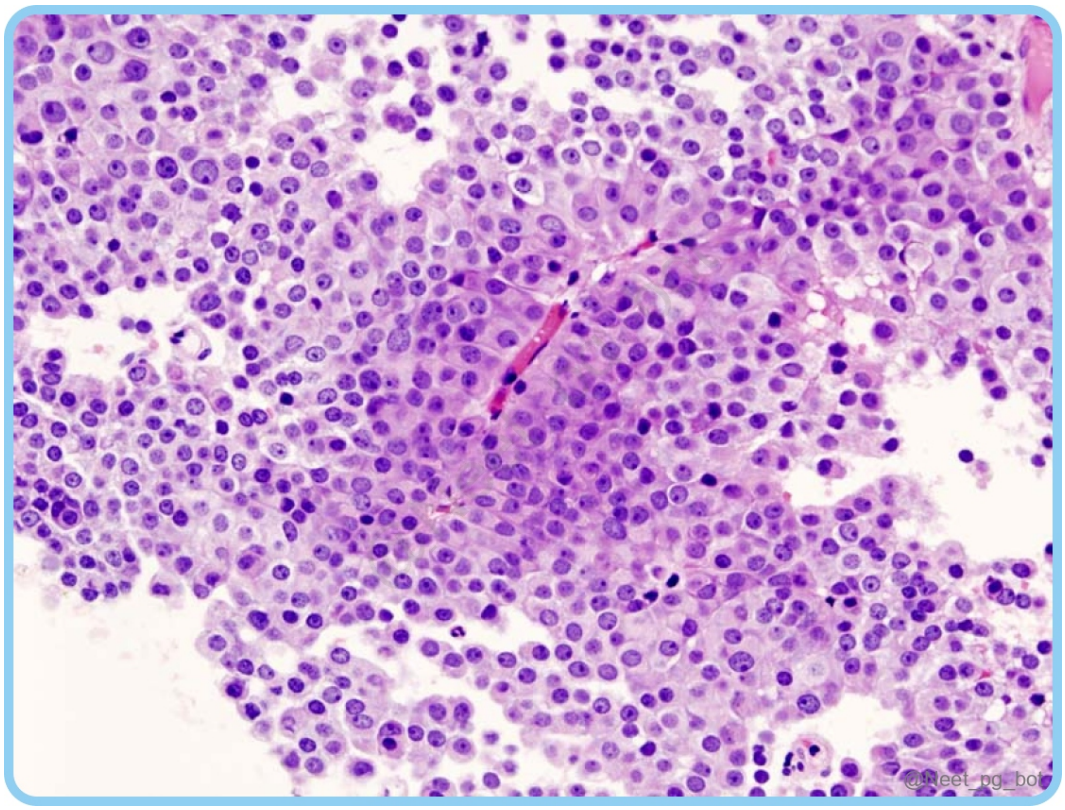
Q3: A pathologist examines a surgically resected pituitary tumour under a microscope. The tumour comprises sheets of monomorphic, round to polygonal cells with central nuclei and sparse to absent reticulin network. What is the most likely diagnosis? (Q845582)

A. Pituitary adenoma

B. Pituitary carcinoma

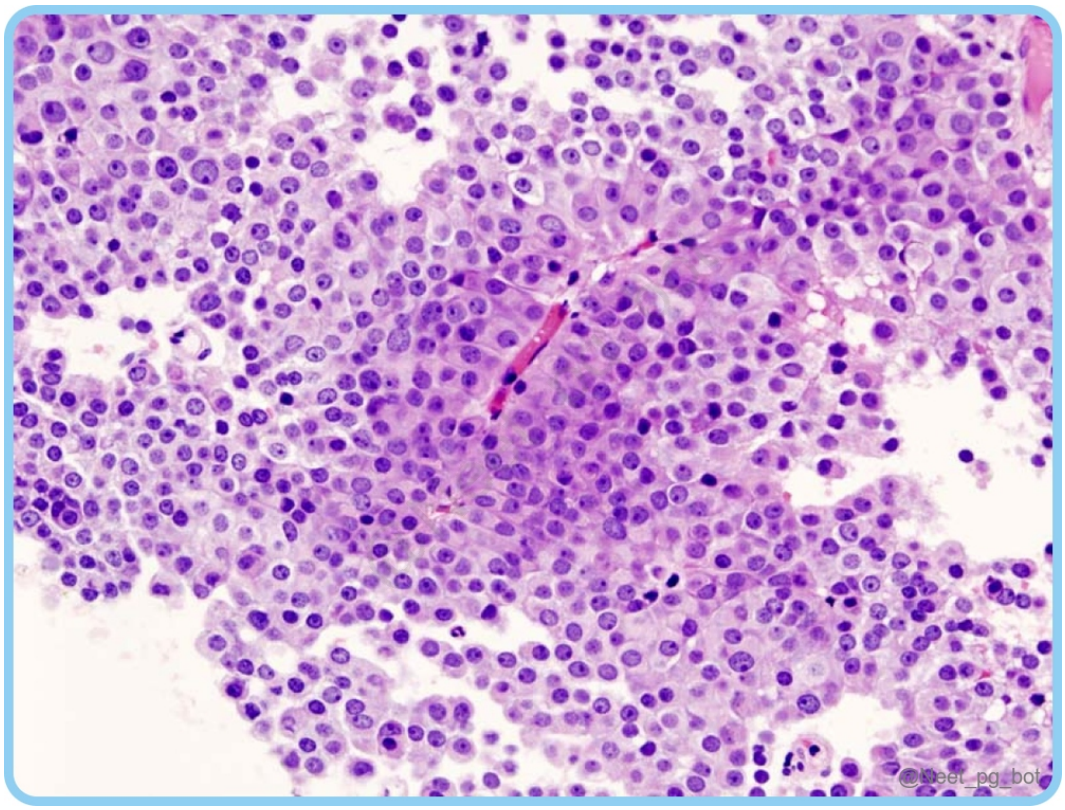
C. Craniopharyngioma

D. Schwannoma



Correct Answer: A. Pituitary adenoma

Explanation: Pituitary adenoma: Pituitary adenomas are benign tumors that arise from the pituitary gland and are characterized by sheets of monomorphic, round to polygonal cells with central nuclei and a sparse to absent reticulin network Cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from normal anterior pituitary parenchyma. ■They are well-circumscribed and encapsulated. ■They are the most common type of pituitary tumor and can be classified based on size as follows. Pituitary carcinoma (Option B) : Is very rare and have malignant cells showing nuclear pleomorphism along with invasive growth and metastasis. Schwannoma (Option D) : Schwannomas are tumors of Schwann cells found along peripheral nerves. They display spindle-shaped cells in a palisading pattern and stain positive for S-100 protein. They do not arise in the pituitary gland. Craniopharyngioma (Option C): Origin: Rathke's pouch Site: Suprasellar location (compression of optic chiasm) Age: Children Clinical feature: Vision disturbance & headaches Radiology: Calcification Microscopic Examination: Adamantinomatous Palisading nuclei Stellate reticulum Wet keratin on gross examination: Machine oil appearance ■■■■■■■ Papillary



@Neet_pg_bot

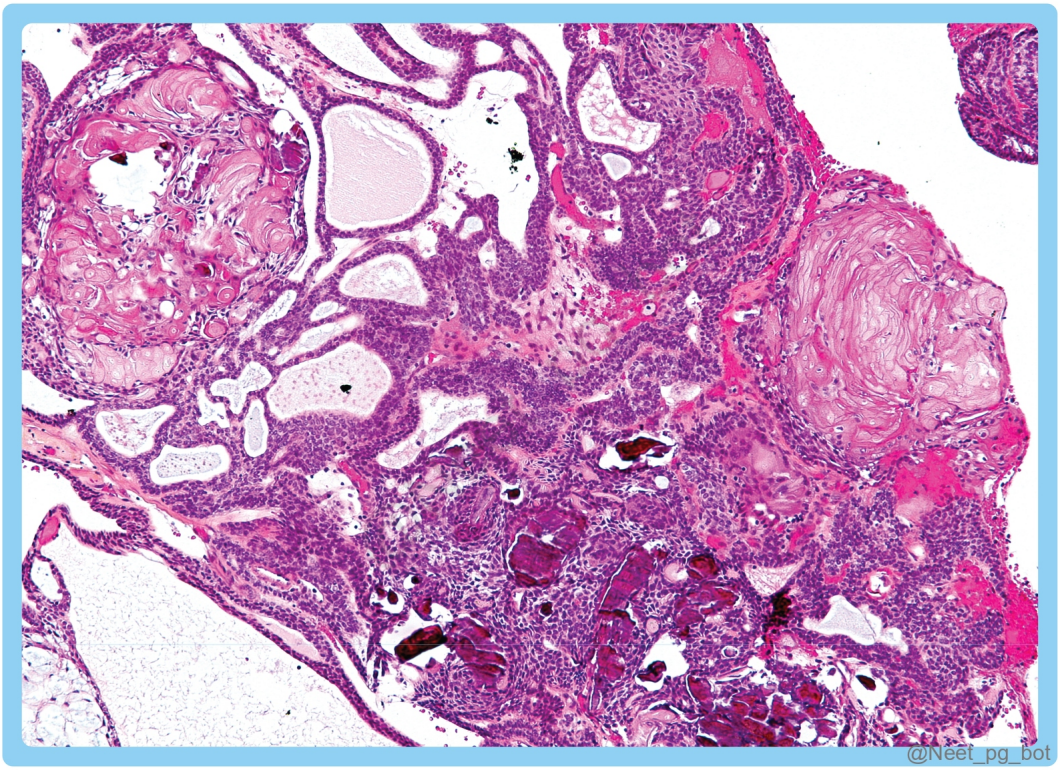
Q4: A 12-year-old child presents with headaches, visual disturbances, and delayed growth. An MRI of the brain reveals a 3 cm cystic mass with calcifications. The growth was found to be encapsulated and multiloculated. What is the most likely diagnosis? (Q845583)

A. Oligodendroglioma

B. Meningioma

C. Craniopharyngioma

D. Pituitary adenoma

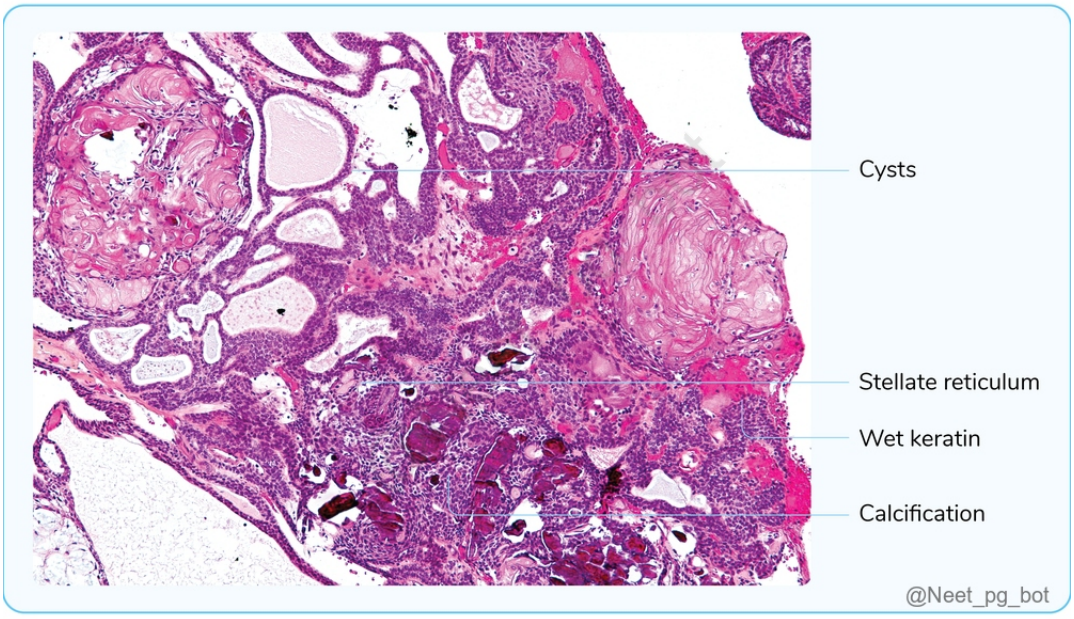


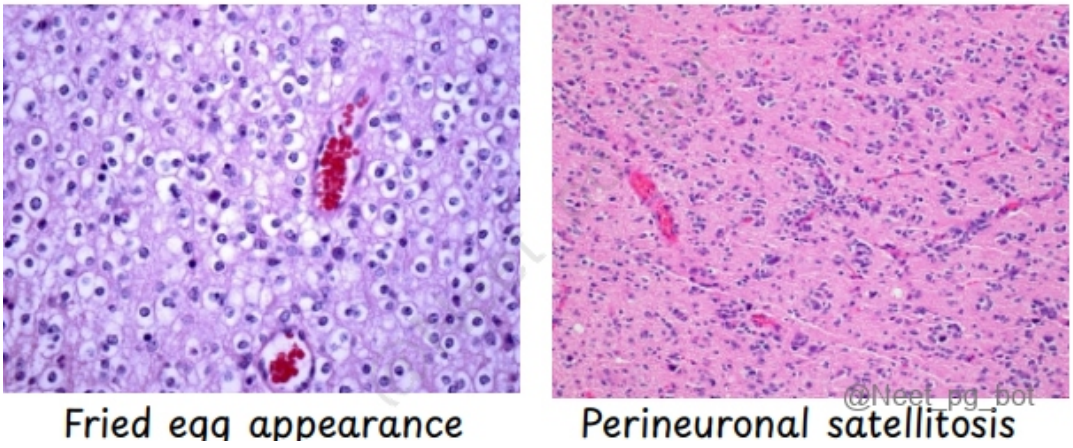
Correct Answer: C. Craniopharyngioma

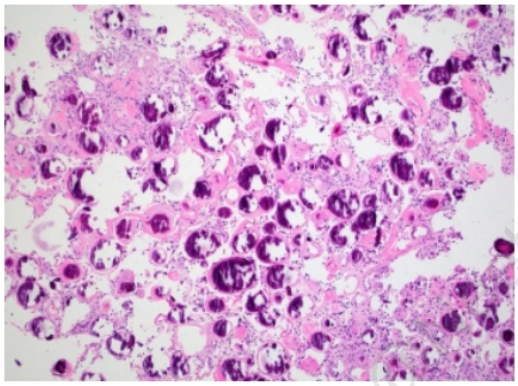
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Craniopharyngiomas are benign tumours arising from vestigial remnants of the Rathke pouch. They commonly occur in the suprasellar region and often present as encapsulated and multiloculated cystic masses with calcifications. The cysts contain cholesterol-rich, thick brownish-yellow fluid (compared to machine oi). It has 2 histological variants: Adamantinomatous and papillary. The common presentations include headaches and visual disturbances like bitemporal hemianopia due to optic chiasma compression, while children present with growth retardation due to pituitary hypofunction and GH deficiency. Oligodendroglioma (Option A): Typically affects adults (30–50 years old). Commonly located in the cerebral hemispheres , not suprasellar. Calcifications can be present, but they are intra-axial and not cystic or multiloculated. Endocrine symptoms are rare . Meningioma (Option B): Rare in children; typically seen in middle-aged to older adults . Usually extra-axial , solid , may calcify but are not cystic or multiloculated. Often found incidentally unless very large. It does not cause hormonal dysfunction in children. Pituitary Adenoma(Option D): Unlikely in a child. Pituitary adenomas are rare in children. Typically, adenomas cause endocrine symptoms, but visual changes in children from adenomas are uncommon. Less likely to be calcified or multiloculated. Usually, solid tumours are not cystic.







Psammoma Bodies

@Neet_pg_bot

Q5: A 35-year-old male presents with a history of recurrent kidney stones, hypercalcemia, and a recent diagnosis of a pituitary adenoma. Which of the following

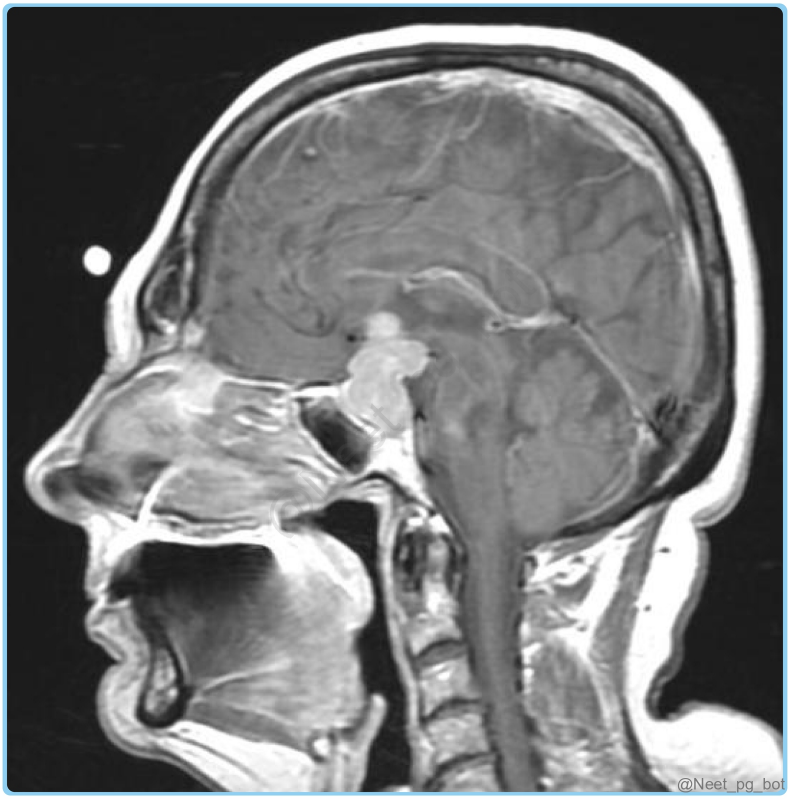
syndromes is most likely associated with his clinical presentation? (Q845584)

A. MEN 2A syndrome

B. MEN 2B syndrome

C. MEN 4 syndrome

D. MEN 1 syndrome



Correct Answer: D. MEN 1 syndrome

Explanation: The given clinical scenario of hypercalcemia and radiological finding of pituitary adenoma is suggestive of MEN1 Genetics: Autosomal dominant; MEN1 mutation on chromosome 11q13. Common Tumors: Anterior Pituitary: Prolactinoma. Parathyroid Adenoma: Most common. Pancreatic Tumors: Gastrinoma (MC, often in the duodenum). Other Associations: Angiofibroma, collagenoma, lipoma, meningioma, VIPoma, foregut carcinoid. Clinical features often include primary hyperparathyroidism (leading to hypercalcemia and recurrent kidney stones), pituitary adenomas, hypoglycemia due to insulinomas, and peptic ulcers in Zollinger-Ellison syndrome. MEN 2A syndrome (Option A) : Associated with mutations in the RET proto-oncogene. Its clinical features include medullary thyroid carcinoma, pheochromocytomas, and parathyroid hyperplasia. MEN 2B syndrome (Option B): Also associated with mutations in the RET proto-oncogene. The clinical features include medullary thyroid carcinoma, pheochromocytomas, mucosal neuromas, and Marfanoid habitus. MEN 4 syndrome (Option D): Caused by mutations in the CDKN1B gene. It is similar to MEN 1 but can include additional features such as tumors of adrenal, kidneys, and reproductive organs.

MEN I	MEN IIa	MEN IIb	MEN IV
Wermer's syndrome	Sipple syndrome		
MENIN mutation	RET mutation	CDKN1B mutation	
• Pituitary adenoma • Parathyroid Hyperplasia • Pancreatic tumor	• Parathyroid Hyperplasia • Medullary carcinoma thyroid • Pheochromocytoma	• Mucosal neuroma • Marfanoid habitus • Medullary carcinoma • Pheochromocytoma	Similar to MEN 1

@Neet_pg_bot

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1129-1130

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which mutation is associated with pituitary carcinoma? (Q845585)

A. AIP

B. CDKN I B

C. HRAS

D. MEN 1

Correct Answer: C. HRAS

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Pituitary adenoma treated with surgery, radiation therapy, and subsequent symptoms that include adjacent structure invasion point to a diagnosis of pituitary carcinoma which has HRAS mutation. HRAS mutation is a somatic activating mutation affecting mitogenic signaling cell growth and survival. HRAS → Proto-oncogene; mutations seen in bladder, thyroid, head & neck cancers . KRAS → Most common RAS mutation; in colon, pancreatic, lung adenocarcinoma ; resistant to EGFR inhibitors. NRAS → Mutations mainly in melanoma and hematologic malignancies (AML, ALL, MDS). Genetic alterations in pituitary tumors Gene affected Commonly associated tumour AIP PRKAR1A Somatotroph or lactotroph adenoma CDKN1 B USP8 Corticotroph adenoma GNAS Somatotroph adenoma HRAS Pituitary carcinoma DICER1 Pituitary blastoma MEN 1 Somatotroph, lactotroph, or corticotroph adenoma

@Neet_pg_bot

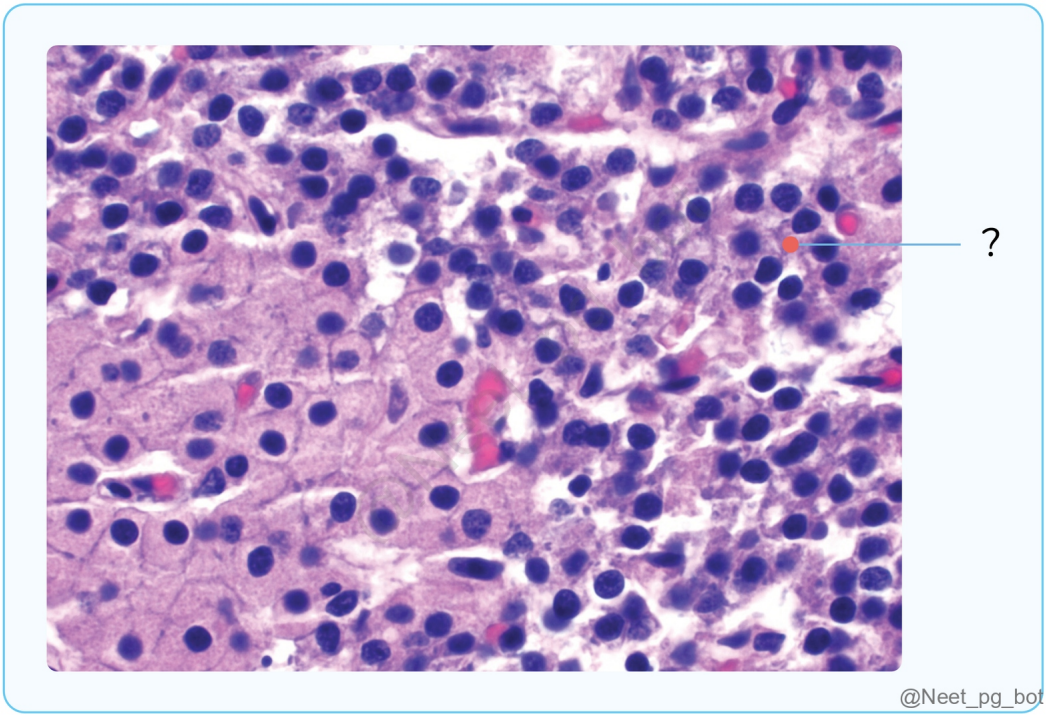
Q7: Identify the marked cells in the histology of the parathyroid below. (Q845586)

A. Oxyphil cells

B. Chief cells

C. Adipocytes

D. Parafollicular cells



Correct Answer: B. Chief cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The marked cells with light pink cytoplasm and centrally placed nuclei in the histology of the parathyroid gland are called chief cells. Oxyphil cells (Option A) are dark pink, and have eosinophilic granular cytoplasm. Adipocytes (Option C) are fat cells with clear cytoplasm due to the dissolution of fat content during tissue processing. Parafollicular cells (Option D) are seen in the thyroid gland, interspersed between thyroid follicles, and stain pale.

Robbins and Cotran Pathologic basis of disease, 10th edition, Page 1094

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following microscopic features is most indicative of a parathyroid adenoma rather than parathyroid hyperplasia? (Q845587)

A. Diffuse hyperplasia of chief cells throughout the parathyroid gland

B. Stromal fat infiltration within the parathyroid tissue

C. Intranuclear cytoplasmic inclusions within chief cells

D. Difficult to distinguish on microscopy

Correct Answer: D. Difficult to distinguish on microscopy

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Parathyroid adenoma and parathyroid hyperplasia are microscopically identical and difficult to differentiate. All microscopic features mentioned are seen in both parathyroid adenoma and parathyroid hyperplasia. Diffuse hyperplasia of chief cells throughout the parathyroid gland Stromal fat infiltration within the parathyroid tissue Intranuclear cytoplasmic inclusions within chief cells Grossly, parathyroid adenoma occurs as a distinct nodule within a capsule and parathyroid hyperplasia classically affects all four glands. Syndromes associated with parathyroid adenomas: MEN-1 MEN-2 MEN-4 Familial hypocalciuric hypercalcemia (rare)

@Neet_pg_bot

Q9: Which of the following genetic mutations is most commonly associated with pheochromocytoma? (Q845588)

A. Gain of function mutation in n-Myc gene

B. Gain of function mutation in RET gene

C. Loss of function mutation in the RET gene

D. Loss of function mutation in MEN 1 gene

Correct Answer: B. Gain of function mutation in RET gene

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The genetic mutation most commonly associated with pheochromocytoma is the Gain of function mutation in the RET gene. Genetics of pheochromocytoma 25% familial Rule of TENS-1/10 patients with pheochromocytoma it is malignant, in 1/10 of cases the tumor is bilateral, in 1/10 extra-adrenal and in 1/10

familial RET(Chromosome 10) EPAS 1 VHL(deletion of chromosome 3p) NF1 SDH B, C, D

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1127

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: The 4-year-old kid is brought with complaints of periorbital ecchymosis, miosis, and ptosis. CT scan reveals a tumour on the right kidney with calcifications. A biopsy reveals small, dark blue cells with scanty cytoplasm. Which mutation is most likely connected to this mass? (Q845589)

A. ALK gene mutation

B. RET gene mutation

C. L-MYC gene mutation

D. VHL gene mutation

Correct Answer: A. ALK gene mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Neuroblastoma Neural crest cell origin Most common extracranial solid tumors of childhood. Pathogenesis N-Myc amplification, and ALK gene mutation Involves adrenal medulla, sympathetic chain Clinical features Age < 4 years Abdominal mass Opsoclonus myoclonus syndrome Periorbital ecchymoses (orbital metastases) Spinal cord compression from epidural invasion (horner syndrome) Diagnostic findings N-MYC gene amplification Microscopy: small round blue cells with scanty cytoplasm, Homer Wright rosettes. Labs: elevated catecholamines Gene Role Notes ALK Proto-oncogene Most common familial neuroblastoma mutation (~50% of familial cases), sporadic cases also occur RET (option B) Medullary thyroid carcinoma / MEN2 Not associated with neuroblastoma L-MYC (option C) Oncogene Primarily associated with Small Cell Lung Cancer (SCLC) ; amplification is rarely the primary driver in neuroblastoma compared to N-MYC. N-MYC Oncogene Amplification associated with poor prognosis in neuroblastoma, but mutation not the primary driver VHL (option B) Von Hippel–Lindau disease Associated with renal cell carcinoma, pheochromocytoma; not neuroblastoma Wilm's tumor: Wilms tumor (Nephroblastoma) is the most common primary renal malignancy of childhood, typically presenting in children aged 2–5 years . Feature Description Origin Derived from nephrogenic rests (primitive metanephric blastema). Presentation Large, palpable, unilateral flank mass ; usually smooth and firm. Associated Signs Hematuria (25%), hypertension (due to increased renin), and abdominal pain. Imaging CT/Ultrasound shows a mass that does NOT cross the midline (displaces the kidney). Histology Triphasic pattern : Blastemal (small blue cells), Stromal (fibrocystic), and Epithelial (tubules/glomeruli).

References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 477, 478

↑ *Back to this question in Part A*

@Neet_pg_bot

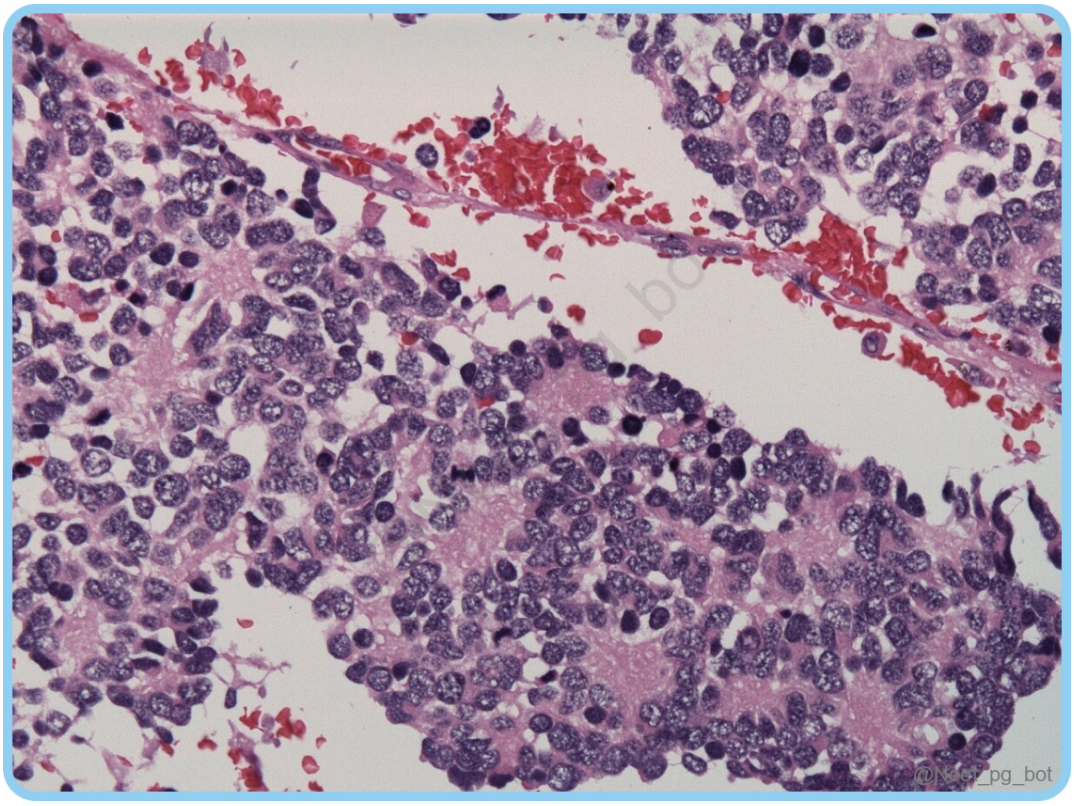
Q11: A 2-year-old boy is brought with complaints of abdominal lump for 2 months. HPE of the mass is shown below. Which of the following conditions is not associated with a similar finding? (Q845590)

A. Neuroblastoma

B. Medulloblastoma

C. Retinoblastoma

D. Primitive neuroectodermal tumors

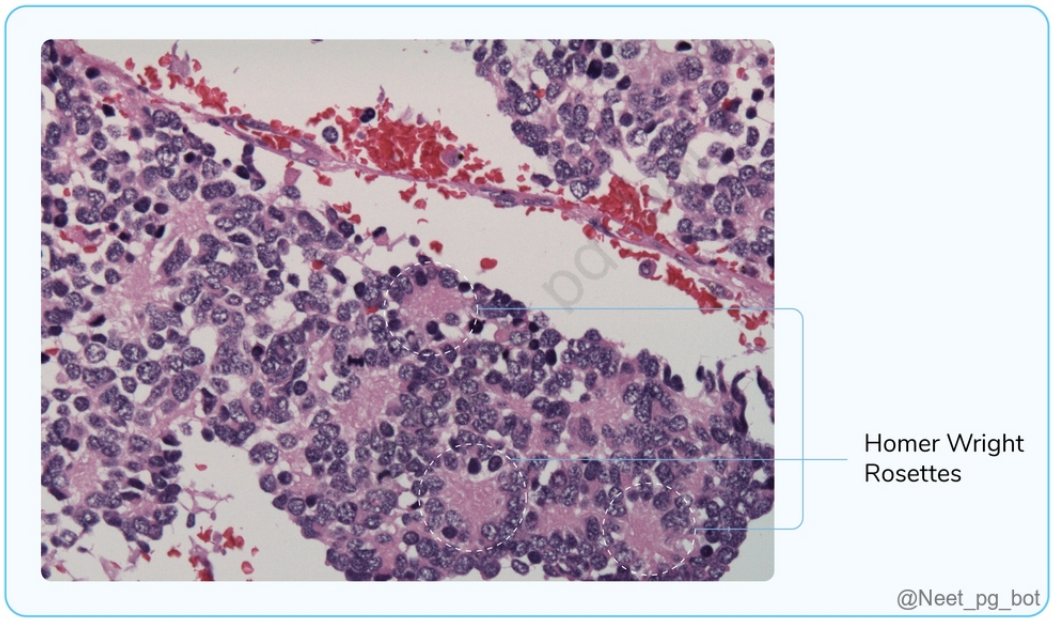


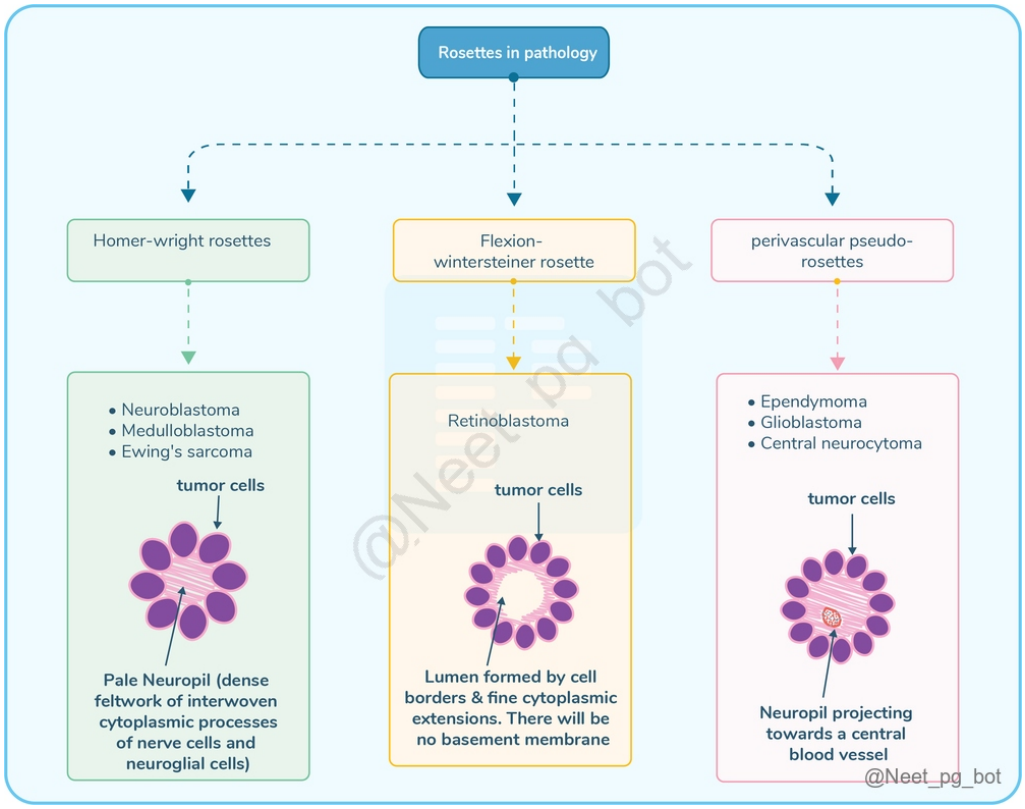
Correct Answer: C. Retinoblastoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Homer Wright rosettes are also seen in Neuroblastoma, Medulloblastoma and primitive neuroectodermal tumors.





References:

Robbins and Cotran Pathologic basis of disease, 10th edition, 478, 1298, 1193, 723

↑ *Back to this question in Part A*

@Neet_pg_bot

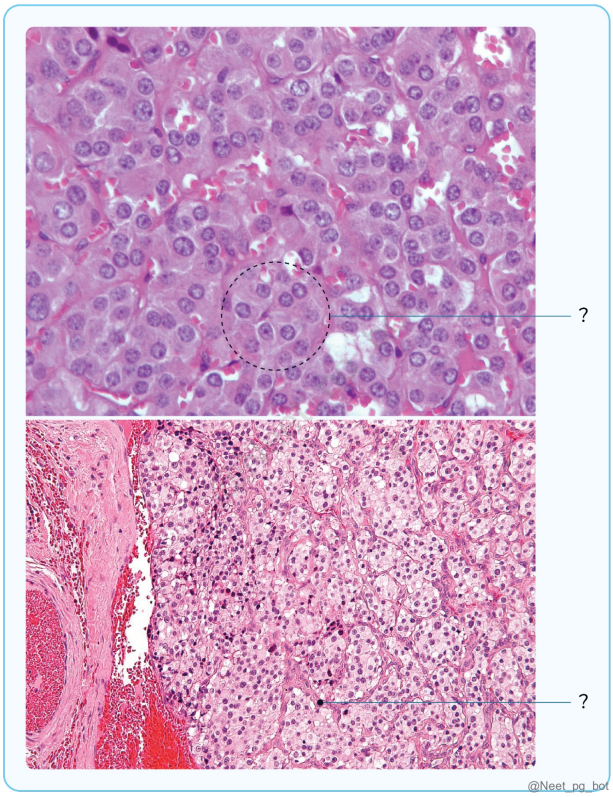
Q12: This histology finding is seen in all these tumors except? (Q845591)

A. Pheochromocytoma

B. Carotid body tumor

C. Neuroblastoma

D. Medullary carcinoma of the thyroid



Correct Answer: C. Neuroblastoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The image shows nests (Zellballen) of round to oval chief cells with abundant, clear, or granular, eosinophilic cytoplasm and uniform, round nuclei surrounded by delicate vascular septae. The nuclei show a stippled “salt-and-pepper” chromatin that is characteristic of tumors like: Pheochromocytoma (Option A) Carotid body tumour (Option B) Medullary carcinoma of the thyroid (Option D) Small cell carcinoma of the lungs Neuroblastoma (Option C) on histology has small round blue cells with scanty cytoplasm. These cells resemble a

rosette which means ‘flower-like’ called Homer-Wright rosettes.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 746 & 1128.

↑ *Back to this question in Part A*

@Neet_pg_bot

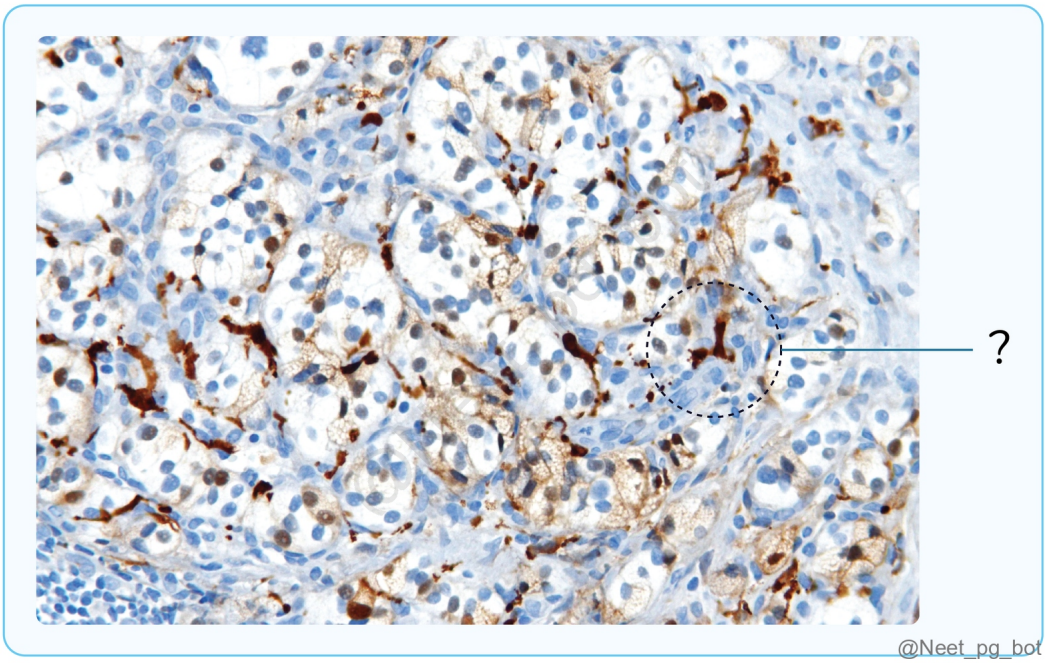
Q13: A 40-year-old woman has been evaluated for intermittent headaches, insomnia, diaphoresis, and unintentional weight loss over the past several months. The patient is found to have a neoplastic mass producing excessive hormones causing symptoms. Histopathology of the same is shown below. These cells marked below stain positive for which of the following immunohistochemical markers? (Q845592)

A. Synaptophysin

B. Chromogranin

C. Neuron-specific enolase

D. S-100

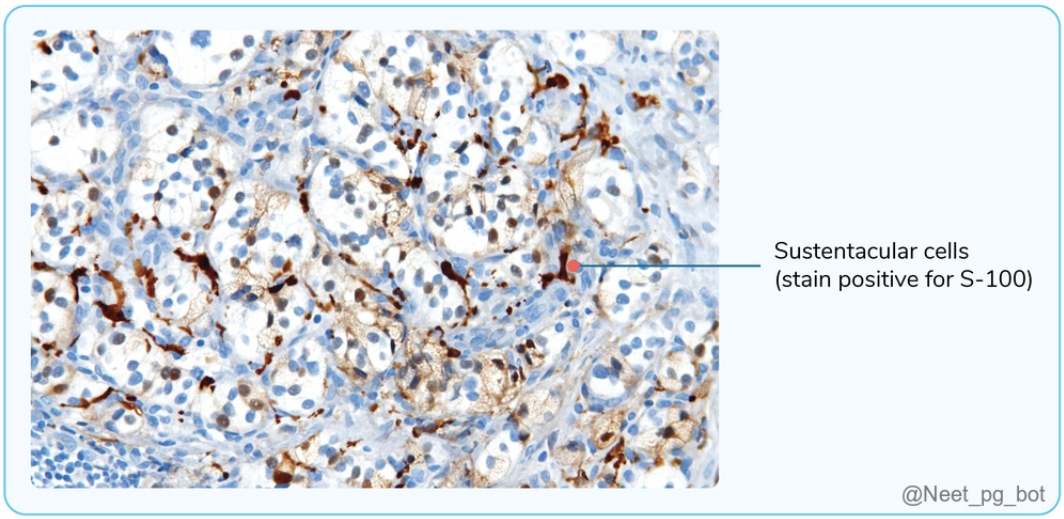


Correct Answer: D. S-100

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given scenario and HPE is suggestive of pheochromocytoma with a marked structure containing sustentacular cells that stain positive for S-100 protein . Pheochromocytoma is a tumour of the chromaffin cells or the chief cells of the adrenal medulla. The diagnosis is confirmed by histology showing a highly vascular tumor with nests of spindle-shaped or polygonal cells (zelleballen pattern). The chief cells are neuroendocrine in origin and stain strongly for synaptophysin, chromogranin, and neuron-specific enolase(NSE). The supporting network of spindle-shaped stromal cells, collectively called sustentacular cells stain positive for S-100 protein a calcium-binding protein expressed by a variety of mesenchymal cell types. (Option D) .



References:

Robbins and Cotran Pathologic basis of disease, 10th Edition, Page 1128

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 40-year-old woman presents to her primary care physician with a recent diagnosis of medullary thyroid carcinoma (MTC). She reports no significant family history of endocrine disorders. Laboratory investigations show elevated levels of serum calcium and plasma catecholamines and metanephrines. What is the most likely diagnosis in this patient? (Q845593)

A. MEN 1 syndrome

B. MEN 2 A syndrome

C. MEN 2 B syndrome

D. Neurofibromatosis type 1

Correct Answer: B. MEN 2 A syndrome

Explanation: The most likely diagnosis in this patient is MEN 2 A syndrome, which is characterized by medullary thyroid carcinoma (MTC), primary hyperparathyroidism and pheochromocytoma. Elevated serum calcium → suggests primary hyperparathyroidism Elevated plasma catecholamines and metanephrines → suggests pheochromocytoma

MEN I	MEN IIa	MEN IIb	MEN IV
Wermer's syndrome	Sipple syndrome		
MENIN mutation	RET mutation	CDKN1B mutation	
• Pituitary adenoma • Parathyroid Hyperplasia • Pancreatic tumor	• Parathyroid Hyperplasia • Medullary carcinoma thyroid • Pheochromocytoma	• Mucosal neuroma • Marfanoid habitus • Medullary carcinoma • Pheochromocytoma	Similar to MEN 1

« Back to Folder Directory

[13_Endocrinology] 058 Previous Year Questions — Quick Jump

Q1 (p. 2388) *Q2 (p. 2388)* *Q3 (p. 2389)* *Q4 (p. 2390)* *Q5 (p. 2391)* *Q6 (p. 2393)*
Q7 (p. 2394) *Q8 (p. 2395)* *Q9 (p. 2395)* *Q10 (p. 2398)* *Q11 (p. 2402)* *Q12 (p. 2403)*
Q13 (p. 2404) *Q14 (p. 2406)* *Q15 (p. 2408)*

Q1: Mutation in which of the following genes is most commonly associated with medullary thyroid carcinoma? (Q866734)

A. RAS

B. BRAF

C. RET

D. TP53

Correct Answer: C. RET

Explanation: Medullary thyroid carcinomas are associated with RET proto-oncogene mutation. Medullary carcinoma of the thyroid a neuroendocrine tumour arising from parafollicular C cells. They secrete calcitonin, which regulates calcium levels and is also a marker for diagnosis and postoperative follow-up. Carcinoembryonic antigen (CEA) is a marker in whom calcitonin is negative. They can be sporadic or associated with familial syndromes like MEN 2. Both have associated RET mutations. Sporadic tumors usually present with solitary nodules whereas familial are characterized by bilaterality and multicentricity, and can have features of other associated tumors. A biopsy would show amyloid deposits (Acal) derived from calcitonin polypeptides. Thyroid Malignancy Mutations/Genetic Alterations Follicular Thyroid Adenoma (Benign Condition) RAS (Option A) Papillary Thyroid Carcinoma (PTC) BRAF V600E (Option B) RET/PTC rearrangements Follicular Thyroid Carcinoma (FTC) RAS (Option A) PAX8-PPARγ rearrangements PIK3CA Medullary Thyroid Carcinoma (MTC) RET (Option C) Anaplastic Thyroid Carcinoma (ATC) TP53 (Option D)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A patient presents with a mass in the front of the neck, along with odynophagia and dyspnea. Histopathology reveals tumour cells positive for TTF-1, synaptophysin, and chromogranin, and there is evidence of amyloid deposition. What is the most

likely diagnosis? (Q866374)

A. Papillary thyroid carcinoma

B. Follicular thyroid carcinoma

C. Medullary thyroid carcinoma

D. Anaplastic thyroid carcinoma

Correct Answer: C. Medullary thyroid carcinoma

Explanation: The given clinical scenario with IHC positive for TTF-1, synaptophysin, and chromogranin and evidence of amyloid deposition is all suggestive of medullary thyroid carcinoma, which has amyloid deposition derived from calcitonin, known as A-CAL. 1. Clinical Features Origin: Parafollicular C cells of the thyroid (neuroendocrine cells). Hormone secreted: Calcitonin (does not cause hypocalcemia in most cases). Presentations: Neck mass: Firm, non-tender, may be solitary or multiple. Local compressive symptoms: Odynophagia (painful swallowing) Dyspnea (tracheal compression) Hoarseness (recurrent laryngeal nerve involvement) Systemic symptoms Diarrhea and flushing (due to hormone secretion like calcitonin, serotonin, VIP in some cases) Family history: MEN 2A or 2B syndromes (pheochromocytoma, parathyroid hyperplasia in 2A; mucosal neuromas and Marfanoid habitus in 2B). 2. Investigations A. Laboratory tests Serum calcitonin: Elevated (marker for diagnosis and follow-up). Carcinoembryonic antigen (CEA): Often elevated; used for prognosis. RET proto-oncogene mutation testing: In patients and first-degree relatives. B. Imaging Neck ultrasound: Hypoechoic solid nodule, may show cervical lymphadenopathy. CT/MRI: For extent and metastasis assessment. Radioiodine scan: Usually negative (C cells do not take up iodine). C. Histopathology Tumour cells: Polygonal/spindle-shaped, arranged in nests/trabeculae. Amyloid deposition in stroma (derived from calcitonin). Immunohistochemistry: TTF-1 → confirms thyroid origin Synaptophysin & chromogranin → confirm neuroendocrine nature Calcitonin positive in tumour cells. 3. Diagnosis Definitive diagnosis : Fine-needle aspiration (FNA) cytology → suspicious for MTC. Confirmed by immunohistochemistry for calcitonin and neuroendocrine markers + histologic amyloid. Elevated serum calcitonin strongly supports the diagnosis.

↑ *Back to this question in Part A*

@Neet_pg_bot

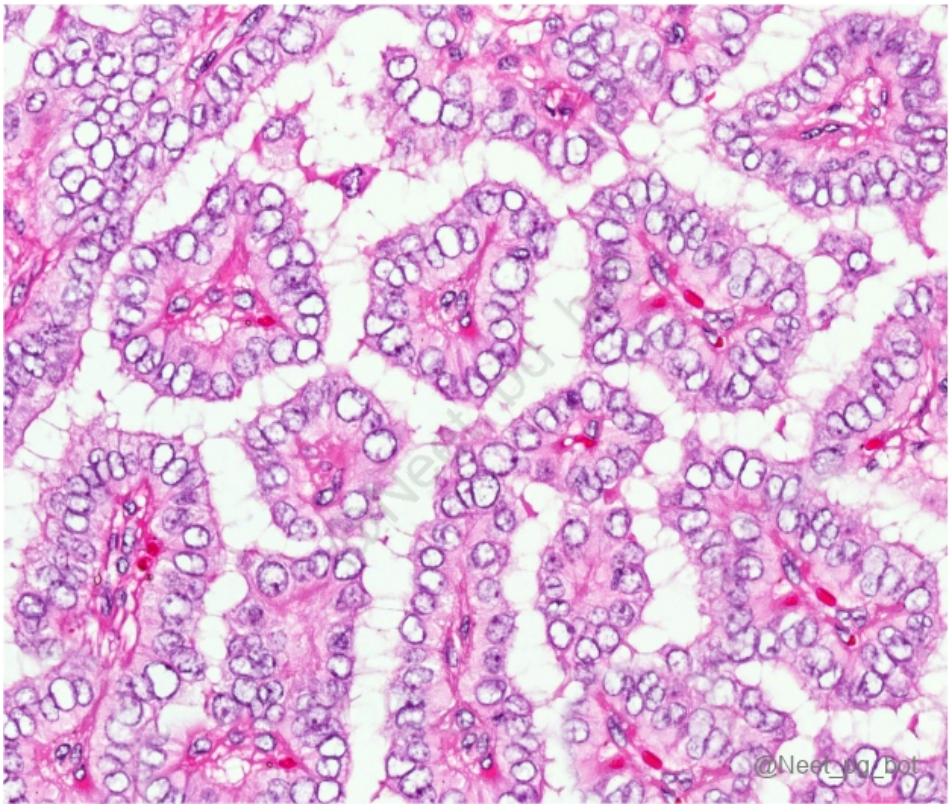
Q3: Identify the gene commonly involved in the carcinoma shown in the image below: (Q843990)

A. RAS

B. PAX8–PPARγ

C. BRAF V600

D. P53



Correct Answer: C. BRAF V600

Explanation: Correct Option C - BRAF V600: The image shows Orphan Annie's eye nucleus, which is seen in papillary thyroid cancer. It is associated with BRAF V600 mutation. Orphan Annie Eye Nuclei These nuclei appear empty, clear, and ground-glass–like. Caused by chromatin clearing. Highly characteristic of papillary thyroid carcinoma (PTC). Other nuclear features in PTC: Nuclear grooves, Intranuclear cytoplasmic inclusions Overlapping nuclei, Psammoma bodies BRAF V600E Mutation One of the most common mutations in PTC, especially the classical and tall-cell variant. Leads to constitutive activation of the MAPK pathway, driving tumor growth. Mutation associated with: More aggressive disease Extrathyroidal extension Lymph node metastasis Higher recurrence risk Incorrect Options: Options A, B, and D are not associated with papillary thyroid cancer.

@Neet_pg_bot

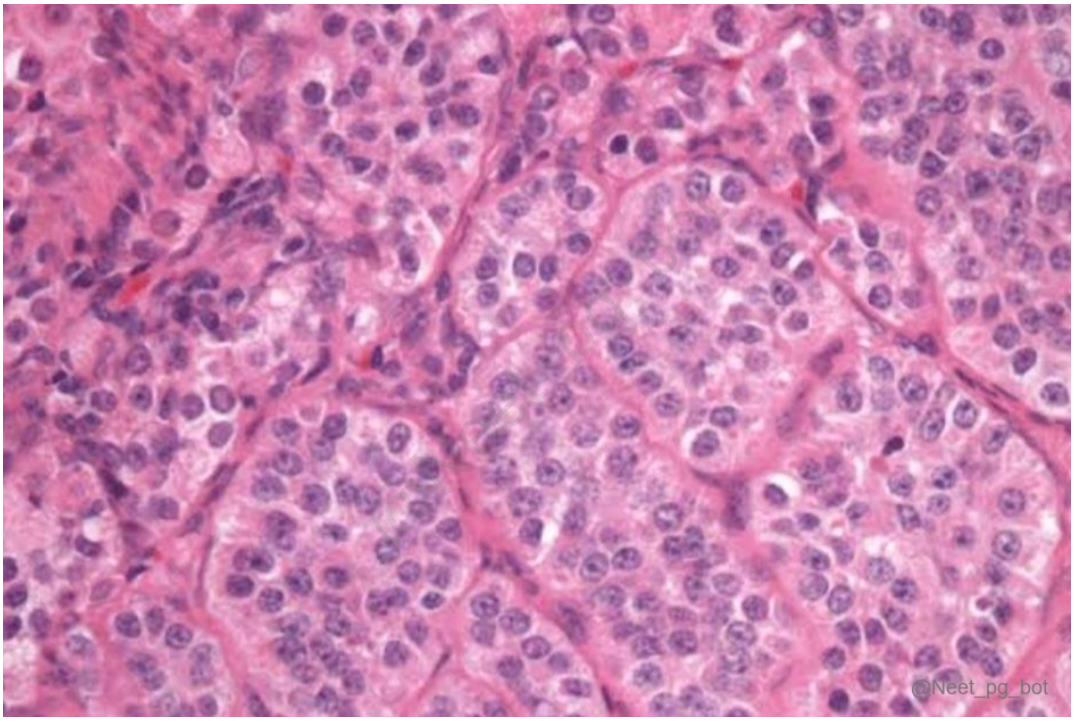
Q4: A patient presents with headaches, palpitations, and hypertension. On laboratory examination, urine VMA is positive. His biopsy findings are given below. Which of the following is a correct statement? (Q844236)

A. Mostly malignant

B. Mostly in children

C. Mostly bilateral

D. Associated with MEN2A



Correct Answer: D. Associated with MEN2A

Explanation: Correct Option D - Associated with MEN2A: The given biopsy shows a nesting pattern or Zellballen pattern, which is suggestive of pheochromocytoma. It is associated with Multiple Endocrine Neoplasia type 2A (MEN2A). Incorrect Options: Option A - Mostly malignant: Pheochromocytomas are mostly benign, only 10% malignant. Option B - Mostly in children: Pheochromocytomas are more common in adults; only 10% occur in children. Option C - Mostly bilateral: Pheochromocytomas are mostly unilateral, and only 10% are bilateral.

@Neet_pg_bot

Q6: Which of the following is a new intranuclear immunohistochemistry marker for neuroendocrine tumors? (Q840013)

A. Synaptophysin

B. Chromogranin

C. INSM1

D. NCAM1/ CD56

Correct Answer: C. INSM1

Explanation: INSM1 (Insulinoma-associated protein 1) is a newer intranuclear marker used in pathology for identifying neuroendocrine tumors (NETs). It stains the nucleus, unlike older markers which are cytoplasmic or membranous. INSM1 has high sensitivity and specificity for NETs including carcinoid tumors, small-cell carcinoma, medullary thyroid carcinoma, and pheochromocytoma. Because of its strong and clear nuclear staining, it is now widely adopted as a modern, reliable NET marker. Incorrect Options: Option A) Synaptophysin – A cytoplasmic neuroendocrine marker; not intranuclear. Option B) Chromogranin – A cytoplasmic secretory granule marker; not new and not intranuclear. Option D) NCAM1 / CD56 – A cell surface adhesion molecule; less specific and not intranuclear.

↑ *Back to this question in Part A*

Q7: A patient presents with neck swelling with compression of the trachea and esophagus. Histopathological assessment shows cell nest and pink extracellular amyloid stroma. What is the origin of the tumor? (Q840079)

A. Parafollicular C cells

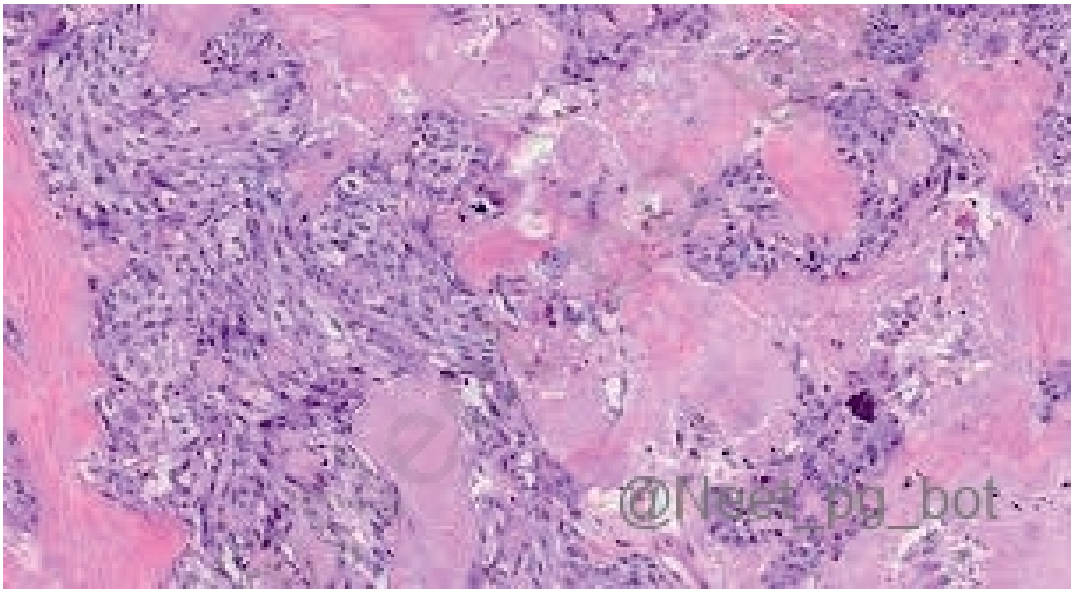
B. Hurthle cell

C. Follicular cells

D. Askanazy cells

Correct Answer: A. Parafollicular C cells

Explanation: Correct Option A - Parafollicular C cells: The presence of an amyloid stroma and nesting pattern suggests the likelihood of medullary carcinoma of the thyroid. It originates from the Parafollicular C cells. Incorrect Options: Options B & D - Hurthle cells & Askanazy cells: Hurthle cells or Askanazy cells are seen in Hashimoto's thyroiditis. They are not associated with medullary carcinoma. Option C - Follicular cells: Follicular cells give rise to papillary, follicular, and anaplastic thyroid carcinomas but not medullary carcinoma.



References:

.

↑ *Back to this question in Part A*

Q8: A 26-year-old female patient presents with a palpable thyroid nodule and occasional neck discomfort. She has no history of radiation exposure to the neck. On physical examination, a solitary, firm, non-tender thyroid nodule is noted. Ultrasound reveals a hypoechoic nodule with microcalcifications. Fine-needle aspiration biopsy is performed, and histological analysis reveals characteristic nuclear changes. What is the most common thyroid cancer in this patient? (Q820517)

A. Papillary carcinoma

B. Follicular carcinoma

C. Medullary carcinoma

D. Anaplastic carcinoma

Correct Answer: A. Papillary carcinoma

Explanation: Correct Option A - Papillary carcinoma: This is the most common type of thyroid cancer, especially in young adults. It often presents as a solitary thyroid nodule, and its characteristics on ultrasound, such as hypoechoic appearance and microcalcifications, along with the patient's demographic and clinical profile, are consistent with the case described. Papillary carcinoma is known for its characteristic nuclear changes, including nuclear grooves and pseudoinclusions. It usually has an excellent prognosis with a high survival rate. Incorrect Options: Option B - Follicular carcinoma: This type of thyroid cancer also presents as a thyroid nodule. However, it is less common than papillary carcinoma. Fine-needle aspiration biopsy alone might not be able to distinguish between follicular adenoma and follicular carcinoma. Histopathological examination of the tumor capsule and vascular invasion is required to make the distinction. Option C - Medullary carcinoma: Medullary carcinoma arises from parafollicular C cells and is associated with calcitonin production. It is typically not associated with microcalcifications on ultrasound and does not have the characteristic nuclear changes mentioned in the case. It's less common than papillary carcinoma and is often familial or associated with multiple endocrine neoplasia syndromes. Option D - Anaplastic carcinoma: This is an aggressive and rare type of thyroid cancer. It usually presents with rapid growth, hoarseness, dyspnea (difficulty breathing), and is commonly seen in older patients. It is not associated with the characteristic nuclear changes mentioned in the case and does not typically present with microcalcifications.

@Neet_pg_bot

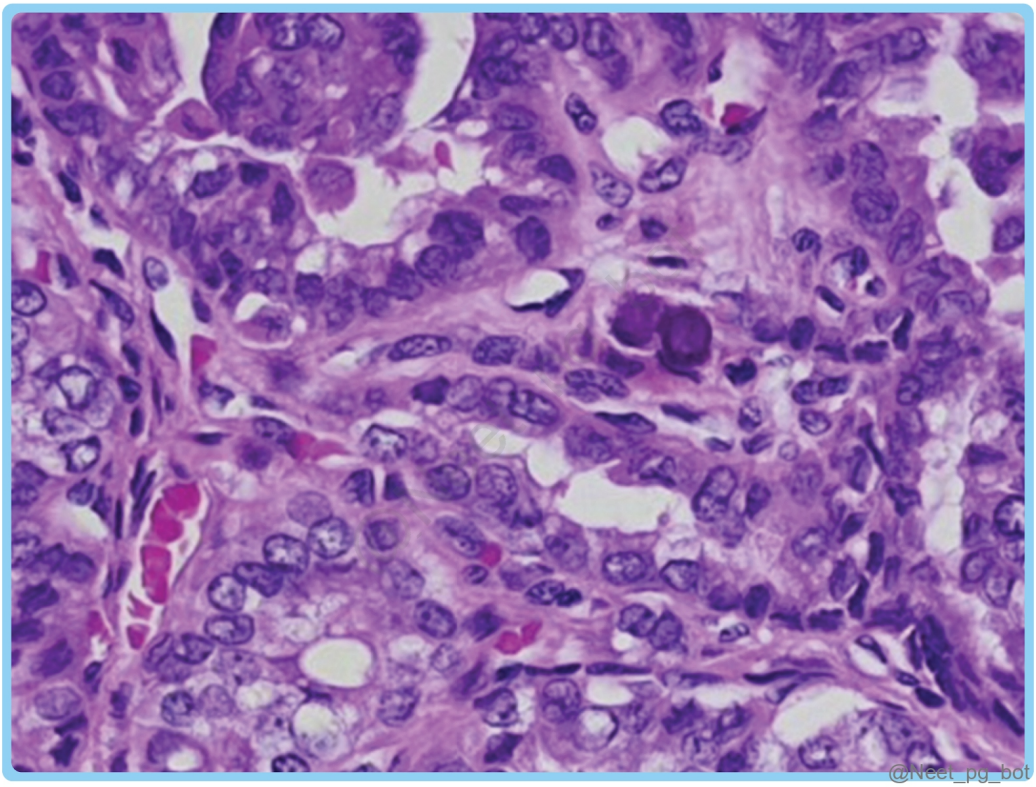
Q9: A 19-year-old female presents with a neck swelling that shifts during swallowing. Ultrasound reveals a 2 cm x 2 cm mass in the left lobe of the thyroid, reaching the strap muscles. Histopathology shows findings as shown in the image. What is the most probable diagnosis? (Q855119)

A. Medullary CA thyroid

B. Follicular CA thyroid

C. Thyroglossal cyst

D. Papillary CA thyroid



Correct Answer: D. Papillary CA thyroid

Explanation: The clinical presentation with neck swelling that shifts during swallowing, along with the ultrasound findings of a mass in the thyroid reaching the strap muscles, raises suspicion for a thyroid pathology. The histopathology showing papillae lined with overlapping nuclei and the characteristic " Orphan Annie eye" nuclei is highly indicative of papillary carcinoma of the thyroid . Papillary carcinoma of the thyroid: This is the most common type of thyroid cancer and is characterized by lymphatic spread. It often presents with a nodule in the anterior neck and lymphadenopathy. Associated with BRAF mutations and RET-PTC fusion HPE shows: True papillae: Fingerlike projections with fibrovascular core. Orphan Annie eye nuclei: Optically clear nucleus produced due to artefact. Intranuclear cytoplasmic inclusions (INCI). Nuclear groove or coffee bean nucleus. Presence of psammoma bodies: Dystrophic calcifications {{caption_text}} {{caption_text}} It has the best

prognosis among thyroid malignancies. Medullary Carcinoma of the Thyroid (Option A) arises from the parafollicular C cells , which produce calcitonin. The provided histopathology does not show the typical features of medullary carcinoma, such as nests or clusters of polygonal cells with amyloid deposits. Follicular Carcinoma of the Thyroid (Option B) arises from the thyroid follicular cells. The histopathology image does not display the characteristic features of follicular carcinomas, such as invasion of the tumour capsule or blood vessels. Thyroglossal Cyst (Option C) is a congenital anomaly resulting from the persistence of thyroglossal duct remnants. It typically presents as a midline neck swelling that moves during swallowing. However, the histopathology does not show features typical of a thyroglossal cyst, such as a cystic structure lined by stratified squamous or columnar epithelium.

↑ *Back to this question in Part A*

@Neet_pg_bot

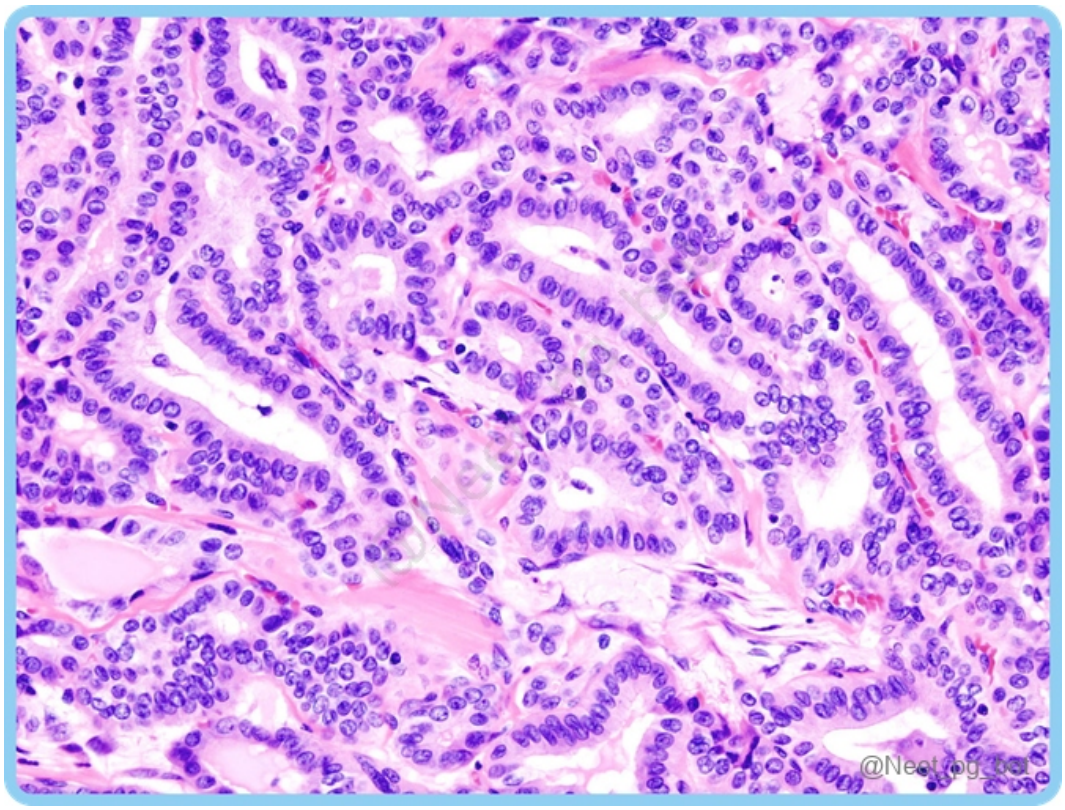
Q10: What is the likely diagnosis for a patient who presents with a swelling in the midline of the neck, based on the biopsy findings, which reveal orphan Annie's eye nuclei as depicted in the image provided? (Q857571)

A. Follicular carcinoma

B. Papillary carcinoma

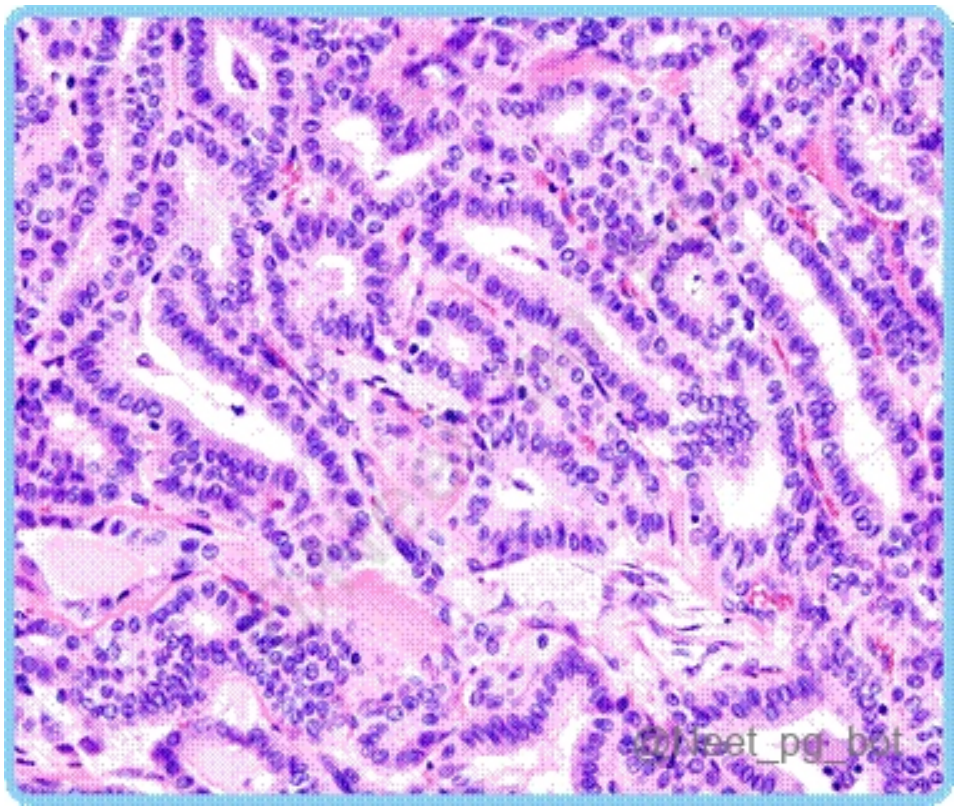
C. Toxic nodular goiter

D. Medullary carcinoma



Correct Answer: B. Papillary carcinoma

Explanation: Papillary thyroid carcinoma, the most common thyroid cancer, is characterised by "orphan Annie's eye" nuclei, which appear empty with a pale, ground-glass appearance under microscopy. Papillary carcinoma thyroid: It is the most common type of thyroid cancer and is characterised by lymphatic spread. It often presents with a nodule in the anterior neck and lymphadenopathy. Associated with BRAF mutations and RET-PTC fusion. HPE shows True papillae: Fingerlike projections with fibrovascular core. Orphan Annie eye nuclei: Optically clear nucleus produced due to artefact. Intranuclear cytoplasmic inclusions (INCI). Nuclear groove or coffee bean nucleus. Presence of psammoma bodies: Dystrophic calcifications It has the best prognosis among thyroid malignancies. {{caption_text}} {{caption_text}} Follicular carcinoma (Option A) is a malignant thyroid tumour of follicular cells lacking papillary carcinoma's distinctive features. It typically affects older individuals and presents as a solitary thyroid mass or, less commonly, as bone metastases. It is more cellular, with a thick, irregular capsule, necrosis, and frequent mitotic activity. {{caption_text}} Toxic nodular goitre (Option C) , also known as Plummer disease or a toxic multi-nodular goitre (MNG), is characterised by a hormonally active and leads to hyperthyroidism. Treatment often includes radioactive iodine, which is absorbed by the thyroid and destroys hormone-producing cells, reducing or eliminating hormone production and potentially decreasing the size of the goitre. {{caption_text}} Medullary carcinoma (Option D) of the thyroid (MTC), a neuroendocrine tumour, originates from the C cells of the thyroid, which produce calcitonin. MTC accounts for less than 5% of all thyroid cancers. Unlike other thyroid cancers, MTC does not accumulate radioiodine but secretes calcitonin. Symptoms may include a lump in the throat, hoarseness due to vocal cord involvement, or difficulty breathing if the tumour obstructs the windpipe. {{caption_text}}



@Neet_pg_bot

Q11: A patient presented to the OPD with long hands and feet and a protruding lower jaw. Which of the following genes is most likely implicated in this scenario? (Q856900)

A. GATA1

B. PIT1

C. TPIT

D. SF1

Correct Answer: B. PIT1

Explanation: The features of long hands and feet, along with a protruding lower jaw, are characteristic of acromegaly , often caused by overproduction of growth hormone (GH). The gene most commonly implicated in this condition is PIT1 (Pituitary-specific gene), a transcription factor that regulates the development and function of pituitary cells responsible for GH production, particularly: Somatotrophs (Growth hormone-producing cells) Lactotrophs (Prolactin-producing cells) Thyrotrophs (TSH-producing cells). PIT1 is essential for the

differentiation of specific pituitary cell types during embryonic development. Its mutations or dysregulation can lead to abnormal pituitary function, causing excess growth hormone production and acromegaly.

@Neet_pg_bot

Q12: What is the minimum biopsy specimen requirement for an adequate sample in the case of a thyroid biopsy? (Q856910)

A. 15 follicular cell clusters containing 10-12 cells

B. 10 follicular cell clusters containing 6-8 cells

C. 3 follicular cell clusters containing 10-15 cells

D. 6 follicular cell clusters containing 10-15 cells

Correct Answer: D. 6 follicular cell clusters containing 10-15 cells

Explanation: For an adequate thyroid biopsy, the specimen should ideally contain at least 6 follicular cell clusters, each having 10-15 cells. Fine Needle Aspiration Cytology (FNAC) is a minimally invasive diagnostic procedure to evaluate abnormalities in various tissues, including thyroid nodules. Provides cytological details but not the Architecture. It is useful in papillary/medullary (amyloid)/anaplastic carcinomas, colloid nodules, and autoimmune or granulomatous thyroiditis. A 23G needle is used. Suspicious solitary/multiple nodules/ dominant nodules should be aspirated. A minimum of six aspirations should be done. An adequate FNAC smear should have six aspirations with six groups of cells, each containing 20 cells. USG-guided aspiration is better. Diagnostic accuracy of FNAC is 95%; sensitivity 85%; specificity 94%. Classification of FNAC reports: Thy 1 Non-diagnostic Thy 1c Non-diagnostic cystic Thy 2 Non-neoplastic Thy 3 Follicular Thy 4 Suspicion of malignancy Thy 5 Malignant Limitations of FNAC: Follicular Neoplasms: FNAC cannot differentiate between follicular adenoma and follicular carcinoma because it does not provide information about the capsule or vascular invasion . A further biopsy is needed for a definitive diagnosis. Riedel’s Thyroiditis: In this, the thyroid gland is replaced by fibrous tissue, which can result in a poor yield of cells, reducing the effectiveness of FNAC. Thyroid Lymphoma: FNAC may not provide sufficient information to diagnose thyroid lymphoma accurately. A biopsy is required to obtain tissue samples for specific markers and a more comprehensive diagnosis.

Bailey & Love’s Short Practice of Surgery, 28th Edition, Page 866

SRB’s Manual of Surgery, 6th Edition, Page 449

↑ *Back to this question in Part A*

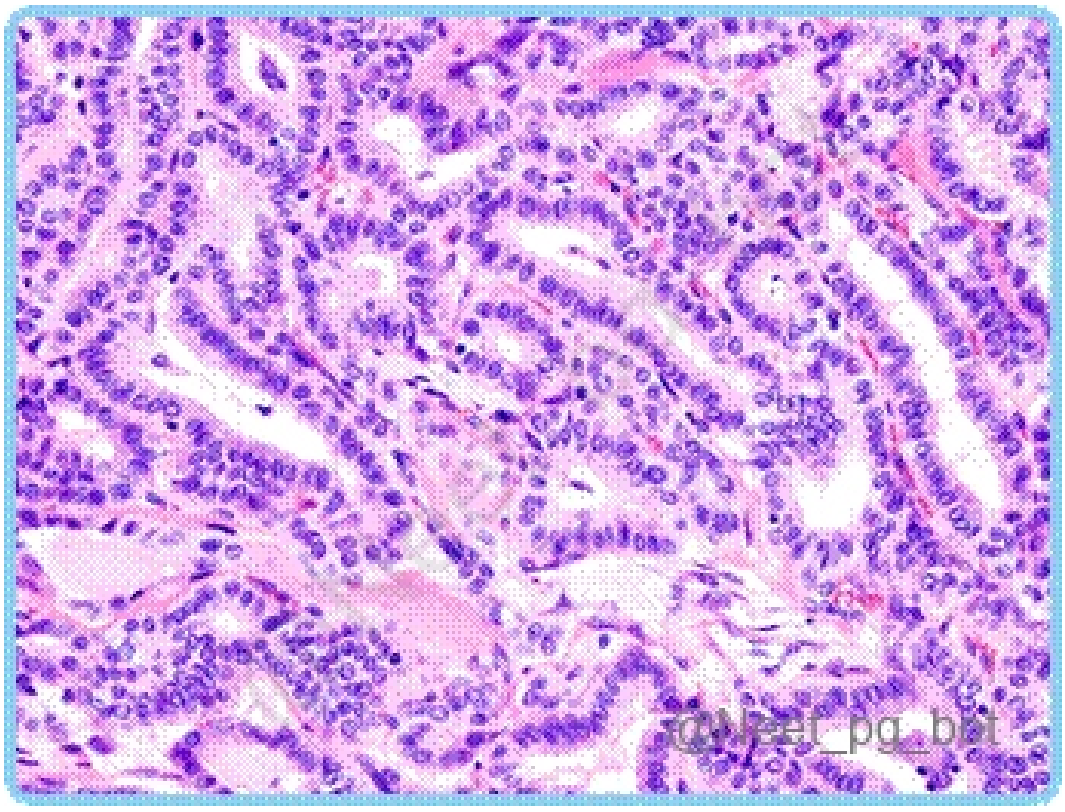
Q13: A patient presents with a midline swelling in the neck. A biopsy reveals Orphan Annie's eye nuclei, as shown in the image below. What is the diagnosis? (Q854832)

A. Follicular carcinoma

B. Papillary carcinoma

C. Toxic nodular goitre

D. Medullary carcinoma



Correct Answer: B. Papillary carcinoma

Explanation: The above features and HPE showing psammoma bodies, nuclear grooves, and "Orphan Annie eye" nuclei indicate papillary thyroid carcinoma, the most common type of thyroid cancer & characterised by lymphatic spread. It often presents with a nodule in the anterior neck and lymphadenopathy. Associated with BRAF mutations and RET-PTC fusion. Histopathological Features: True papillae- Fingerlike projections with fibrovascular core. Orphan Annie eye nuclei - Optically clear nucleus produced due to artefact. Intranuclear cytoplasmic inclusions (INCI). Nuclear groove or coffee bean nucleus. Presence of psammoma bodies- dystrophic calcifications {{caption_text}} {{caption_text}} It has the best prognosis among thyroid malignancies.

@Neet_pg_bot

Q14: A middle-aged woman presents with thyroid swelling. Blood tests show elevated TSH levels and the presence of thyroid peroxidase antibodies. Histopathological examination revealed the presence of Hurthle cells. What is the most likely diagnosis? (Q854852)

A. Hashimoto thyroiditis

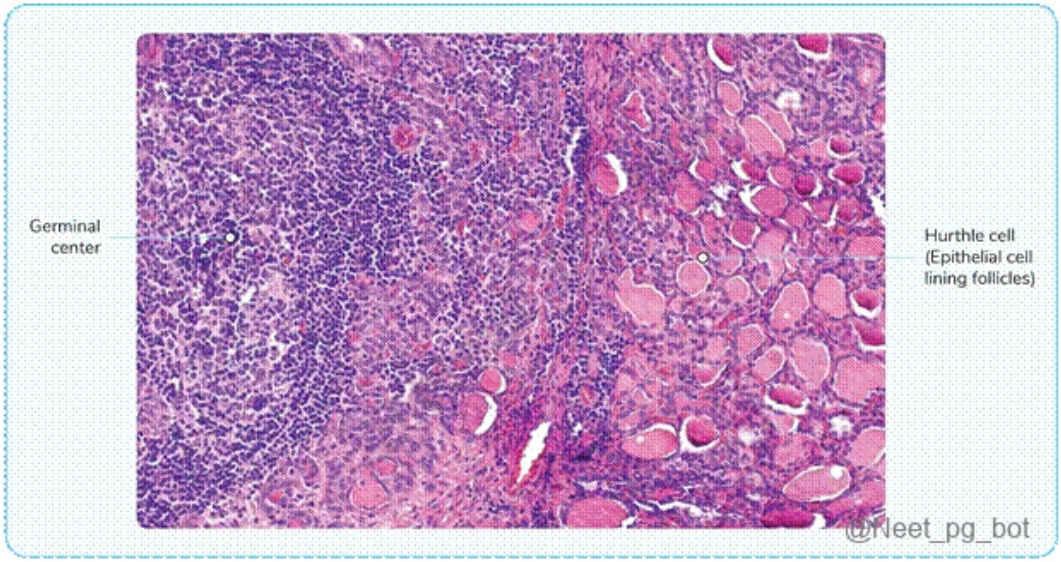
B. Graves’ disease

C. Follicular carcinoma of thyroid

D. Medullary carcinoma of thyroid

Correct Answer: A. Hashimoto thyroiditis

Explanation: The clinical scenario with thyroid swelling and elevated TSH levels & presence of thyroid peroxidase antibodies along with the presence of hurthle cells points towards Hashimoto thyroiditis. Hashimoto thyroiditis: An autoimmune disorder that causes chronic inflammation of the thyroid gland. It is the most common cause of hypothyroidism. The characteristic features include elevated TSH levels (due to thyroid failure) and the presence of thyroid peroxidase (TPO) antibodies , which attack the thyroid tissue. It is the most common cause of hypothyroidism in iodine-sufficient areas. It is characterised by painless enlargement of the thyroid, commonly in middle-aged women. The enlargement of the gland is generally symmetric and diffuse. In histopathology, there is extensive lymphocytic infiltration with well-developed germinal centres. The thyroid follicles are atrophic and are lined in many areas by epithelial cells with abundant eosinophilic, granular cytoplasm, termed Hürthle cells, that represent a metaplastic response of the normally low cuboidal follicular epithelium to chronic injury. {{caption_text}} The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centres. Graves' disease (Option B) is an autoimmune disorder leading to hyperthyroidism, characterised by low TSH levels and the presence of thyroid-stimulating immunoglobulins (TSI), not thyroid peroxidase antibodies. Hurthle cells are not a feature of Graves’ disease. Follicular carcinoma of the thyroid (Option C) is a malignant tumour of the thyroid, usually presenting with a solitary nodule and not typically associated with Hurthle cells or elevated TSH levels. Histopathologically, it features follicular cells arranged in a follicular pattern , with capsular and vascular invasion . {{caption_text}} Medullary carcinoma of the thyroid (Option D) is a neuroendocrine cancer arising from the C-cells of the thyroid, and it is associated with elevated calcitonin levels. Histopathologically, it features polygonal or spindle-shaped cells arranged in nests or follicles , with amyloid deposits often present. {{caption_text}}



Germinal center
Hurthle cell (Epithelial cell lining follicles)

@Neet_pg_bot

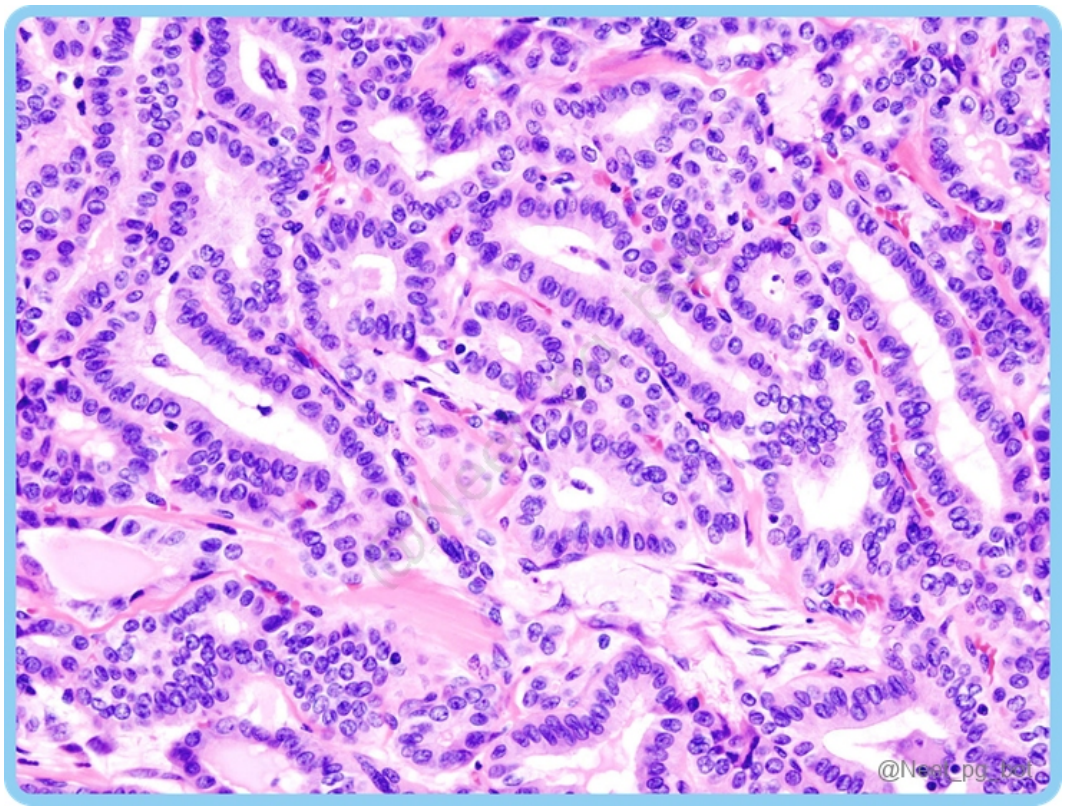
Q15: What is the probable diagnosis for a patient who has swelling in the middle of their neck, along with weight loss, and a thyroid biopsy showing the presence of 'Orphan Annie eye nuclei? (Q859243)

A. Follicular thyroid carcinoma

B. Papillary thyroid carcinoma

C. Anaplastic thyroid carcinoma

D. Medullary thyroid carcinoma



Correct Answer: B. Papillary thyroid carcinoma

Explanation: The histopathological features of psammoma bodies, nuclear grooves, and "Orphan Annie eye" nuclei are indicative of papillary thyroid carcinoma. It is the most common type of thyroid cancer and is characterised by lymphatic spread. It often presents with a nodule in the anterior neck and lymphadenopathy. Associated with BRAF mutations and RET-PTC fusion HPE shows True papillae: Fingerlike projections with fibrovascular core. Orphan Annie eye nuclei: Optically clear nucleus produced due to artefact. Intranuclear cytoplasmic inclusions (INCI). Nuclear groove or coffee bean nucleus. Presence of psammoma bodies: Dystrophic calcifications. It has the best prognosis among thyroid malignancies. {{caption_text}} {{caption_text}} Follicular thyroid carcinoma (Option A) typically does not exhibit "Orphan Annie eye nuclei." Instead, it is characterised by follicular cell differentiation and the presence of follicular patterns. {{caption_text}} Anaplastic thyroid carcinoma (Option C) is a highly aggressive and undifferentiated form of thyroid cancer. It typically does not exhibit "Orphan Annie eye nuclei." Instead, it is characterised by marked cellular pleomorphism and loss of cellular differentiation. {{caption_text}} Medullary thyroid carcinoma (Option D) arises from the parafollicular C cells of the thyroid gland and is associated with the production of calcitonin. {{caption_text}}

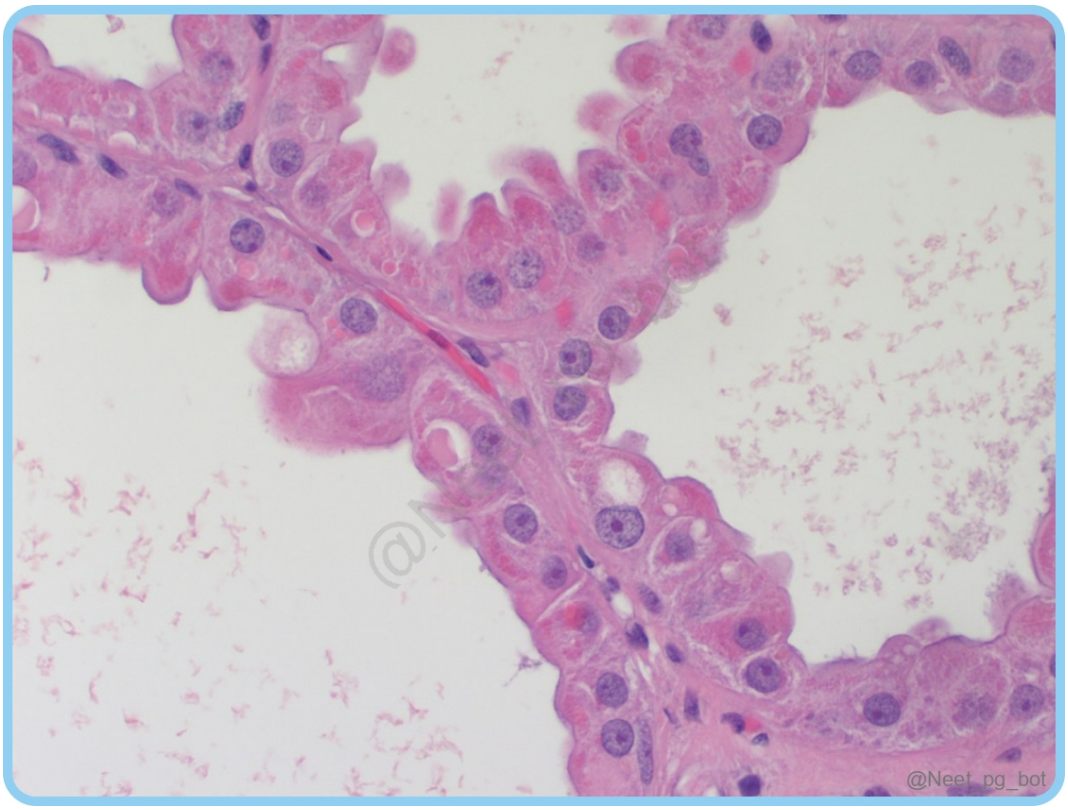
Q1: Which of the following breast lesions are correctly paired with their histopathological characteristics? 1. Fibrocystic changes 2. Duct ectasia 3. Phyllodes tumor 4. Invasive Ductal Carcinoma (Q846606)

A. 1, 2, 3

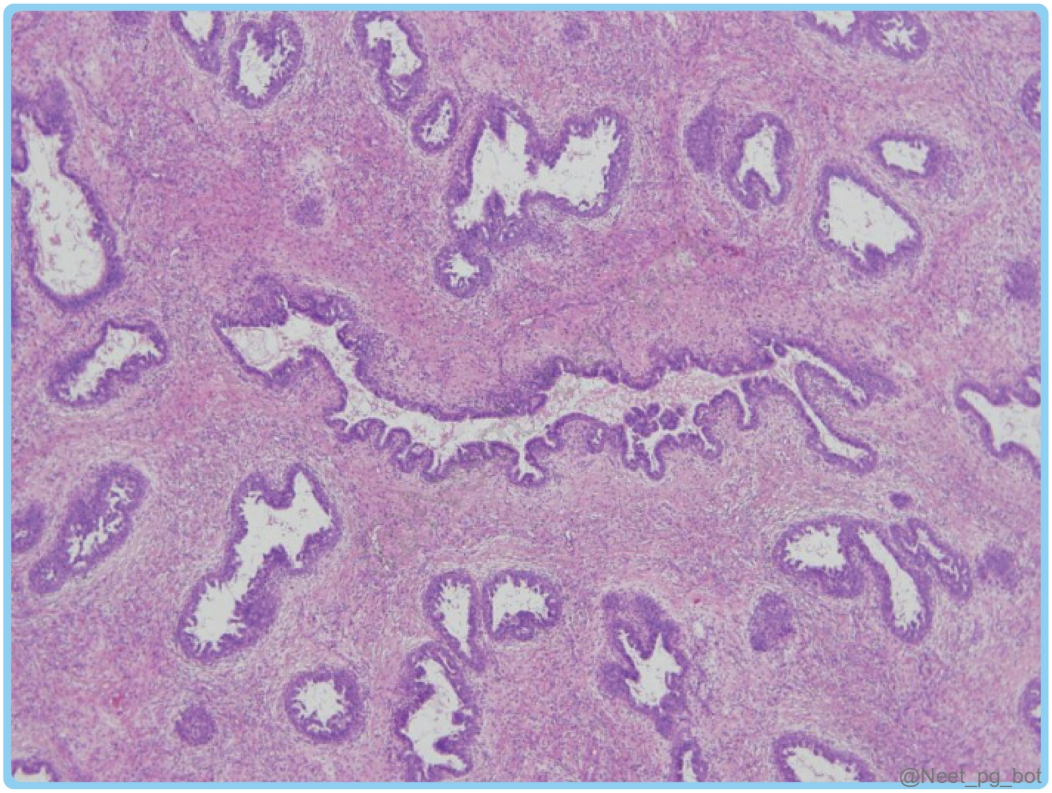
B. 2, 3, 4

C. 1, 3, 4

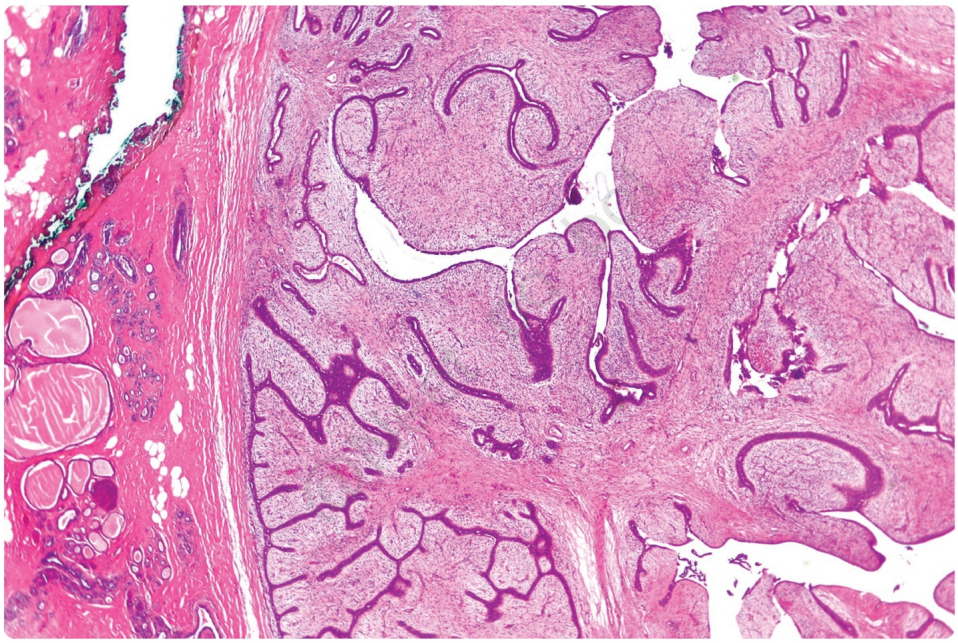
D. 1, 2, 3, 4



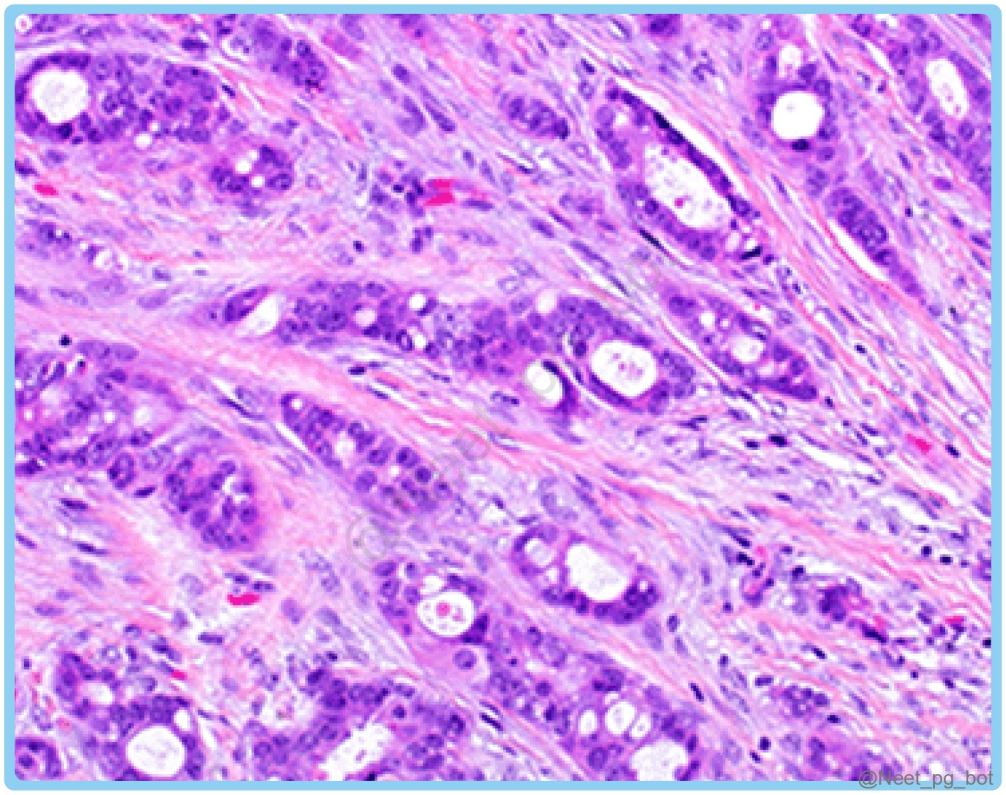
@Neet_pg_bot



@Neet_pg_bot



@Neet_pg_bot



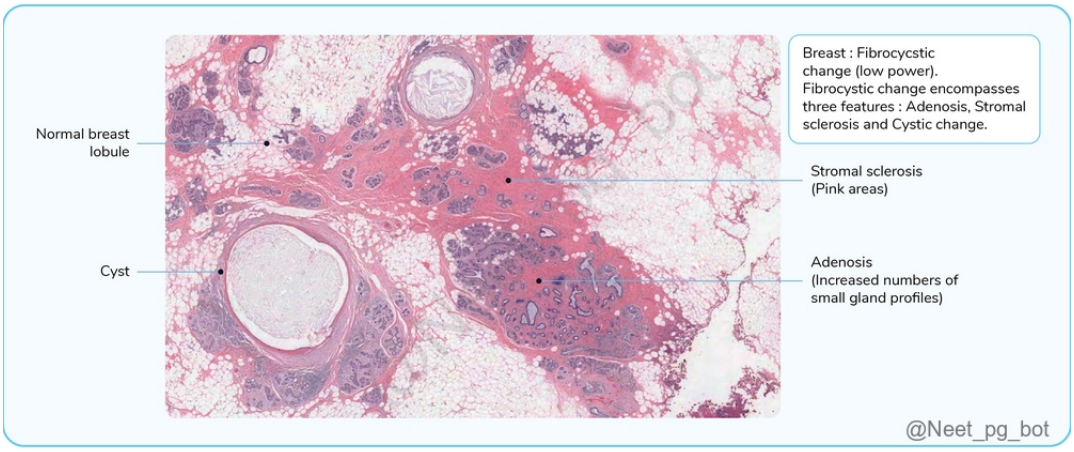
@Neet_pg_bot

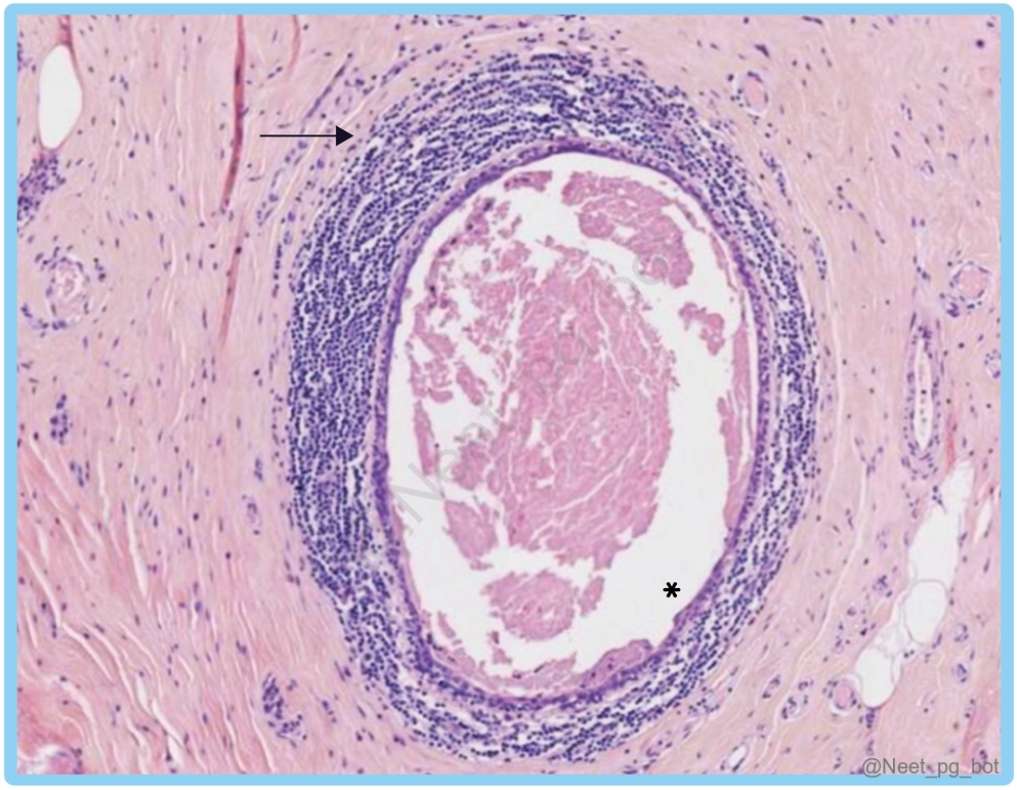
Correct Answer: C. 1, 3, 4

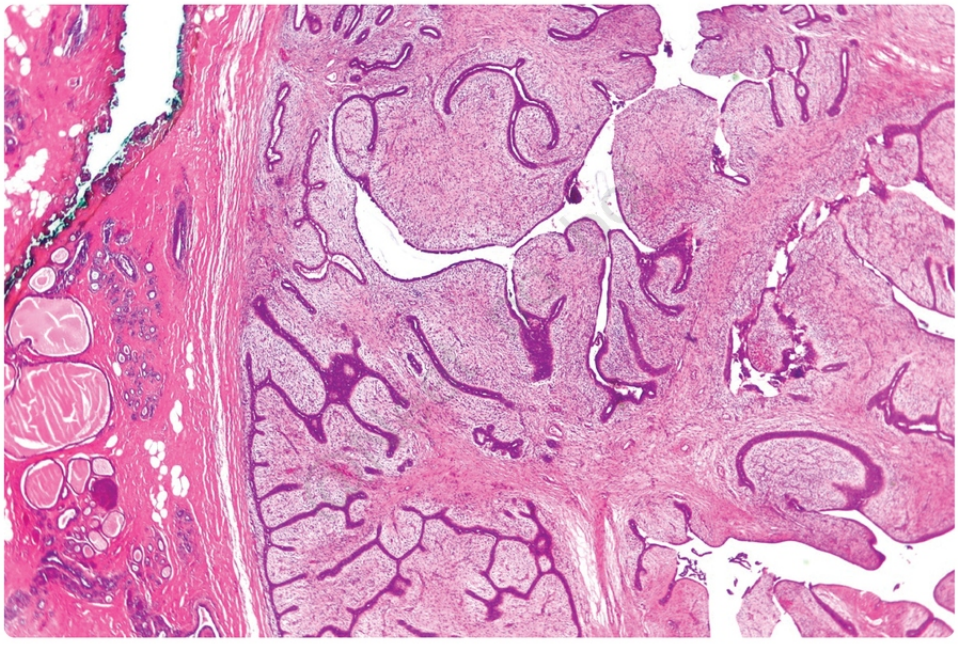
■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Breast tumors with their histopathological findings: Fibrocystic changes Cysts: Fluid-filled sacs within the breast tissue, often surrounded by fibrous tissue. Fibrosis: Thickening and scarring of breast tissue, which may result in palpable lumps or areas of increased density on imaging studies. Apocrine Metaplasia: Transformation of ductal epithelial cells into apocrine-like cells, characterized by abundant eosinophilic cytoplasm and apical snouts. Duct ectasia A lot of foamy macrophages, periductal lymphocytic infiltrates can be observed. Phyllodes tumor Increased stromal cellularity and overgrowth, giving rise to the typical leaf-like architecture. Ductal Carcinoma In Situ (DCIS) Types of DCIS: Micropapillary tumors : Additional epithelial cells within the lumen. Cribriform tumors: Ducts filled with cells that form multiple lumena. Solid tumors: Completely filled ducts. Comedo tumors: Solid with a necrotic core Invasive Ductal Carcinoma (IDC) Shows more mucin both extracellular and intracellular with signet ring cells. Fibroadenoma Well-defined borders due to a fibrous capsule , with proliferating stroma potentially compressing and distorting glandular components. Intracanalicular fibroadenoma - Ducts are compressed. Pericanalicular fibroadenoma - Ducts are open.







@Neet_pg_bot

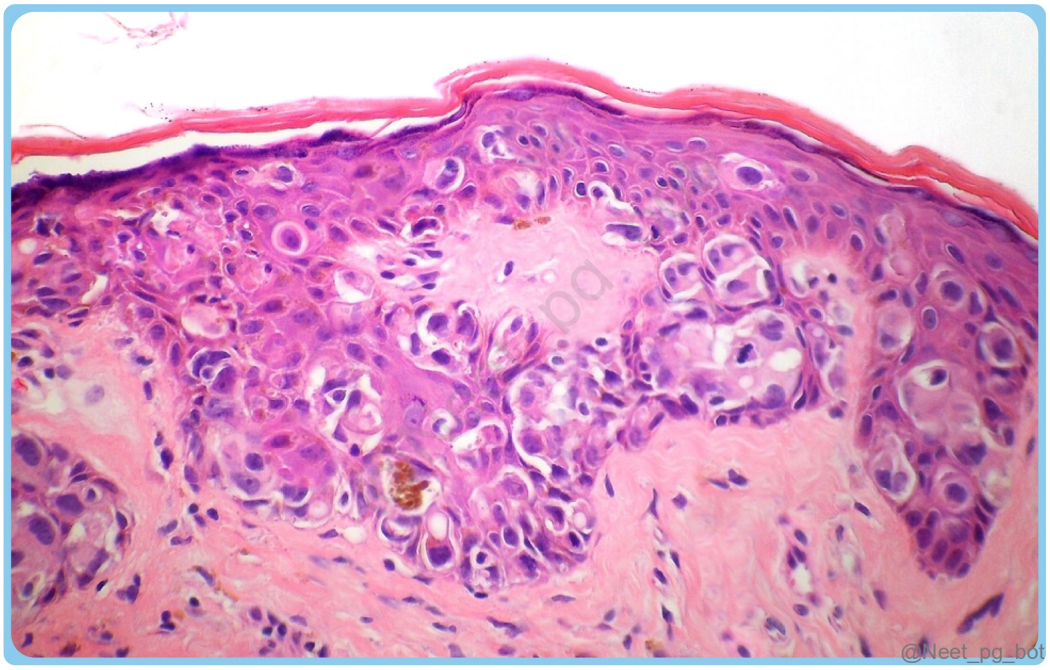
Q2: A 58-year-old woman has a eczematous lesion of the nipple not responding to treatment. Histopathology is shown. What is the most likely diagnosis? (Q890380)

A. Commonly associated with underlying DCIS

B. Malignant cells are present within the nipple epidermis

C. Shows CK7 positivity

D. It commonly presents as a bilateral nipple lesion



Correct Answer: D. It commonly presents as a bilateral nipple lesion

Explanation: A treatment-resistant nipple eczema with histology showing large pale intraepidermal malignant cells (Paget cells) is diagnostic of Mammary Paget's disease. It typically presents as a unilateral eczematous lesion of the nipple and is usually associated with underlying DCIS or invasive ductal carcinoma . Mammary Paget Disease: Rare manifestation of breast cancer (~1-4% of cases). Clinical features: Unilateral erythematous, scaly crusted lesion of the nipple Pruritus common Often mistaken for eczema Pathogenesis: Malignant Paget cells spread from ductal carcinoma in situ (DCIS) through lactiferous ducts/sinuses into the nipple epidermis (Option B) Tumour cells disrupt the epithelial barrier , causing serous fluid exudation on the nipple surface. Associated lesions: DCIS (most common) (Option A) Invasive ductal carcinoma IHC: Positive: CK7 (Option C) , HER2/neu, EMA, CEA Negative: S100 Diagnosis: Nipple biopsy

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 952

https://www.ncbi.nlm.nih.gov/books/NBK563228/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 56-year-old woman presents with persistent unilateral erythematous, scaly crusting of the nipple associated with itching for 3 months. Topical treatment for eczema has not improved the lesion. What is the next step in management? (Q890379)

A. Repeat topical corticosteroids

B. Fine-needle aspiration of the breast mass

C. Nipple biopsy

D. Reassurance and follow-up

Correct Answer: C. Nipple biopsy

Explanation: The patient has a persistent unilateral erythematous, scaly, crusted lesion of the nipple with pruritus that does not respond to eczema treatment , which is classic for Paget disease of the breast . The next step in management is a nipple biopsy to identify Paget cells within the epidermis , which confirms the diagnosis. Paget's disease of the nipple: Rare manifestation of breast cancer (~1-4% of cases). Clinical features: Unilateral erythematous, scaly, crusted lesion of the nipple Pruritus common Often mistaken for eczema Pathogenesis: Malignant Paget cells spread from underlying ductal carcinoma in situ (DCIS) through lactiferous ducts/sinuses into the nipple epidermis Tumour cells disrupt the epithelial barrier , causing serous fluid exudation on the nipple surface. Diagnosis: Nipple biopsy Cytology of nipple discharge/exudate Repeat topical corticosteroids (Option A) : Persistent unilateral nipple eczema unresponsive to treatment requires biopsy , not further topical therapy.

Fine-needle aspiration of the breast mass (Option B) : FNA is useful only if a palpable mass exists , but diagnosis of Paget disease requires biopsy of the nipple lesion . Reassurance and follow-up (Option D) : Inappropriate because the lesion may represent underlying breast carcinoma .

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 952

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following markers is most useful for distinguishing invasive carcinoma from DCIS? (Q890364)

A. p53

B. p63

C. Cytokeratin 7

D. Estrogen receptor (ER)

Correct Answer: B. p63

Explanation: p63 is a nuclear myoepithelial marker used to distinguish ductal carcinoma in situ (DCIS) from invasive carcinoma. Myoepithelial cells normally surround ducts and lobules and maintain basement membrane integrity. In DCIS , the myoepithelial layer is preserved → p63 shows continuous nuclear staining around ducts. In invasive carcinoma , the myoepithelial layer is lost → absence of p63 staining supports invasion . However, p63 should not be used in isolation , as focal positivity may occasionally be seen in invasive lesions. Therefore, interpretation is done in conjunction with morphology and a panel of myoepithelial markers. Myoepithelial Markers in Breast Lesions: P63 Calponin α-Smooth Muscle Actin (α-SMA) Smooth Muscle Myosin (SMM)

https://pmc.ncbi.nlm.nih.gov/articles/PMC4630168/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following findings does not indicate a low risk for breast cancer? (Q890362)

A. Cysts with apocrine metaplasia

B. Fibrosis

C. Adenosis

D. Florid hyperplasia

Correct Answer: D. Florid hyperplasia

Explanation: Nonproliferative fibrocystic changes are associated with low breast cancer risk . Florid hyperplasia is a proliferative lesion with significant epithelial overgrowth → higher risk of breast cancer. Nonproliferative Breast Changes (Fibrocystic Changes): Common breast alterations in women aged 30–50 , often linked to hormonal changes during menstruation . Principal Morphologic Features: Cysts: Formed by lobular dilation , may coalesce into larger cysts. Contain turbid, brown/blue fluid ("blue-dome cysts"). Lined by flattened atrophic epithelium or apocrine metaplasia . Apocrine change (Option A) : abundant granular eosinophilic cytoplasm, resembling sweat gland epithelium. Calcifications are common. Solitary, firm cysts may mimic tumours; diagnosis confirmed by fnac . Fibrosis: (Option B) Occurs when cysts rupture , releasing secretory material into the stroma. Leads to chronic inflammation and palpable nodularity . Adenosis: (Option C) Increase in acini per lobule . Lined by columnar epithelial cells . Calcifications may be present.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 947, 948

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 52-year-old man presents with a painless swelling of the breast as seen in the image. Which of the following conditions are associated with the development of this condition? Liver cirrhosis Marijuana use Klinefelter syndrome Classical Seminoma (Q890352)

A. 1 and 3 only

B. 1, 2 and 3 only

C. 1, 3 and 4 only

D. 1, 2, 3 and 4

Correct Answer: B. 1, 2 and 3 only

Explanation: The image shows gynecomastia , the most common benign lesion of the male breast, characterized by subareolar enlargement due to proliferation of ductal tissue . Classical seminomas are non–hormone-producing germ cell tumors Gynecomastia results from an increased estrogen-to-androgen ratio : Estrogens → stimulate breast tissue growth Androgens → inhibit estrogenic effects Associations: Liver cirrhosis → impaired estrogen metabolism Drugs: Alcohol, Marijuana & Heroin Antiretroviral therapy Anabolic steroids Klinefelter syndrome (47, XXY) Functioning testicular tumors Leydig cell tumor Sertoli cell tumor

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 948

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following conditions is most commonly associated with bloody nipple discharge? (Q890350)

A. Intraductal papilloma

B. Mammary duct ectasia

C. Fibrocystic change

D. Sclerosing adenosis

Correct Answer: A. Intraductal papilloma

Explanation: The most common cause of bloody nipple discharge (especially when it is spontaneous and coming from a single duct) is intraductal papilloma . Intraductal Papilloma: Benign papillary tumour arising within a dilated breast duct Composed of multiple branching fibrovascular cores Associated changes: Usual ductal hyperplasia Apocrine metaplasia Large Duct Papilloma (Central): Located in the lactiferous sinuses near the nipple Usually solitary >80% cause nipple discharge Often bloody (due to stalk torsion and infarction) May be serous Small Duct Papillomas (Peripheral): Occurs in the peripheral ductal system Often multiple Usually clinically silent May present as: Small palpable mass Mammographic density or calcification Mammary duct ectasia (Option B) : Usually causes thick, sticky green or brown nipple discharge , not typically bloody. Fibrocystic change (Option C) : Presents with breast pain, nodularity, and cysts , not bloody discharge. Sclerosing adenosis (Option D) : A proliferative breast lesion without atypia that may mimic carcinoma but rarely causes nipple discharge.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 948

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following is a non-proliferative change of the breast? (Q890349)

A. Sclerosing adenosis

B. Radial scar

C. Adenosis

D. Atypical ductal hyperplasia

Correct Answer: C. Adenosis

Explanation: Adenosis is one of the three principal morphologic features of non-proliferative breast change , defined as an increase in the number of acini per lobule . Non-Proliferative Breast Changes: Cysts Fibrosis Adenosis Proliferative Breast Disease Without Atypia: Usual ductal hyperplasia Sclerosing adenosis (Option A) Radial scar (complex sclerosing lesion) (Option B) Intraductal papilloma Proliferative Breast Disease With Atypia: Atypical ductal hyperplasia (ADH) (Option D) Atypical lobular hyperplasia (ALH)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 947-950

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following is not a proliferative breast lesion? (Q890348)

A. Intraductal papilloma

B. Sclerosing adenosis

C. Radial scar

D. Cystic change with apocrine metaplasia

Correct Answer: D. Cystic change with apocrine metaplasia

Explanation: Cystic change with apocrine metaplasia is part of non-proliferative fibrocystic breast change . Non-Proliferative Breast Changes: Cysts Fibrosis Adenosis Proliferative Breast Disease Without Atypia: Usual ductal hyperplasia Sclerosing adenosis (Option B) Radial scar (complex sclerosing lesion) (Option C) Intraductal papilloma (Option A) Proliferative Breast Disease With Atypia: Atypical ductal hyperplasia (ADH) Atypical lobular hyperplasia (ALH)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 947-950

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 36-year-old woman presents with a painful subareolar mass and recurrent nipple discharge. Examination reveals nipple inversion, and histology shows keratinising squamous metaplasia of lactiferous ducts with keratin plugging. Which of the following is the most important risk factor for this condition? (Q890347)

A. Cigarette smoking

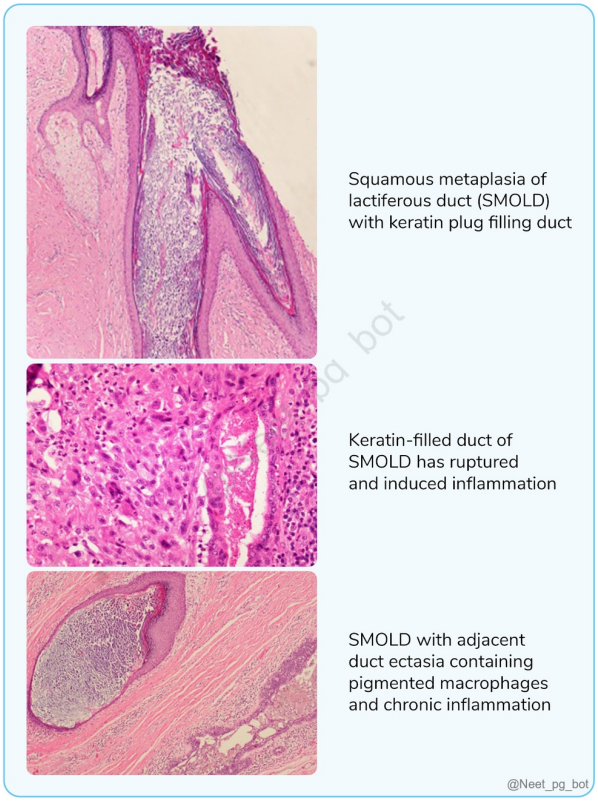
B. Alcohol

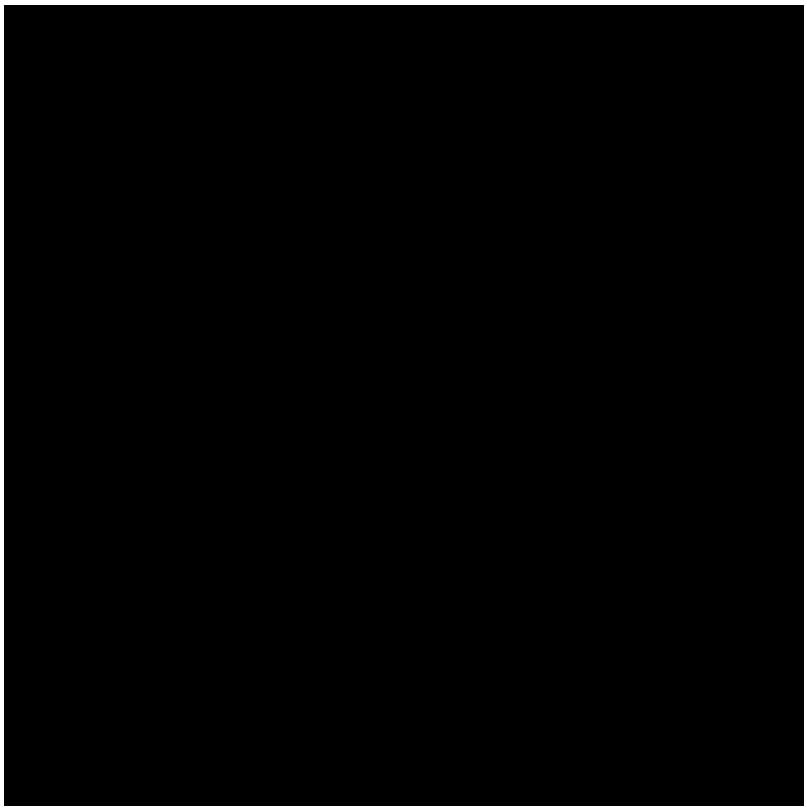
C. Nulliparity

D. Family history of breast carcinoma

Correct Answer: A. Cigarette smoking

Explanation: >90% of cases of squamous metaplasia of lactiferous ducts (periductal mastitis) occur in smokers. Smoking may cause relative vitamin A deficiency , leading to abnormal squamous differentiation of duct epithelium and keratin plugging. Squamous Metaplasia of Lactiferous Ducts (Periductal mastitis, Recurrent subareolar abscess, Zuska disease): A condition involving keratinising squamous metaplasia of lactiferous ducts leading to duct obstruction, inflammation, and recurrent abscess formation . Painful erythematous subareolar mass May mimic a bacterial abscess Recurrent cases → fistula tract opening near the areola Nipple inversion due to inflammation and scarring Occurs in women and occasionally in men Major risk factor: Smoking (>90% of cases) Morphology: ■ ■■ Keratinising squamous metaplasia of lactiferous duct epithelium Keratin plugs in the ducts Duct dilation and rupture Chronic granulomatous periductal inflammation





References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 946

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following conditions involves the large ducts of the breast? Mammary duct ectasia Large duct papilloma Paget disease of the nipple Atypical lobular hyperplasia Sclerosing adenosis (Q890346)

A. 1, 2, 3

B. 2, 3, 4

C. 1, 2, 3, 4

D. 2, 4, 5

Correct Answer: A. 1, 2, 3

Explanation: Large duct (subareolar/lactiferous duct) involvement is seen in mammary duct ectasia, large duct papilloma, and Paget disease of the nipple. Mammary duct ectasia: Dilatation of major ducts near the nipple with periductal inflammation and fibrosis → presents with nipple discharge and subareolar mass Large duct papilloma (central papilloma): Benign tumor arising in major ducts → commonly causes serous or bloody nipple discharge Paget disease of nipple: Intraepidermal spread of malignant ductal cells from underlying DCIS via lactiferous ducts Atypical lobular hyperplasia: Proliferative lesion arising from the terminal duct lobular unit (TDLU) ; associated with increased breast cancer risk. Sclerosing adenosis: TDLU lesion characterized by increased acini per lobule with stromal fibrosis; may mimic carcinoma.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 948

https://www.ncbi.nlm.nih.gov/books/NBK563228/

https://www.ncbi.nlm.nih.gov/books/NBK557665/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following conditions does not arise from the terminal duct lobular unit? (Q890345)

A. DCIS

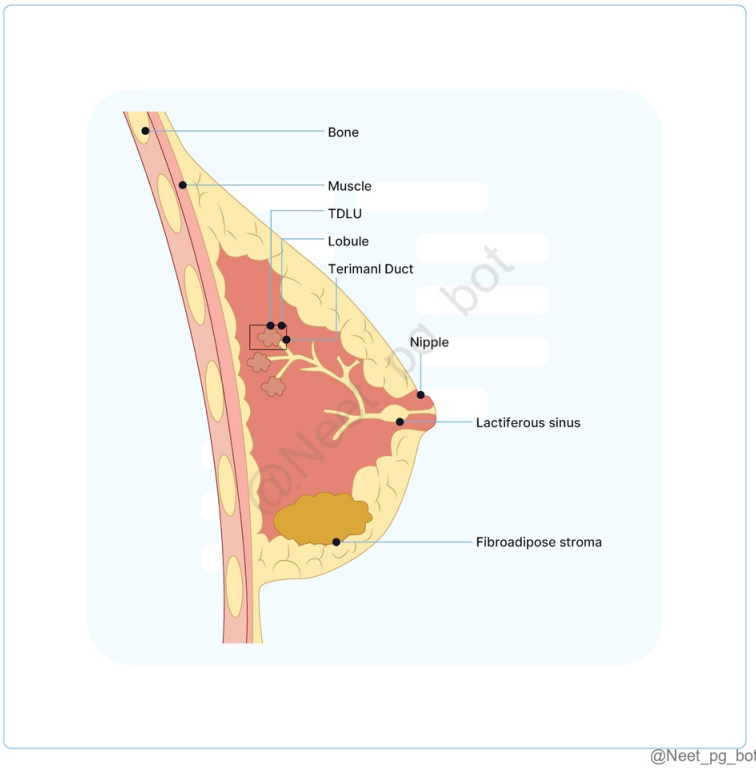
B. Sclerosing adenosis

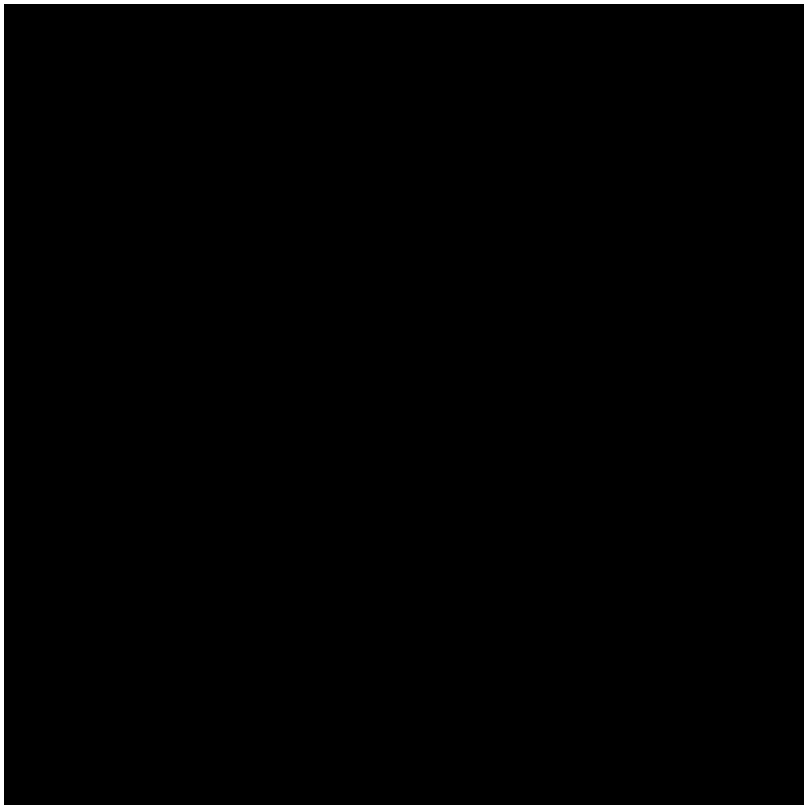
C. Intraductal papilloma

D. Mammary duct ectasia

Correct Answer: D. Mammary duct ectasia

Explanation: Mammary duct ectasia primarily involves large subareolar ducts near the nipple , not the terminal duct lobular unit. It is characterised by dilatation of major ducts with periductal inflammation and fibrosis , often presenting with nipple discharge and subareolar mass . Therefore, it does not originate from the TDLU . Terminal Duct Lobular Unit (TDLU): Formed by the terminal duct + lobule . It is the structural and functional unit of the breast . ■ ■■ Conditions Arising from the Terminal Duct Lobular Unit (TDLU): Non-Proliferative Breast Changes (Fibrocystic Changes): Cysts Apocrine metaplasia Fibrosis Adenosis Lactational adenoma Proliferative Breast Disease Without Atypia: Usual ductal hyperplasia Sclerosing adenosis (Option B) Radial scar (complex sclerosing lesion) Intraductal papilloma (Option C) Proliferative Breast Disease With Atypia: Columnar cell lesions Flat epithelial atypia Atypical ductal hyperplasia (ADH) Atypical lobular hyperplasia (ALH) Ductal carcinoma in situ (DCIS) (Option A) Lobular carcinoma in situ (LCIS)





References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 944, 947, 949, 953

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 24-year-old with a 2-month-old infant presents to the OPD with pain in her left breast. The baby is exclusively breastfed. On examination, the nipple is tender and erythematous with a fluctuant mass beneath the areola. Which of the following is the most common cause of this condition? (Q846611)

A. Pseudomonas aeruginosa

B. Staphylococcus aureus

C. Streptococcus sp.

D. Listeria monocytogenes

Correct Answer: B. Staphylococcus aureus

Explanation: The clinical scenario suggests acute breast abscess from lactational mastitis which is commonly caused by Staphylococcus aureus . It is caused by a local infection through cracks and fissures in the nipples that occur commonly during the 1st month of breastfeeding. It is often preceded by either engorgement or a focally blocked duct. Patients can develop a focal area of erythema, pain, fever, and swelling. This can further develop into single or multiple abscesses. Streptococcus pyogenes, Escherichia coli, Bacteroides species, and coagulase-negative Staphylococci are other organisms that cause mastitis.

References:

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Pg 1040

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: The terminal duct lobular unit (TDLU) is the functional unit of the breast. Which of the following is not a part of the TDLU? (Q845782)

A. Intralobular terminal duct

B. Extralobular terminal duct

C. Lactiferous duct

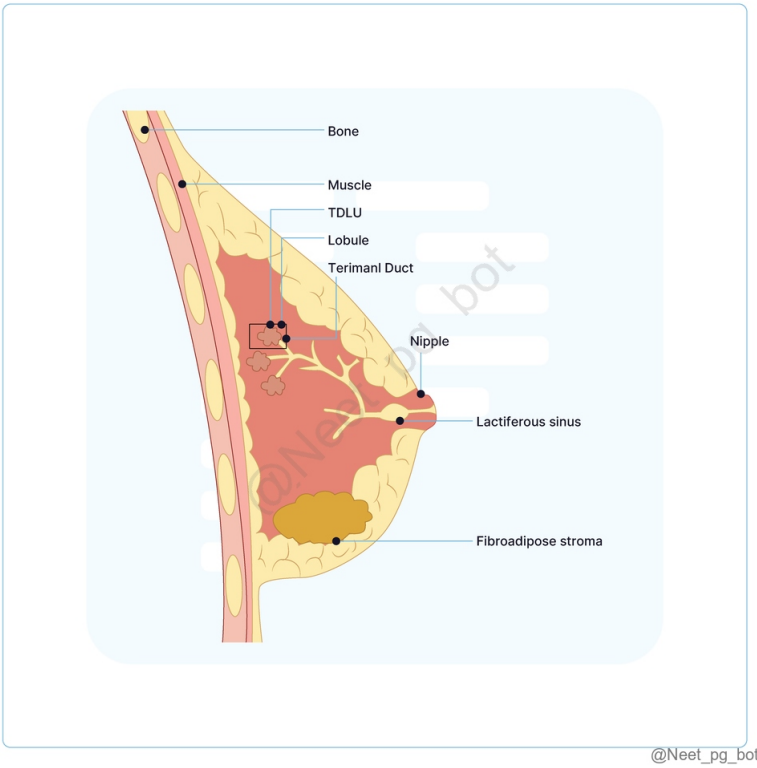
D. Ductules

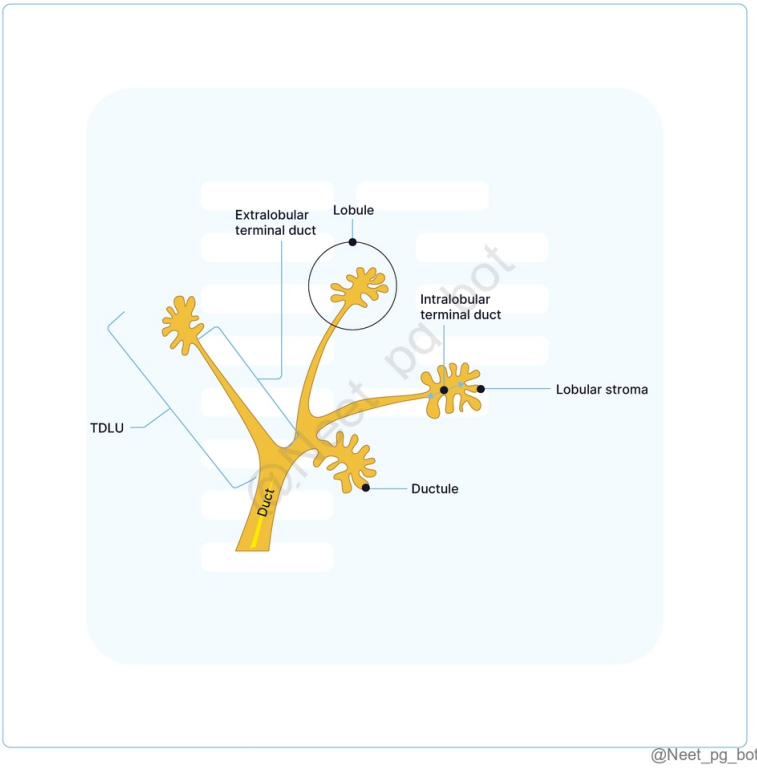
Correct Answer: C. Lactiferous duct

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Lactiferous ducts are not a part of the TDLU. The morpho-functional unit of the breast is the terminal duct lobular unit(TDLU). TDLU is a grapelike cluster of small alveoli that comprises lobule and terminal duct. A lobule is a collection of multiple ductules, which are epithelial structures that produce milk during lactation. Terminal ducts consist of 2 parts: Intralobular terminal duct: A portion of the terminal duct located within the lobule. Extralobular terminal duct is the portion connecting the lobule to the lactiferous duct.





@Neet_pg_bot

Q15: Which of the following statements about phyllodes tumors of the breast is incorrect? (Q845804)

A. They originate in the connective tissue of the breast

B. Often present as rapidly growing breast masses

C. They vary in size from a few centimeters to massive lesions

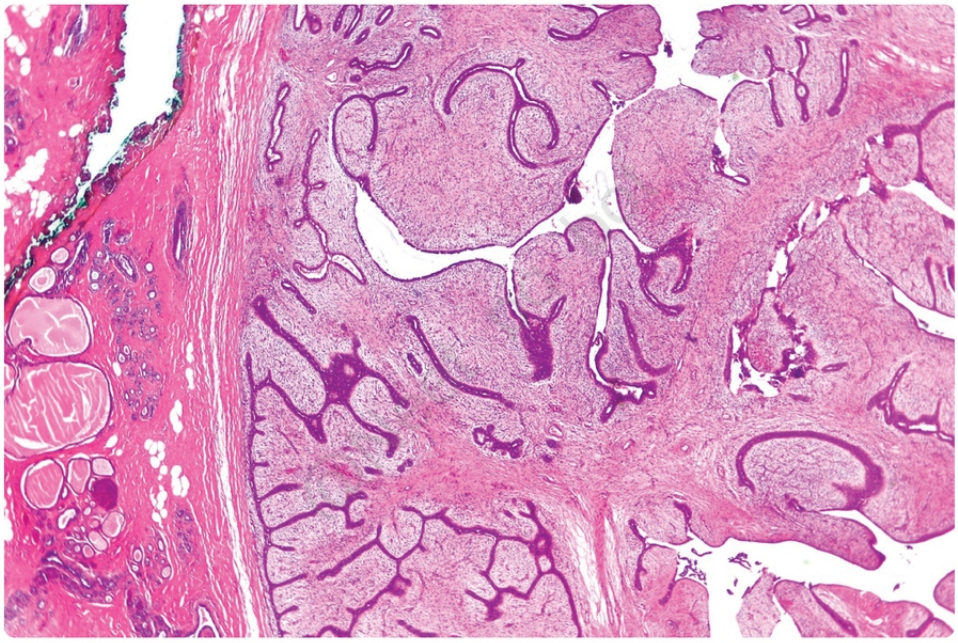
D. These lesions are always benign

Correct Answer: D. These lesions are always benign

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical features and HPE showing increased stromal cellularity and overgrowth, giving rise to the typical leaf-like architecture, suggests phyllodes tumor. It is a rapidly growing tumor, varying in size, ranging from few centimeter to massive lesions. It can be benign or malignant. Genetics: Gain of 1q MED12 mutations TERT mutations The incorrect statement is that these lesions are always benign. Since phylloides tumour can be benign, borderline or malignant, depending on the overgrowth of stroma and the mitotic activity. Criteria (Based on stroma) Benign Borderline Malignant Stromal cellularity and atypia Minimal Moderate Marked Stromal overgrowth Minimal Moderate Marked Mitoses (Definitive criteria) 0-4 mitosis per 10 hpf 5-9 per 10 hpf ≥ 10 per 10 hpf Mitosis ≥ 10/10 hpf (Seen in only 2 condition) Malignant phyllodes Leiomyosarcoma uterus



@Neet_pg_bot

Q16: Which of the following is not a feature of complex fibroadenoma? (Q845803)

A. Cysts larger than 0.3cm

B. Sclerosing adenosis

C. Nodules of proliferating stroma forming bulbous protrusions

D. Papillary apocrine change

Correct Answer: C. Nodules of proliferating stroma forming bulbous protrusions

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Complex fibroadenoma is an example of epithelial proliferative breast lesions without atypia. Fibroadenoma with complex features has a risk of malignancy, whereas, without complexity, it does not. Complex features include, Cysts > 0.3cm Sclerosing adenosis (sclerosis + increase in the acini cells per lobule i.e, adenosis) Epithelial calcifications Papillary apocrine change (metaplastic change in breast tissue)

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Pages 1063, 1045

↑ *Back to this question in Part A*

@Neet_pg_bot

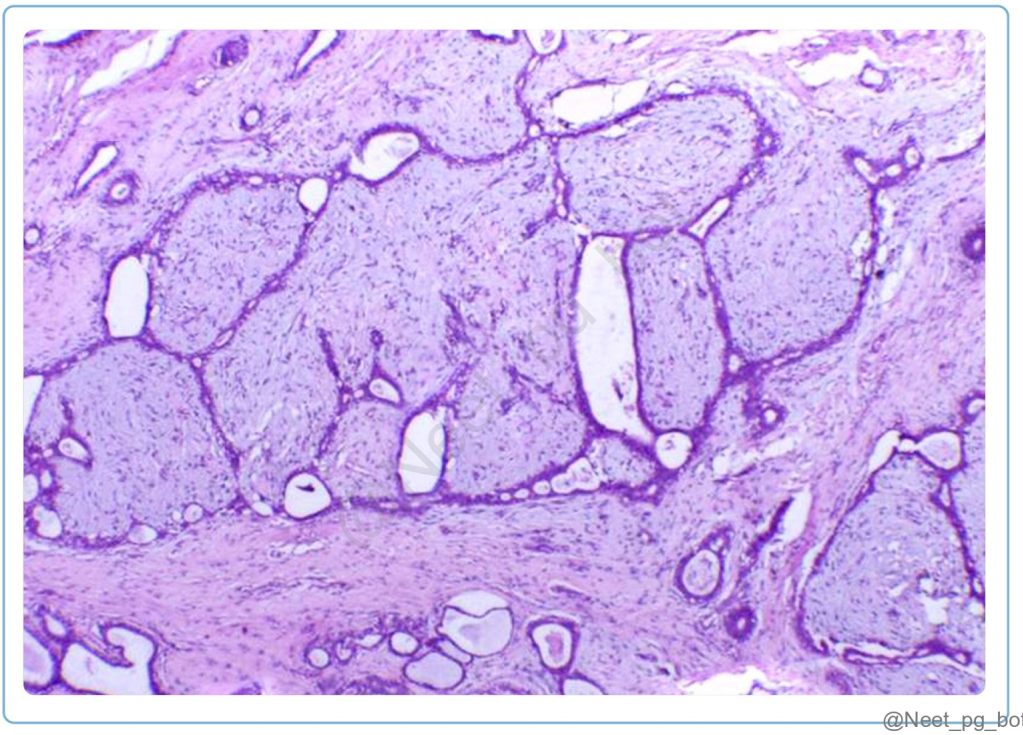
Q17: A 34-year-old woman comes to the clinic due to a mass in her right breast. A 2-cm nodule is noted on breast examination, and the patient is referred for biopsy. Histologic evaluation of the tissue specimen is shown in the image below. What is the most likely diagnosis? (Q845802)

A. Ductal Carcinoma In Situ

B. Intracanalicular Fibroadenoma

C. Sclerosing adenosis

D. Pericanalicular Fibroadenoma



Correct Answer: B. Intracanalicular Fibroadenoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The histopathology image shows epithelial ducts compressed and distorted by surrounding stroma which is characteristic of an intracanalicular fibroadenoma. Fibroadenoma is of 2 types: Intracanalicular - Epithelial ducts compressed due to surrounding stroma Pericanalicular - Ducts would be slightly open Both types have similar prognosis.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 38-year-old woman presents with cyclical breast pain, most severe in the week before her period. She also notices her breasts feeling lumpy and swollen around the time of her period, which subsides later. She denies any fever, nipple discharge, or lumps. What is the most likely finding seen in this pathology? (Q845801)

A. Peau d'orange appearance of the skin

B. Nipple retraction and bloody discharge

C. Blue dome of Bloodgood cyst

D. Eczematous changes of the nipple and areola

Correct Answer: C. Blue dome of Bloodgood cyst

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above features of cyclical pain and breast changes are suggestive of fibrocystic breast disease, which has a blue dome of Bloodgood cyst. Fibrocystic changes of the breast is a benign condition characterized by the development of cysts, fibrosis (thickening and scarring of tissue), and other benign alterations in the breast tissue. Symptoms Breast pain (mastalgia) or tenderness that fluctuates with menstruation Mastalgia (or mastodynia) can be cyclic (with menses, due to premenstrual edema) or noncyclic (localized to one area of the breast and may be caused by ruptured cysts, physical injury, and infections). Breast lumps or nodules Swelling or enlargement of the breasts Fluid-filled cysts with varying size Nipple discharge Gross Features: Blue-domed cyst of Bloodgood- Large cysts that contain turbid, semitranslucent brown or blue-colored fluid which imparts a blue color onto the intact cyst. They are typically fluid-filled and may vary in size. Histopathological Features: Cysts: Fluid-filled sacs within the breast tissue, often surrounded by fibrous tissue. Fibrosis: Thickening and scarring of breast tissue, which may result in palpable lumps or areas of increased density on imaging studies. Apocrine Metaplasia: Transformation of ductal epithelial cells into apocrine-like cells, characterized by abundant eosinophilic cytoplasm and apical snouts. Peau d'orange appearance of the skin (Option A): This describes skin thickening and "orange peel" pitting caused by lymphatic obstruction , a classic sign of Inflammatory Breast Cancer , not cyclical hormonal changes. Nipple retraction and bloody discharge (Option B): These are "red flag" symptoms typically associated with Intraductal Papilloma or an Invasive Carcinoma that has tethered the ducts or Cooper's ligaments. Eczematous changes of the nipple and areola (Option D): Scaly, itchy, or ulcerated skin on the nipple is the hallmark of Paget’s Disease of the Breast , representing malignant cells that have migrated to the epidermis from an underlying cancer.

@Neet_pg_bot

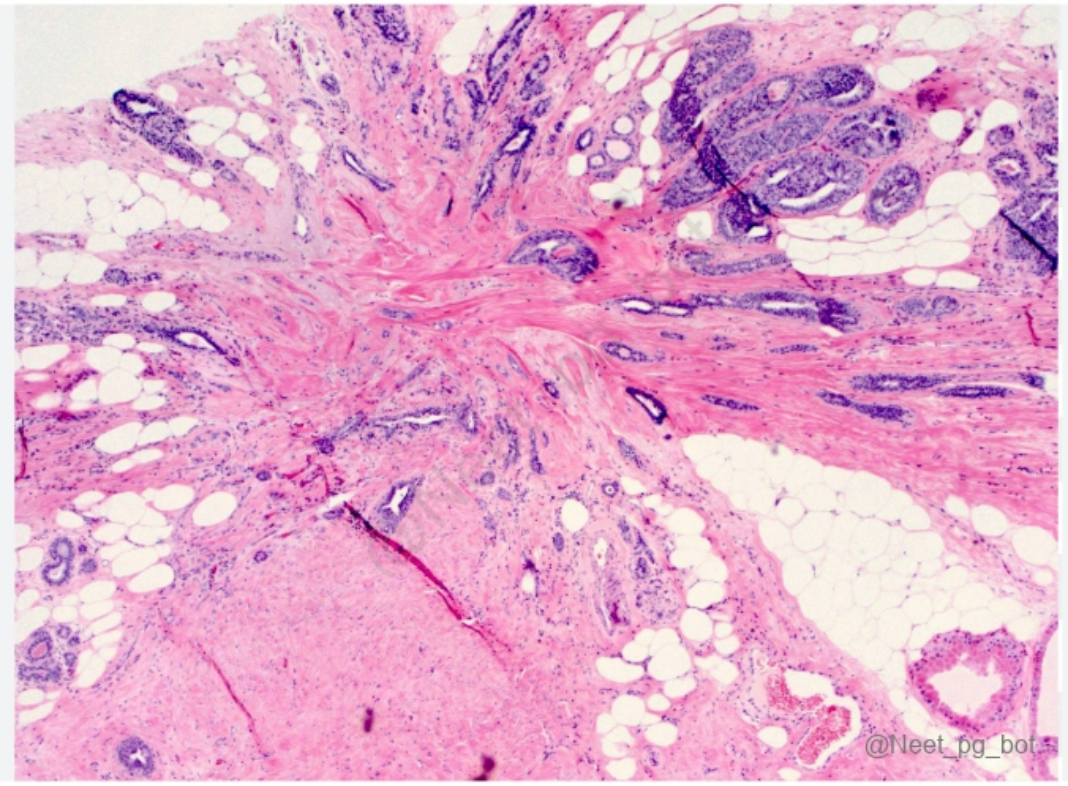
Q19: A 38-year-old woman presents with a firm, irregular mass that has been slowly increasing in size over the past few months. Histopathological examination shows the following, what is the most likely diagnosis? (Q845798)

A. Sclerosing adenosis

B. Radial scar

C. Papilloma

D. Paget’s disease



Correct Answer: B. Radial scar

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical features and HPE showing central sclerosis with fibroelastotic stroma and entrapped glands radiating outwards with hyperplasia are suggestive of radial scar. Radial scars, also known as complex sclerosing lesions , are benign proliferative breast lesions that can mimic breast cancer clinically and radiologically but look like scars when viewed under a microscope. They are characterized by a spiculated appearance on imaging, with a translucent, low-density center. Grossly, a whitish scar is present at the center (central stellate scar). {{caption_text}} HPE shows glands entrapped in a hyalinised stroma surrounded by long radiating projections containing epithelium. Sclerosing adenosis (Option A): While this is often a part of a radial scar, it typically presents as an increased number of distorted acini bundled together in a lobular pattern. It lacks the prominent, centralized "sunburst" fibroelastotic core seen here. Papilloma (Option C): This would show finger-like projections (papillae) with fibrovascular cores growing inside a dilated duct. The image provided shows a solid, radiating stromal process, not an intraductal growth. Paget’s disease (Option D): This involves the nipple epidermis . On Histology: Large, pale malignant cells (Paget cells) infiltrating the skin of the nipple are seen (our image shows deep breast tissue with fat (adipocytes) and ducts, not the skin surface.).

@Neet_pg_bot

Q20: What is the absolute risk of a fibrocystic lesion of the breast converting to malignancy? (Q845797)

A. <1%

B. 3%

C. 5-7%

D. 13-17%

Correct Answer: B. 3%

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Fibrocystic disease presents as “lumpy bumpy” breasts on palpation. Patients present with cyclical pain (Pain during menstrual cycle). They are included in the category of non-proliferative breast changes with a relative risk: of 1% and an absolute risk: of 3% of developing invasive carcinoma. Category Diseases/disorders Relative risk and absolute lifetime risk Non-proliferative breast changes Mild hyperplasia, duct ectasia, cysts, apocrine metaplasia, adenosis, fibroadenoma without complex features Relative risk: 1% Absolute risk: 3% Proliferative diseases without atypia Moderate or florid hyperplasia, sclerosing adenosis, complex sclerosing lesion, fibroadenoma with complex features Relative risk: 1.5-2% (2%) Absolute risk: 5-7% (6%) Proliferative breast diseases with atypia Atypical ductal hyperplasia Atypical lobular hyperplasia Relative risk: 4-5% (4%) Absolute risk: 13-17% (>12%) Carcinoma in situ Precancerous condition Relative risk: 8-10 (8%) Absolute risk: 25-30% (>24%)

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 1045

↑ *Back to this question in Part A*

@Neet_pg_bot

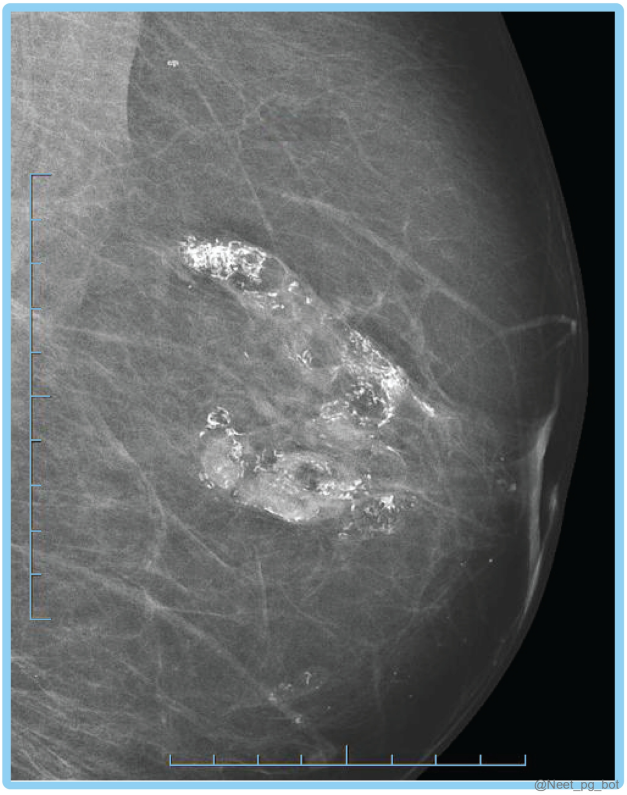
Q22: A 38-year-old woman presents with a firm, immobile mass in her right breast for the past few days. 2 weeks ago, she bruised her breast while exercising. A mammogram reveals scattered punctate calcifications within the lump. What is the most likely diagnosis? (Q845794)

A. Mastitis

B. Breast abscess

C. Fat Necrosis

D. Inflammatory Breast Cancer



Correct Answer: C. Fat Necrosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The most likely diagnosis in this patient with recent trauma and calcification could be fat necrosis. Breast fat necrosis is caused by injured or ischemic breast tissue that is replaced with scar tissue and presents as a palpable nodule. It is commonly caused by breast trauma and breast surgical procedures. It presents as a mammographic density , a painless palpable lump, skin thickening, or deposits of calcium. Fat necrosis can manifest in a variety of ways that closely resemble cancer like irregular breast mass, usually fixed to the dermis, with possible skin tethering and/or nipple retraction as a result of fibrotic bands between necrotic tissue and skin. Calcifications can sometimes occur in fat necrosis, particularly in older lesions. These are typically punctate (tiny dots) and scattered throughout the lump, unlike some cancers (differentiated by biopsy). Mastitis(Option A): This is an infection of breast tissue, often caused by bacteria entering through milk ducts during breastfeeding. It can cause inflammation, redness, pain, fever, and chills, which are absent in this case. Breast Abscess(Option B) This is a localized collection of pus within the breast tissue, often caused by a bacterial infection. It presents with fever, chills, and a more fluctuant (fluid-filled) mass compared to the firm mass often felt with fat necrosis. Inflammatory Breast Cancer(Option D): It typically presents with additional symptoms like skin thickening, peau d'orange (skin resembling an orange peel), and rapid progression.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 1041. Breast Fat Necrosis - StatPearls - NCBI Bookshelf (nih.gov)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q23: Which of the following conditions is most likely to cause a sticky, green, or black discharge from the nipple? (Q845793)

A. Duct Papilloma

B. Paget's Disease

C. Duct Ectasia

D. Breast Cancer

Correct Answer: C. Duct Ectasia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Duct Ectasia: This is a benign (non-cancerous) condition where the milk ducts in the breast widen and thicken. This can cause a blockage and a build-up of fluid, which often appears as a sticky, green, black, or grey discharge from the nipple. Discharge Colour Disorders Clear or Milky Hormonal fluctuations, Pregnancy, Breastfeeding Yellow, Green, or Brown Duct Ectasia, Infection Bloody Duct Papilloma, Paget's Disease, Breast Cancer White or Cloudy Infection

References:

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: Which of the following statements regarding Zuska’s disease is incorrect? (Q845789)

A. There is squamous metaplasia of the lactiferous duct

B. Characterized by the formation of keratin plug

C. Presents as subareolar abscess

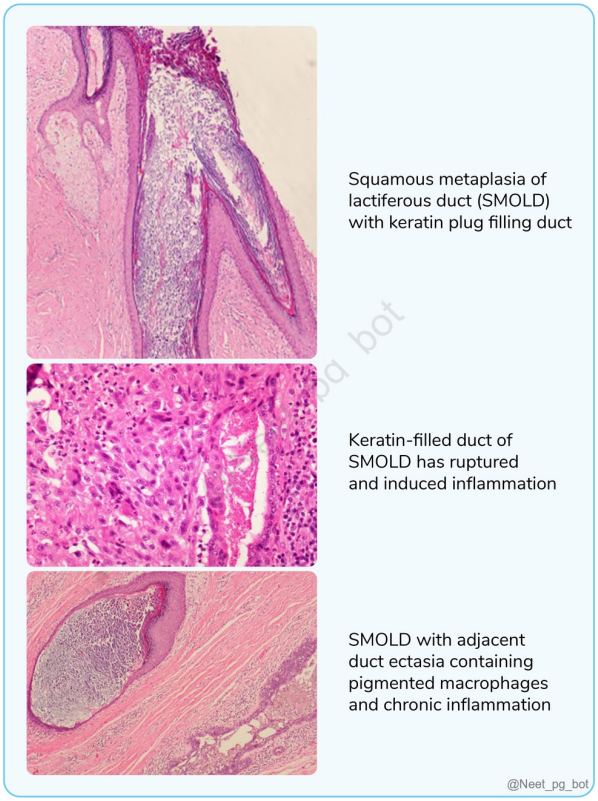
D. Alcohol is a major risk factor

Correct Answer: D. Alcohol is a major risk factor

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Smoking is a major risk factor in Zuska's disease Zuska's disease is also known as Squamous metaplasia of lactiferous ducts(SMOLD), recurrent subareolar abscess, or periductal mastitis. The risk factors include a deficiency of vitamin A associated with smoking(90% of cases). This leads to k eratinizing squamous metaplasia of the ductal epithelium, which is cuboidal. Keratin released from these cells blocks the ductal system. This leads to the formation of subareolar abscess, dilation, and eventually, the rupture of the duct, causing fistulas.



References:

Robbins & Cotran Pathologic Basis of Disease, 9th Edition, Page No. 1040-1041

↑ *Back to this question in Part A*

@Neet_pg_bot

Q25: A 48-year-old woman presents with pain in her left breast and associated nipple discharge for the past few weeks. She denies any fever, chills, or recent lactation. On examination, a small ovoid, well-defined subareolar mass is felt. What is the most likely diagnosis? (Q845788)

A. Acute mastitis

B. Duct ectasia

C. Ductal carcinoma in situ

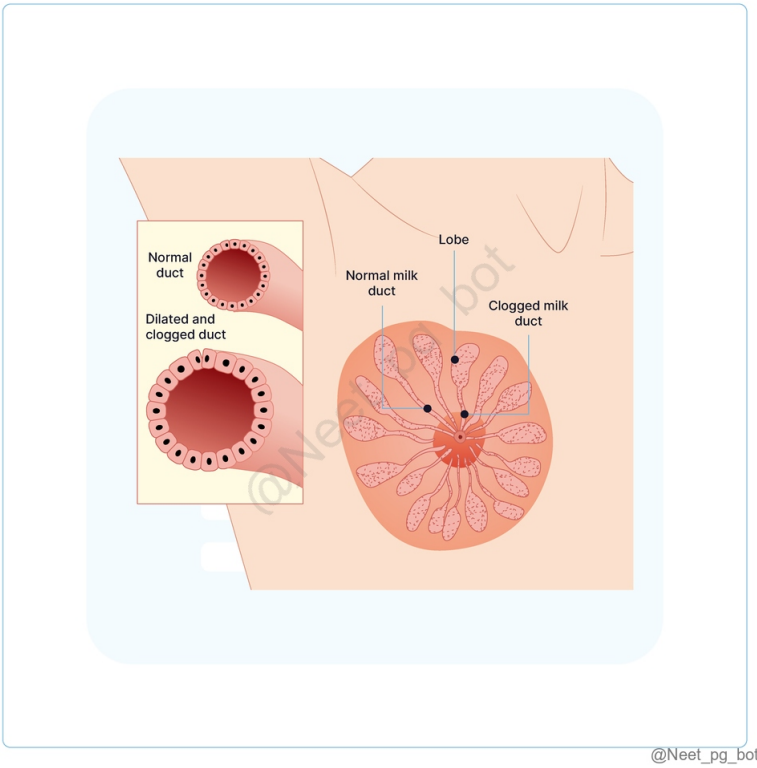
D. Fibroadenoma

Correct Answer: B. Duct ectasia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient presenting with breast pain, nipple discharge, and palpable subareolar mass most likely has duct ectasia. Mammary duct ectasia is a benign, non-proliferative breast disease that affects large ducts. It is most common in women who are nearing menopause, typically between the ages of 45 and 55. The breast ducts become clogged with thick secretion and debris, leading to dilation of the duct. Symptoms Nipple discharge, which can be clear, green, brown, or bloody Breast tenderness or pain , especially around the nipple A tender lump in the subareolar or periareolar region of a breast Inward retraction of the nipple due to repeated episodes and scarring A transverse slit-like or fish-mouth-like retraction of the nipple is classically seen in periductal mastitis but circumferential retraction may indicate a carcinoma. Ductal ectasia is often diagnosed during a routine mammogram or breast exam and managed by excision. If a lump is found, a biopsy may be needed to rule out cancer. Acute mastitis (Option A): This is primarily an inflammatory/infectious condition seen in women who are currently breastfeeding (lactational mastitis). It presents with systemic signs (fever, chills) and a red, swollen, diffuse area of infection rather than a localized, well-defined mass. Key Pathogen: Usually Staphylococcus aureus. Ductal carcinoma in situ (Option C): DCIS is a non-invasive cancer where abnormal cells are found in the lining of a breast duct. It is typically asymptomatic and non-palpable. It is almost always detected as microcalcifications on a mammogram rather than a distinct well-defined mass and discharge. Fibroadenoma (Option D): This is the most common benign breast tumor. It is most common in younger women (ages 15–35). While they are well-defined, they are "rubbery" and highly mobile ("breast mice"). They do not cause nipple discharge .



@Neet_pg_bot

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page No. 1041.

www.ncbi.nlm.nih.gov/books/NBK557665/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q26: A 24-year-old with a 2-month-old infant presents to the OPD with pain in her left breast. The baby is exclusively breastfed. On examination, the nipple is tender and erythematous with a fluctuant mass beneath the areola. Which of the following is the most common cause of this condition? (Q845786)

A. Pseudomonas aeruginosa

B. Staphylococcus aureus

C. Streptococcus sp.

D. Listeria monocytogenes

Correct Answer: B. Staphylococcus aureus

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario suggests acute breast abscess from lactational mastitis which is commonly caused by Staphylococcus aureus . It is caused by a local infection through cracks and fissures in the nipples that occur commonly during the 1st month of breastfeeding. It is often preceded by either engorgement or a focally blocked duct. Patients can develop a focal area of erythema, pain, fever, and swelling. This can further develop into single or multiple abscesses. Streptococcus pyogenes, Escherichia coli, Bacteroides species, and coagulase-negative Staphylococci are other organisms that cause mastitis. Treatment: I&D (Incision and Drainage) + Antibiotics First line agent: Cloxacillin/ Dicloxacillin for 10-14 days

Q25 (p. 2481)					

Q1: A 52-year-old woman presents with a painless palpable breast mass detected during self-examination. Imaging and biopsy confirm carcinoma of the breast. Which of the following is the most common location for breast carcinoma? (Q890381)

A. Upper outer quadrant

B. Upper inner quadrant

C. Lower outer quadrant

D. Lower inner quadrant

Correct Answer: A. Upper outer quadrant

Explanation: reast carcinoma most commonly arises in the upper outer quadrant (~50%) , which contains the greatest volume of glandular breast tissue , including the axillary tail (tail of Spence) —a common site of tumor origin. This region is also clinically significant because tumors here may present with early axillary lymph node involvement due to proximity to lymphatic drainage pathways. Distribution of Breast Carcinoma Upper outer quadrant ~50% Central/subareolar ~20% Other quadrants ~10% each

@Neet_pg_bot

Q2: Which of the following cancers are commonly associated with the BRCA2 mutation? Male breast cancer Ovarian carcinoma Pancreatic carcinoma Prostate

carcinoma Colorectal carcinoma (Q890407)

A. 1, 2, 3, 4

B. 1, 2, 5

C. 1, 2, 4, 5

D. 2, 3, 5

Correct Answer: A. 1, 2, 3, 4

Explanation: Colorectal carcinoma is not a classic cancer associated with BRCA2 mutations. It is more commonly linked to: Lynch syndrome (MMR genes) APC mutations (FAP) BRCA1 and BRCA2 are tumor suppressor genes involved in homologous recombination repair of DNA double-strand breaks . Mutations lead to genomic instability and increased cancer risk. BRCA2-associated cancers Male breast cancer (strong association; hallmark) Ovarian carcinoma Pancreatic carcinoma Prostate carcinoma BRCA1-associated cancers Breast carcinoma (often triple-negative) Ovarian carcinoma (higher risk than BRCA2) Also associated with pancreatic and prostate cancers (less prominently)

@Neet_pg_bot

Q3: Which of the following is the most common stromal malignancy of the breast? (Q890406)

A. Fibrosarcoma

B. Angiosarcoma

C. Liposarcoma

D. Leiomyosarcoma

Correct Answer: B. Angiosarcoma

Explanation: The most common stromal malignancy of the breast is Breast angiosarcoma , a rare malignant vascular tumour arising from endothelial cells . Angiosarcoma of the Breast: Most common malignant stromal tumour of the breast. Primary (Sporadic): Occurs in the breast parenchyma Young women (mean age ~35 years) Poor prognosis Secondary (Therapy-related): Occurs in older women Associated with: Radiation therapy Stewart–Treves syndrome (chronic lymphedema) MYC amplification in >90% Incidence after radiation: ~0.3%

Develops 5-10 years after treatment Fibrosarcoma (Option A): Extremely rare in the breast and not the most common stromal malignancy. Liposarcoma (Option C): Occurs very rarely in the breast and is less common than angiosarcoma among stromal malignancies. Leiomyosarcoma (Option D): A rare smooth muscle tumour of the breast and not the most frequent stromal malignancy.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 968, 969

↑ *Back to this question in Part A*

@Neet_pg_bot

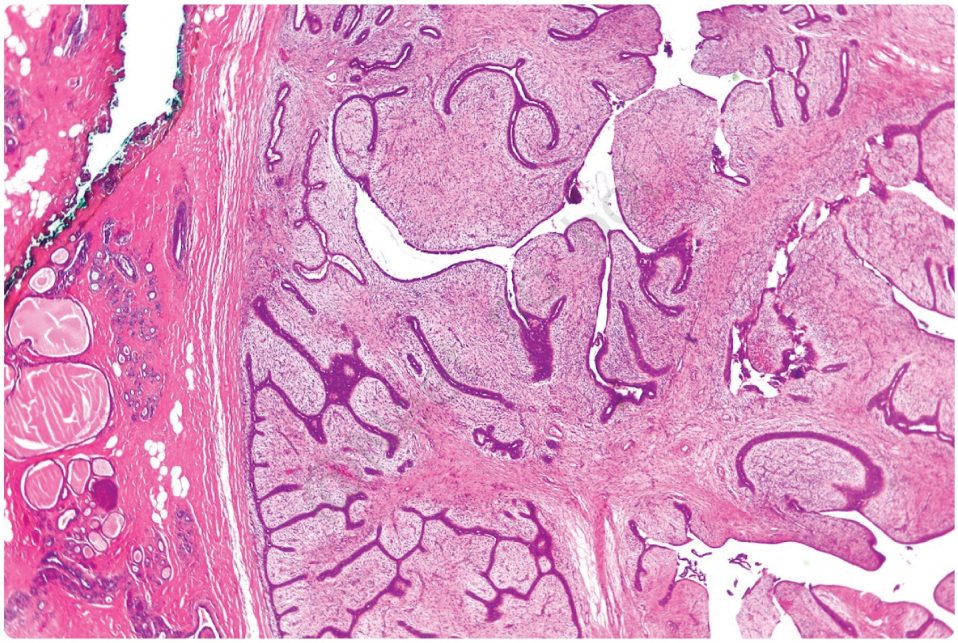
Q4: 60-year-old woman presents with a rapidly enlarging breast mass. Histology shows findings as shown. Which of the following statements regarding the most probable condition is incorrect? (Q890404)

A. Most tumours are benign

B. Metastases contain only the stromal component

C. Arises from the intralobular stroma

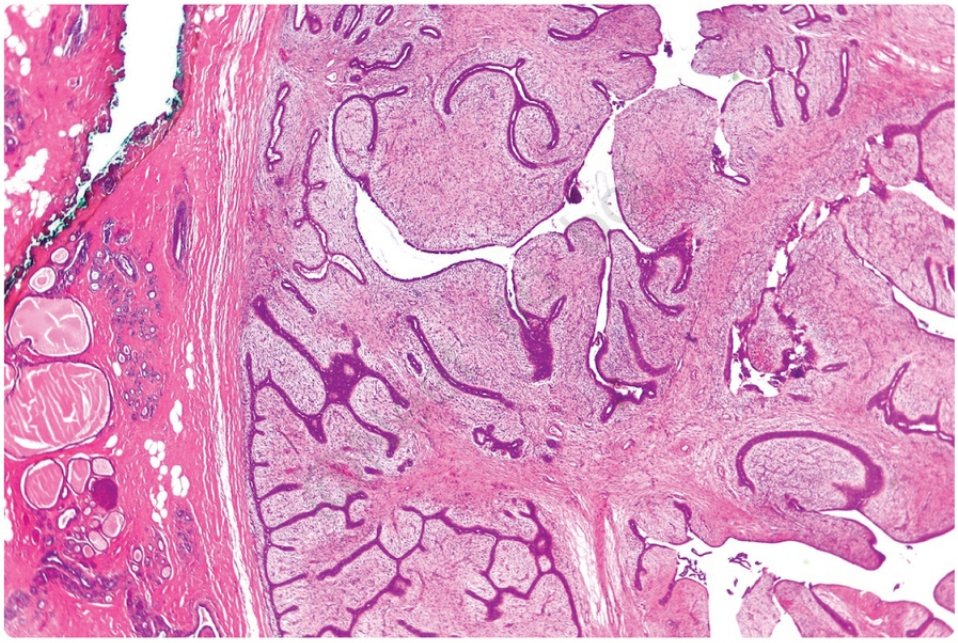
D. Local recurrence is rare



@Neet_pg_bot

Correct Answer: D. Local recurrence is rare

Explanation: The most probable diagnosis is Phyllodes tumour , a fibroepithelial breast tumour characterised by leaf-like stromal projections lined by epithelium . Phyllodes tumours commonly show local recurrence , especially borderline and malignant tumours , and margin status is the most important predictor of recurrence . Phyllodes tumour: Fibroepithelial tumour arising from intralobular stroma (Option C) ~ 2.5% of fibroepithelial breast lesions Mutations: MED12, RARA ; additional TERT, TP53, RB Morphology: Large palpable breast mass Leaf-like stromal projections lined by epithelium May form cystic spaces Clinical features: Peak age: ~6th decade (later than fibroadenoma) ~75% benign (Option A) Local recurrence is common ; margin status predicts recurrence Metastasis: Lymphatic spread rare → no axillary dissection Malignant tumours metastasise hematogenously (~1/3) Metastases contain only the stromal component (Option B)



@Neet_pg_bot

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 968

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 55-year-old woman is diagnosed with invasive breast carcinoma. Several tumour characteristics are evaluated to determine prognosis and guide therapy. Which of the following is considered a good prognostic marker in breast cancer?

(Q890402)

A. HER2 overexpression

B. ER positivity

C. Presence of BRCA mutation

D. Basal-type breast cancer

Correct Answer: B. ER positivity

Explanation: Tumours that express estrogen receptors (ER-positive) generally have a better prognosis and respond well to endocrine therapies such as tamoxifen or aromatase inhibitors . ER positivity is therefore considered an important, favourable prognostic and predictive marker in breast cancer. Breast cancer - Prognostic factor: Disease factors that influence prognosis Histologic Subtypes Invasive Ductal Carcinoma (IDC): Prognosis varies by grade and molecular markers. Invasive Lobular Carcinoma (ILC): Intermediate prognosis. Tubular and Mucinous Carcinomas: Best prognosis. Basal-like Breast Cancer (Option D) : Aggressive, triple-negative, no targeted treatments. Other Subtypes: Medullary, cribriform, papillary, adenoid cystic, and metaplastic carcinomas, vary in prognosis. Tumour Size & Lymph Node Larger tumours (>2cm) and positive lymph nodes = worse prognosis. Molecular Markers Hormone Receptors (ER, PR): ER-positive = better prognosis . HER-2 Status: HER-2 positive = aggressive (Option A) but treatable with targeted therapies. Patient factors that influence prognosis Age Younger, particularly premenopausal women, may have higher local recurrence rates post-surgery, but radiation therapy can reduce this risk. BRCA Mutation (Option C) Associated with aggressive phenotype Family History A strong family history may indicate inherited susceptibility and potentially worse prognosis.

@Neet_pg_bot

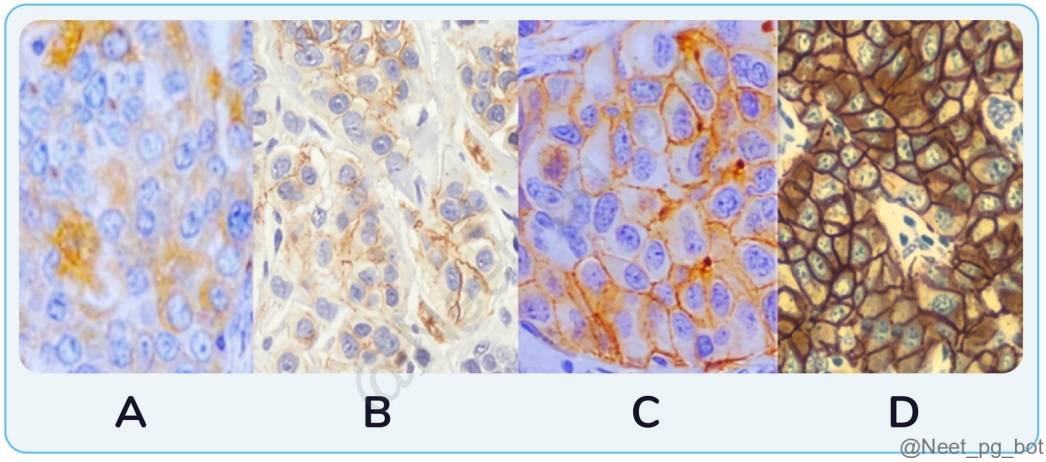
Q6: Which of the following IHC requires confirmation with fluorescence in situ hybridisation (FISH) for HER2 gene amplification? (Q890397)

A. D

B. C

C. B

D. A



Correct Answer: B. C

Explanation: HER2 immunohistochemistry (IHC) scoring determines when fluorescence in situ hybridisation (FISH) is required to confirm HER2 gene amplification . Image C (IHC 2+) is considered Equivocal (borderline). Because the protein expression is unclear, guidelines require confirmation using Fluorescence In Situ Hybridisation (FISH) to look for actual gene amplification. Image Interpretation: A: No significant membrane staining → Score 0 B: Faint incomplete staining → Score 1+ C: Moderate complete membrane staining → Score 2+ (Equivocal) D: Strong circumferential staining → Score 3+ Her2 IHC interpretation: Score IHC Pattern Interpretation FISH Needed 0 No staining or faint, incomplete membrane staining Negative No 1+ Faint/incomplete membrane staining in >10% cells Negative No 2+ Weak–moderate complete membrane staining in >10% cells Equivocal Yes 3+ Strong circumferential membrane staining Positive No

@Neet_pg_bot

Q7: A breast carcinoma is classified as T4d in the TNM staging system. Which of the following features is not characteristic of this stage? (Q890396)

A. Diffuse breast erythema and oedema

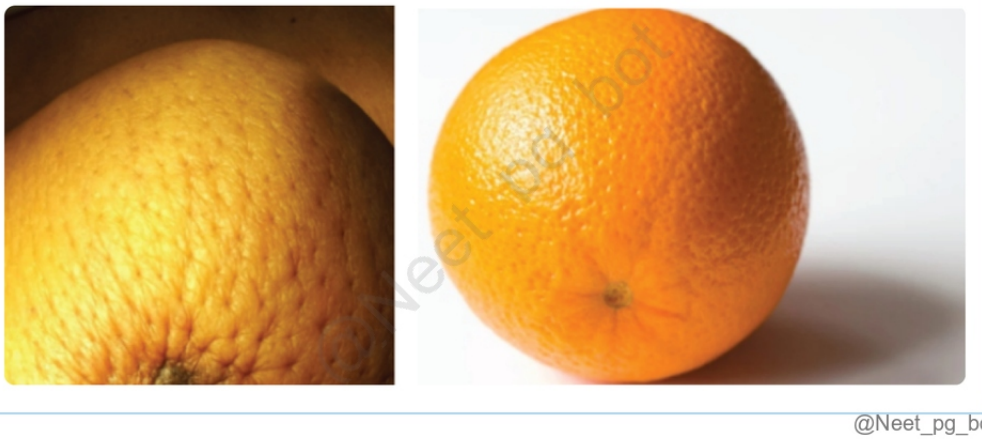
B. Peau d'orange appearance of the skin

C. Tumour emboli within dermal lymphatic vessels

D. Prominent neutrophilic inflammatory infiltrate in the dermis

Correct Answer: D. Prominent neutrophilic inflammatory infiltrate in the dermis

Explanation: A breast carcinoma classified as T4d corresponds to inflammatory breast carcinoma , which is characterised by tumour emboli within dermal lymphatic vessels leading to lymphatic obstruction . Despite the term inflammatory, true inflammatory cell infiltrates are usually absent Inflammatory Breast Carcinoma (IBC): Not a special histologic type; refers to a distinct clinical presentation. Caused by tumour emboli obstructing dermal lymphatic vessels. (Option C) Clinical features: Diffuse breast erythema (Option A) Breast swelling Skin thickening Peau d'orange (orange-peel appearance) (Option B) Dermal oedema + tethering by Cooper ligaments → skin dimpling. Usually high-grade, diffusely infiltrative carcinoma Often no discrete palpable mass



References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 963

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following is the most common clinical presentation of occult breast carcinoma? (Q890395)

A. Palpable breast lump with nipple retraction

B. Axillary lymphadenopathy due to metastatic carcinoma

C. Bloody nipple discharge

D. Diffuse breast skin thickening resembling peau d’orange

Correct Answer: B. Axillary lymphadenopathy due to metastatic carcinoma

Explanation: The most common presentation of occult breast carcinoma is isolated axillary lymph node metastasis , where patients present with painless axillary lymphadenopathy and the primary breast lesion remains undetectable. Occult breast carcinoma (OBC) is a breast malignancy that presents with metastatic disease (most commonly axillary lymph node metastasis) without a detectable primary tumour in the breast on clinical examination or imaging. Rare entity: ~0.1–1% of all breast cancers . Most common presentation: Isolated axillary lymphadenopathy due to metastatic carcinoma. Diagnosis: Histologically proven metastatic carcinoma (usually adenocarcinoma) in lymph nodes. No identifiable breast tumour on: Clinical examination Mammography Ultrasound MRI (often used for detection). Palpable breast lump with nipple retraction (Option A): Indicates a detectable primary breast carcinoma, whereas occult breast carcinoma presents without an identifiable primary lesion. Bloody nipple discharge (Option C): Seen in conditions with a primary ductal lesion such as intraductal papilloma or carcinoma, not in occult breast carcinoma. Diffuse breast skin thickening resembling peau d’orange (Option D): Characteristic of inflammatory breast carcinoma with overt breast involvement, not occult disease where the primary tumor is not detectable.

@Neet_pg_bot

Q9: A breast tumour shows strong ER positivity, PR positivity, HER2 negativity, and a low Ki-67 proliferation index. Which of the following histologic types of breast carcinoma is not associated with this subtype? (Q890394)

A. Tubular carcinoma

B. Papillary carcinoma

C. Mucinous carcinoma

D. Secretory carcinoma

Correct Answer: D. Secretory carcinoma

Explanation: The IHC profile indicates Luminal A breast carcinoma , which typically shows ER/PR positivity, HER2 negativity, and low proliferation . Secretory carcinoma is not associated with Luminal A; it is usually triple-negative . Molecular classification of breast cancer: Classification Hormone receptor HER2/Neu Others Luminal A Positive (either or both ER/PR) Negative Ki-67 low Luminal B Positive (either or both ER/PR) + or - Ki-67 high Basal type (triple -ve) Negative Negative Ki-67 usually high HER2/neu enriched Negative Positive Ki-67 high Claudin low Negative Negative Claudin low Luminal A (Low proliferation rate) Tubular carcinoma (Option A) Papillary carcinoma (Option B) Mucinous carcinoma (Option C) Low-grade ILC Luminal B (High proliferation rate) High-grade ILC. HER2/Neu rich Apocrine carcinoma. Micropapillary carcinoma. Triple-negative Medullary carcinoma Metaplastic carcinoma Secretory carcinoma Adenoid cystic carcinoma

@Neet_pg_bot

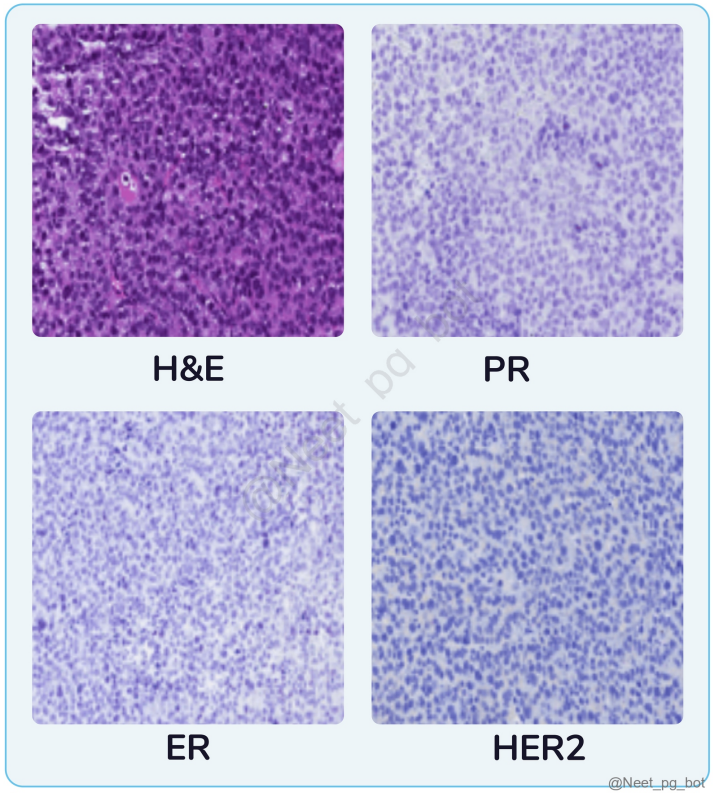
Q10: A 50-year-old woman is diagnosed with an aggressive breast carcinoma. Immunohistochemistry shows findings as shown. Which of the following histologic types of breast carcinoma is not associated with this subtype? (Q890386)

A. Medullary carcinoma

B. Metaplastic carcinoma

C. Adenoid cystic carcinoma

D. Mucinous carcinoma



Correct Answer: D. Mucinous carcinoma

Explanation: Based on the findings in the IHC, the most likely subtype is TNBC. Triple-negative breast cancers (TNBC) lack ER, PR, and HER2 expression. Mucinous carcinoma is not associated with TNBC; it is usually ER-positive and part of the luminal A subtype . Molecular classification of breast cancer: Classification Hormone receptor HER2/Neu Others Luminal A Positive (either or both ER/PR) Negative Ki-67 low Luminal B Positive (either or both ER/PR) + or - Ki-67 high Basal type (triple -ve) Negative Negative Ki-67 usually high HER2/neu enriched Negative Positive Ki-67 high Claudin low Negative Negative Claudin low Luminal A (Low proliferation rate) Tubular carcinoma Papillary carcinoma Mucinous carcinoma Low-grade ILC Luminal B (High proliferation rate) High-grade ILC. HER2/Neu rich Apocrine carcinoma. Micropapillary carcinoma. Triple-negative Medullary carcinoma (Option A) Metaplastic carcinoma (Option B) Secretory carcinoma Adenoid cystic carcinoma (Option C)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 960

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition. Pages 1049, 1056-1058

↑ *Back to this question in Part A*

@Neet_pg_bot

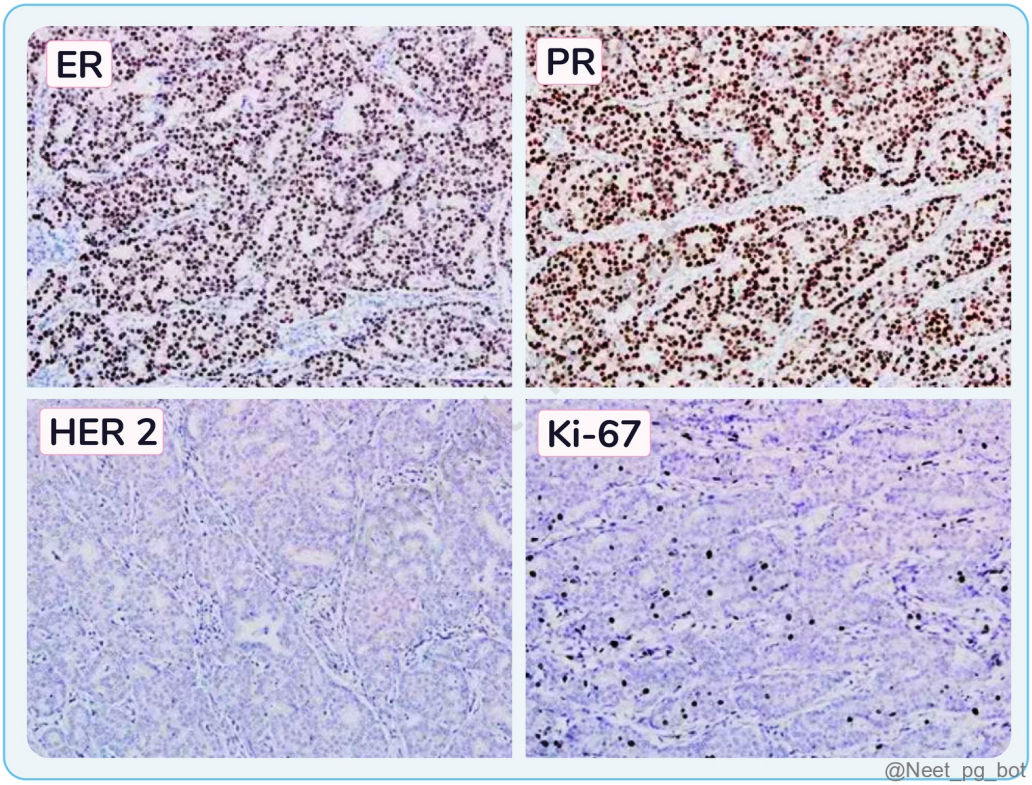
Q11: A 54-year-old woman undergoes a biopsy for a breast mass. Immunohistochemistry shows findings as shown. Which of the following is not a feature of the most probable molecular subtype? (Q890384)

A. Well differentiated

B. Strong luminal gene expression

C. Best prognosis

D. 1q loss



Correct Answer: D. 1q loss

Explanation: The findings suggest Luminal A breast carcinoma , which is characterised by ER/PR positivity, HER2 negativity, low proliferation, and well-differentiated tumours with strong luminal gene expression and a favourable prognosis . Luminal A tumours usually show 1q gain , not loss. Luminal A Breast Cancer: ER positive PR positive HER2 negative Low Ki-67 / low proliferation rate Well-differentiated tumours (Option A) Strong luminal (estrogen-regulated) gene expression (Option B) Common genomic changes: 1q gain 16q loss PIK3CA mutations Best prognosis among molecular subtypes of breast cancer. (Option C) Molecular classification of breast cancer: Subtype ER Status PR Status HER2 Status Ki-67 Status Characteristics Luminal A + + - Low Generally low grade, better prognosis, responsive to hormonal therapy. Luminal B + + or - + or - High Higher grade, poor prognosis compared to Luminal A, may require targeted HER2 therapy following status. HER2-enriched - - + High Aggressive, higher grade, poor prognosis, requires targeted HER2 therapy. Basal-like - - - High Includes triple-negative breast cancer (TNBC), which is highly aggressive and has no targeted hormonal

therapy. Claudin-low - - + or - Often High Often associated with poor prognosis and aggressive behaviour, typically lacks response to hormonal therapy.

@Neet_pg_bot

Q12: A 48-year-old woman is diagnosed with an aggressive breast carcinoma. Molecular testing reveals a mutation in the TP53 gene, which is the most common genetic alteration seen in this tumor subtype. Which of the following types of breast carcinoma is most likely present? (Q890383)

A. Luminal A breast carcinoma

B. Luminal B breast carcinoma

C. HER2-enriched carcinoma

D. Triple-negative breast carcinoma

Correct Answer: D. Triple-negative breast carcinoma

Explanation: Triple-negative breast carcinoma most commonly harbours TP53 mutations and typically presents as an aggressive, high-grade tumour lacking ER, PR, and HER2 expression . Triple-Negative Breast Cancer (TNBC): Morphology: Most tumours are high-grade with: Solid growth Nuclear pleomorphism Necrosis High proliferation Genetics: TP53 mutation - most common mutation BRCA1 / BRCA2 defects in familial cases Sporadic TNBC: BRCA1 is often epigenetically silenced Molecular classification of breast cancer: Subtype ER Status PR Status HER2 Status Ki-67 Status Characteristics Luminal A (Option A) + + - Low Generally low grade, better prognosis, responsive to hormonal therapy. Luminal B (Option B) + + or - + or - High Higher grade, poor prognosis compared to Luminal A, may require targeted HER2 therapy following status. HER2-enriched (Option C) - - + High Aggressive, higher grade, poor prognosis, requires targeted HER2 therapy. Basal-like - - - High Includes triple-negative breast cancer (TNBC), which is highly aggressive and has no targeted hormonal therapy. Claudin-low - - + or - Often High Often associated with poor prognosis and aggressive behaviour, typically lacks response to hormonal therapy.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 38-year-old woman with a strong family history of early-onset breast and ovarian cancer undergoes genetic testing. Which of the following correctly states the chromosomal locations of BRCA1 and BRCA2? (Q890382)

A. BRCA1 - 17q21; BRCA2 - 13q12.3

B. BRCA1 - 13q12.3; BRCA2 - 17q21

C. BRCA1 - 11p15; BRCA2 - 17p13

D. BRCA1 - 9p21; BRCA2 - 10q23

Correct Answer: A. BRCA1 - 17q21; BRCA2 - 13q12.3

Explanation: BRCA1 is located on chromosome 17q21, while BRCA2 is located on chromosome 13q12.3. These tumour suppressor genes are involved in DNA double-strand break repair through homologous recombination , and their mutations significantly increase the risk of hereditary breast and ovarian cancers. BRCA Genes: BRCA1 (chromosome 17q21) BRCA2 (chromosome 13q12.3) Responsible for 80-90% of single-gene familial breast cancers Account for 3-6% of all breast cancers Most female carriers develop cancer before age 70 Male breast cancer risk ↑ (especially BRCA2) Associated cancers: Ovarian carcinoma Prostate carcinoma Pancreatic carcinoma

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 957

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 35-year-old woman comes to the clinic presenting with swelling in the upper quadrant of her left breast. She reports changes in the skin and surrounding nipple areola complex as well. All of the following are risk factors for this condition except? (Q845693)

A. Alcohol

B. Early menarche

C. Age

D. Multiparity

Correct Answer: D. Multiparity

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Multiparity is not a risk factor for breast carcinoma. The clinical presentation of a 35-year-old female with swelling in the upper quadrant of her breast with skin changes in the skin and the surrounding nipple-areola complex is highly suggestive of carcinoma of the breast. Risk factors for breast carcinoma : Risk factors Relative risk Female gender. Increasing age. (Option C) Germline mutations of high penetrance. Strong family history (>1 first-degree relative, young age, multiple cancers). Personal history of breast cancer. High breast density. >4.0 Germline mutations of moderate penetrance. High-dose radiation to the chest at a young age. Family history (1 first-degree relative). 2.1-4.0 Early menarche (age <12 years). (Option B) Late menopause (age >55 years). Late first pregnancy (age >35 years). Nulliparity . Absence of breastfeeding. Exogenous hormone therapy. Postmenopausal obesity. Physical inactivity. High alcohol consumption. (Option A) 1.1-2.0 Relative risk is the likelihood of developing invasive carcinoma compared to women without any risk factors. Protective factors Early full term pregnancy Multiparity Lactation and breastfeeding Late menarche and early menopause

@Neet_pg_bot

Q15: Which of the following parameters is not assessed in the Bloom-Richardson scoring system? (Q845723)

A. Nuclear size

B. Tubule formation

C. Size of the tumor

D. Mitotic count

Correct Answer: C. Size of the tumor

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The size of the tumor is a part of the Van Nuys Prognostic Index and it is not assessed in the BLoom-Richardson scoring ssystem Bloom-Richardson scoring system (Also known as Nottingham grading system): The parameters include: Tubule formation (Option B) , which assesses the degree of glandular formation in tumor tissue. Nuclear pleomorphism (Option A) refers to variations in the size and shape of cell nuclei. Mitotic count (Option D) indicates the number of actively dividing cells per high-power field. Each parameter is assigned from 1 to 3 points according to the degree of deviation from normal breast epithelium. Score Grade 3-5 I 6 or 7 II 8 or 9 III Van Nuys Prognostic Index (VNPI): It predicts the risk of local recurrence for DCIS (non-invasive breast cancer) to guide treatment. Factor 1 Point (Low Risk) 2 Points (Medium Risk) 3 Points (High Risk) Tumor Size ≤ 15 mm 16 - 40 mm > 40 mm Margin Width ≥ 10 mm 1 - 9 mm < 1 mm Pathologic Class Low/Intermediate grade, no necrosis Low/Intermediate grade with necrosis High grade (Grade 3) Patient Age > 60 years 40 - 60 years < 40 years Treatment Recommendations: 4, 5, or 6 (Low Risk): Surgery only (lumpectomy). 7, 8, or 9 (Intermediate Risk): Surgery + Radiation. 10, 11, or 12 (High Risk): Mastectomy generally recommended.

Bailey & Love's Short Practice of Surgery, 28th edition, Page 872.

www.ncbi.nlm.nih.gov/pmc/articles/PMC5161065/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A biopsy taken from a patient's breast lump is subjected to histopathological examination. Upon staining, it is found to be a luminal breast carcinoma with a high proliferative rate. Overexpression of which of the following cellular proteins has led to this interpretation? (Q845721)

A. Alpha catenin

B. Arp-2/3

C. Ki-67

D. Vimentin

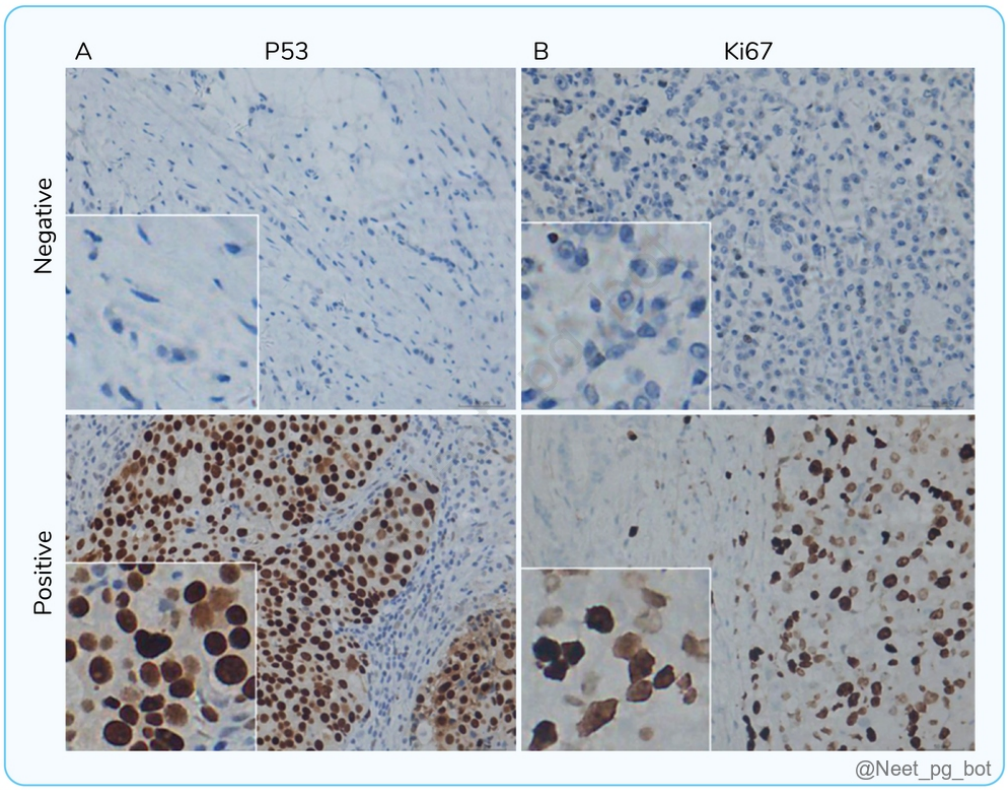
Correct Answer: C. Ki-67

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Ki-67 is a nuclear protein associated with cellular proliferation . Luminal A: ER and PR positive, HER2 negative, Ki-67 < 14% (low proliferation rate). Luminal B: ER and PR positive, HER2 negative/positive, Ki-67 > 14% (high proliferation rate). Alpha catenin (Option A): This protein is involved in cell-to-cell adhesion; its loss (along with E-cadherin) is a hallmark of lobular carcinoma rather than an indicator of proliferative speed.

Arp-2/3 (Option B): This complex regulates the actin cytoskeleton and is associated with cell motility and metastasis (forming lamellipodia), but it is not used to quantify the proliferation rate in a standard biopsy.
Vimentin (Option D): his is a marker for mesenchymal cells ; in breast cancer, it is often expressed in "triple-negative" or metaplastic carcinomas undergoing epithelial-mesenchymal transition (EMT), not specifically "luminal" types.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Page 1048

↑ *Back to this question in Part A*

@Neet_pg_bot

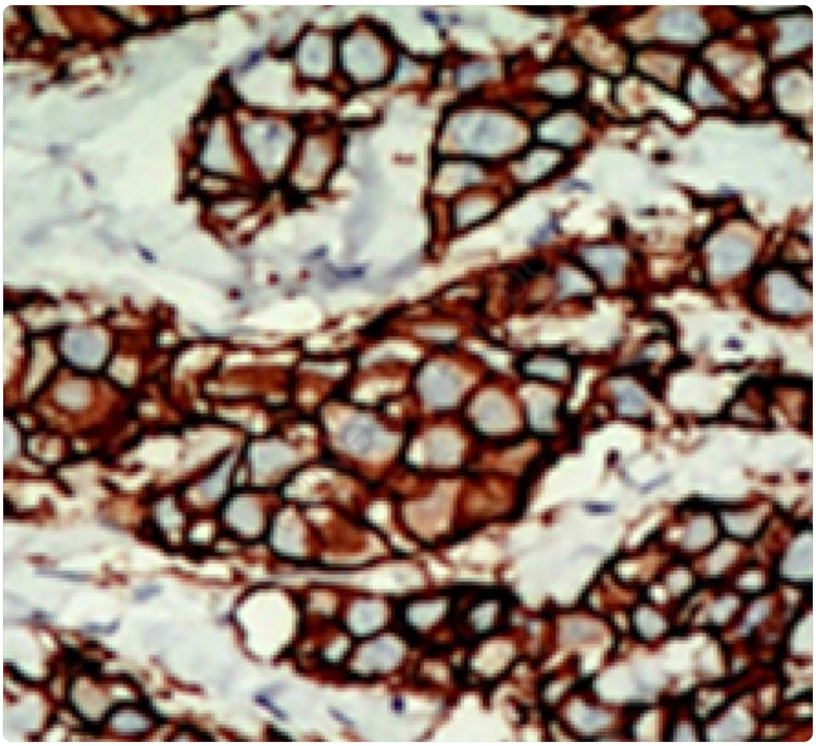
Q17: A patient with a lump in her left breast is subjected to a biopsy. Subsequent immunohistochemistry was done and the image is given below. After an MDT discussion, a decision was made to prescribe Trastuzumab as the appropriate management for this patient. What would have been the diagnosis based on the above clinical scenario? (Q845716)

A. Apocrine carcinoma

B. Medullary carcinoma

C. Tubular carcinoma

D. Papillary carcinoma

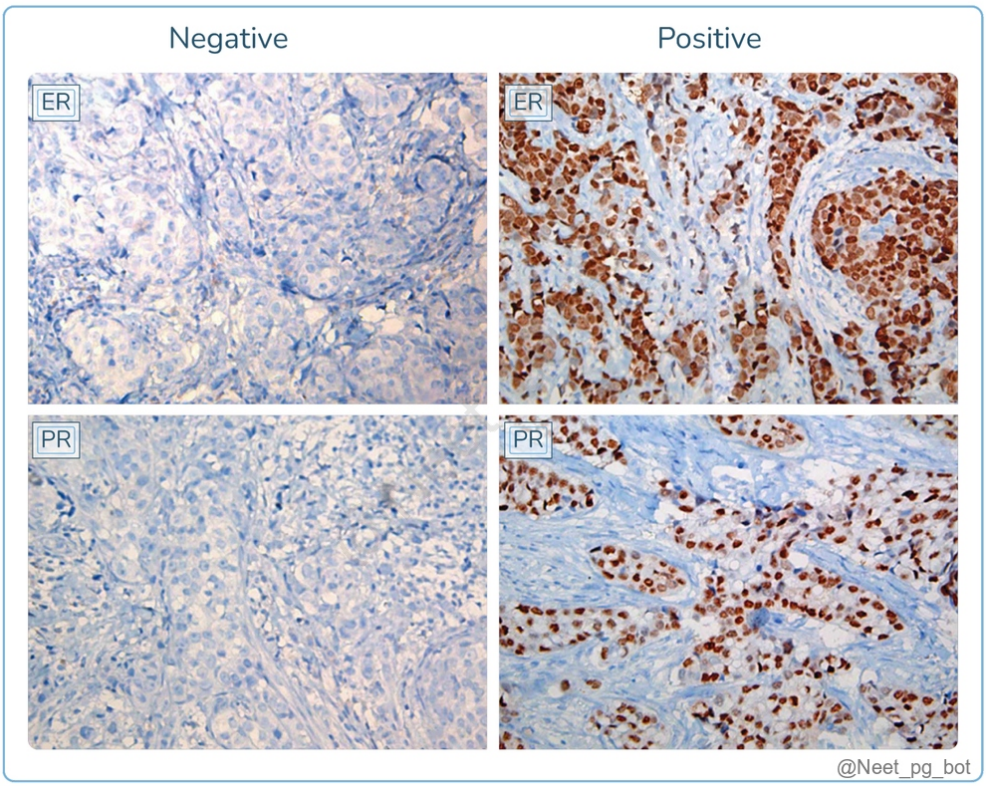


Correct Answer: A. Apocrine carcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical vignette along with the immunohistochemical finding that shows staining of membranes rather than the nucleus suggest the diagnosis of a HER2 receptor-rich breast carcinoma. In breast biopsy, we test for three important markers: ER (estrogen receptor), PR (progesterone receptor), and HER2/neu Apocrine carcinoma is one of the two most common HER2 receptor-rich subtypes of invasive breast carcinoma, the other one being micropapillary carcinoma. Trastuzumab is a monoclonal antibody that acts by inhibiting the HER2 receptors and prevents further growth of the tumor, since HER2 receptor rich tumors respond well to HER2 inhibitor therapy. Medullary carcinoma (Option B) is a triple-negative subtype. Tubular and papillary carcinomas (Option C and D) are ER/PR positive subtypes hence considered Luminal A. Molecular classification of breast cancer : Classification Hormone receptor HER2/Neu Proliferative marker Luminal A Positive (either or both ER/PR) Negative Ki-67 <14% (low) Luminal B (triple +ve) Positive (either or both ER/PR) Negative / Positive Ki-67 >14% (high) Basal type (triple -ve) Negative Negative Ki-67 usually high HER2/neu enriched Negative Positive Ki-67 high Claudin low (triple -ve) Negative Negative Claudin low Luminal A (Low proliferation rate) Tubular carcinoma Papillary carcinoma Mucinous carcinoma Low-grade ILC Luminal B (High proliferation rate) High-grade ILC HER2/Neu rich Apocrine carcinoma Micropapillary carcinoma Triple-negative Medullary carcinoma Metaplastic carcinoma Secretory carcinoma Adenoid cystic carcinoma



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 1048, 1053, 1058.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: You are provided with results of receptor status from the biopsy obtained from a patient's breast lump. You realize that her molecular subtype carries a low proliferative rate and a better prognosis. Which of the following will not be the likely histological subtype in this patient? (Q845714)

A. Tubular carcinoma

B. Medullary carcinoma

C. Papillary carcinoma

D. Mucinous carcinoma

Correct Answer: B. Medullary carcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The biopsy results obtained from a patient’s breast lump carrying a low proliferative rate (better prognosis) is indicative of a luminal type A malignancy. Among the given options, medullary carcinoma of the breast does not belong to luminal type A; rather it is a luminal type B malignancy. Molecular classification of breast cancer is based on the results of receptor status such as ER, PR and HER2. Molecular classification of breast cancer : Classification Hormone receptor HER2/Neu Proliferative marker Luminal A Positive (either or both ER/PR) Negative Ki-67 <14% (low) Luminal B (triple +ve) Positive (either or both ER/PR) Negative / Positive Ki-67 >14% (high) Basal type (triple -ve) Negative Negative Ki-67 usually high HER2/neu enriched Negative Positive Ki-67 high Claudin low (triple -ve) Negative Negative Claudin low Luminal A (Low proliferation rate) Tubular carcinoma (Option A ruled out). Papillary carcinoma (Option C ruled out). Mucinous carcinoma (Option D ruled out). Low-grade ILC. Luminal B (High proliferation rate) High-grade ILC. HER2/Neu rich Apocrine carcinoma. Micropapillary carcinoma. Triple-negative Medullary carcinoma. (Option B) Metaplastic carcinoma. Secretory carcinoma. Adenoid cystic carcinoma.

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 1049, 1056-1058.

Bailey and Love, Short Practice of Surgery, 28th Edition, Page 931

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: Consider the following statements about Paget's disease of the breast? 1. It is an in-situ cancer. 2. Presence of Paget cells is needed for diagnosis. 3. Underlying carcinoma is usually LCIS. 4. Immunostaining is positive for carcinoembryonic antigen (CEA). Which of the above are true statements? (Q845712)

A. 1,3, and 4

B. 1,2, and 4

C. 1,2, and 3

D. All of the above

Correct Answer: B. 1,2, and 4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Paget’s disease Mammary Paget's: Paget's disease of the breast. (Most common) Extramammary Paget's: Paget's disease of the vulva. Clinically, the patient usually tends to visit the dermatology department because the skin over the breast and the nipple–areola region becomes reddened and encrusted , so the patient

mistakes this as a dermatological disorder. There is a cancer sitting underneath , and that cancer is usually a ductal carcinoma in situ (DCIS) . From this underlying cancer, the malignant process spreads to the overlying skin . (Statement 3) Clear cancer cells can be seen within the epidermis, called as Paget cells . Paget cells must be seen in the skin for diagnosis (Statement 2) On immunohistochemistry: Cytokeratin (CK) positivity Indicates that the cells are derived from an epithelial cancer . Carcinoembryonic antigen (CEA) positive. It is an in-situ cancer . (Statement 1) Immunostaining is positive for CEA. (Statement 4)

Sabiston textbook of surgery, 20th edition, Page no 883

Bailey & Love's Short Practice of Surgery, 28th edition, Page no 924

↑ *Back to this question in Part A*

@Neet_pg_bot

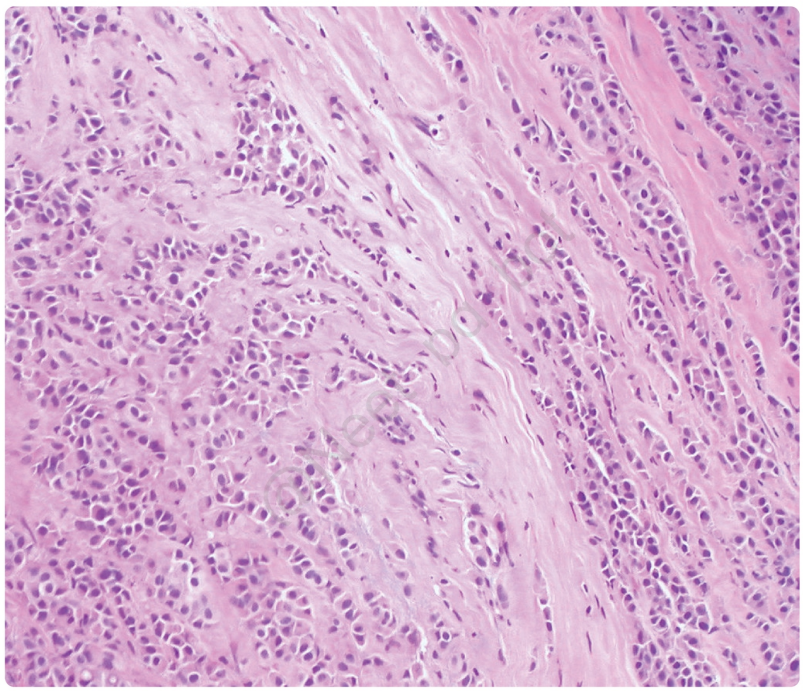
Q20: A 60-year-old woman presents with a newly diagnosed left-sided breast mass on routine mammography. Core needle biopsy shows the following findings. Further molecular study revealed the involvement of the CDH1 gene. Which of the following statements are incorrect concerning this type of breast cancer? 1) Increased E-cadherin expression is observed in tumor cells. 2) Minimal desmoplasia and fibrosis were observed on microscopy. 3) A contralateral breast examination is usually required due to bilateral involvement. 4) It is associated with a poor prognosis compared to other types of breast cancer. 5) Metastatic spread affects leptomeninges and retroperitoneum. (Q845710)

A. 1, 2, 3, 4

B. 1, 2, 3

C. 1, 4

D. 1, 2, 4, 5

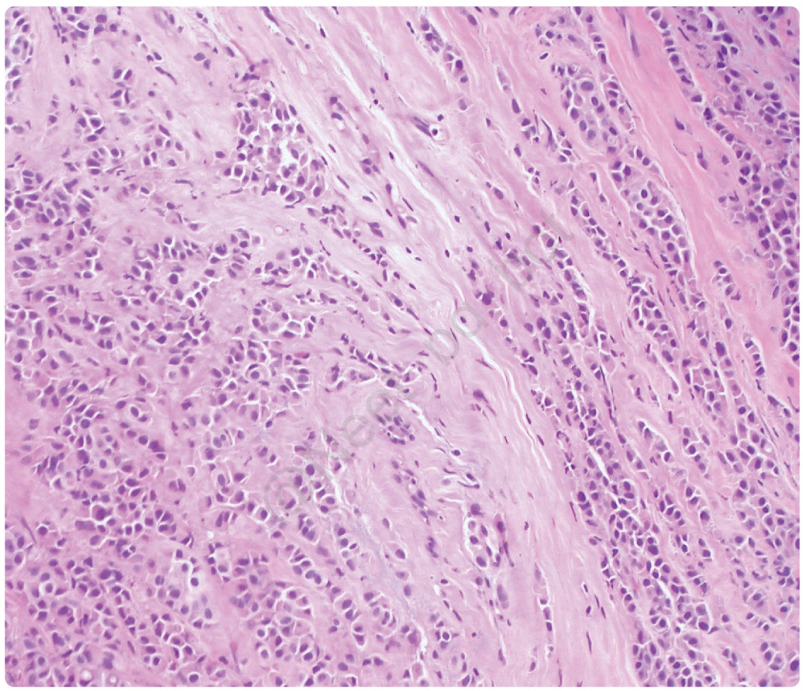


@Neet_pg_bot

Correct Answer: C. 1, 4

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Invasive lobular breast carcinoma: CDH1 gene mutation : Decreased E-cadherin levels (also seen in signet ring gastric adenocarcinoma). (Statement 1) Clinically: Bilateral and multicentric lesions; if one breast has ILC, both breasts should be examined. (Statement 3) Microscopy Features: The tumor cells are dyscohesive, present back to back, and are called Indian file pattern. Shows minimal desmoplasia and fibrosis. (Statement 2) Metastatic spread to the retroperitoneum and leptomeninges is called carcinomatous meningitis. (Statement 5) Excellent prognosis because it usually belongs to Luminal A and B categories. (Statement 4)



@Neet_pg_bot

References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 1053- 57.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: Which of the following is associated with the worst prognosis? (Q845707)

A. Paget’s disease

B. Metaplastic carcinoma

C. Medullary carcinoma

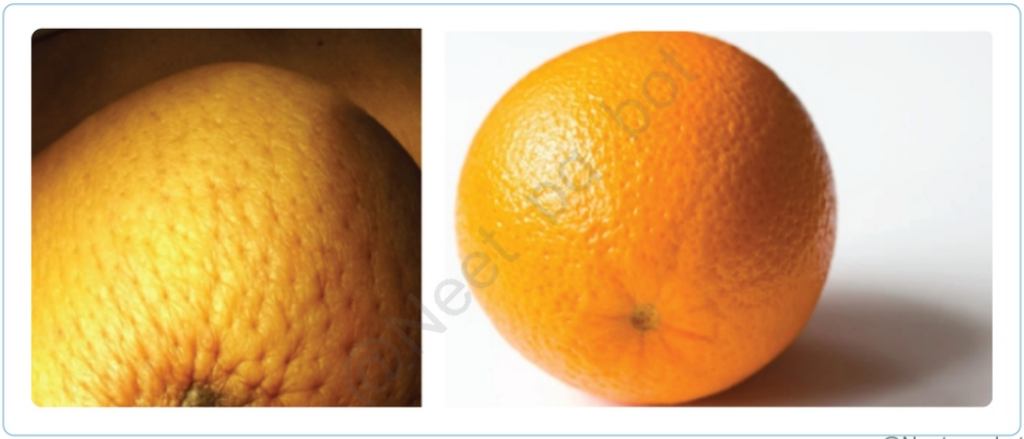
D. Inflammatory carcinoma

Correct Answer: D. Inflammatory carcinoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Inflammatory breast carcinoma has a poor prognosis, with extensive invasion of subdermal lymphovascular channels. Inflammatory Breast Carcinoma: It presents as breast erythema, swelling, and skin thickening. Edematous skin is tethered to the breast by Cooper ligaments and mimics orange peel or peau d'orange because cancer has spread into subdermal lymphatics. Usually high grade with very poor prognosis.



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Page 1058

↑ *Back to this question in Part A*

@Neet_pg_bot

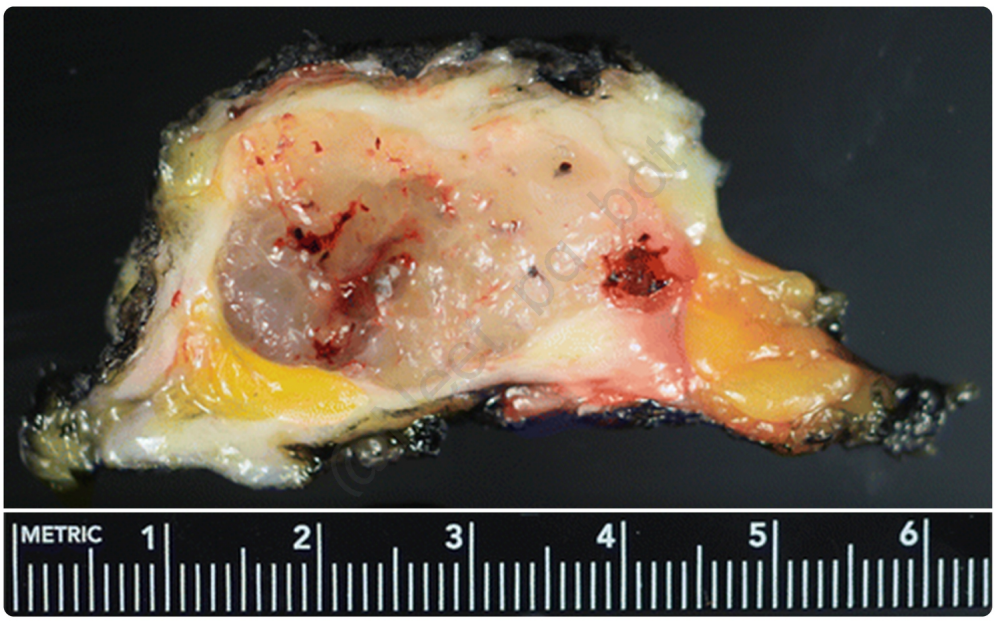
Q22: A 50-year-old woman presents with discomfort in her left breast. Mammography reveals a suspicious mass. Ultrasound-guided core needle biopsy is performed. Based on the histopathological findings, what is the most likely diagnosis? (Q845703)

A. Lobular carcinoma

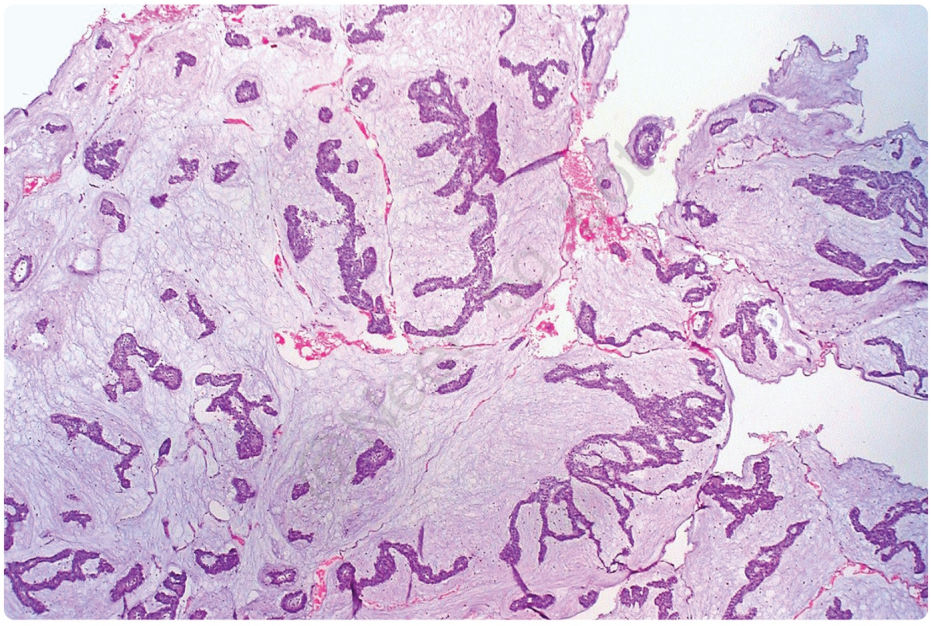
B. Ductal carcinoma in situ

C. Medullary carcinoma

D. Mucinous carcinoma



@Neet_pg_bot



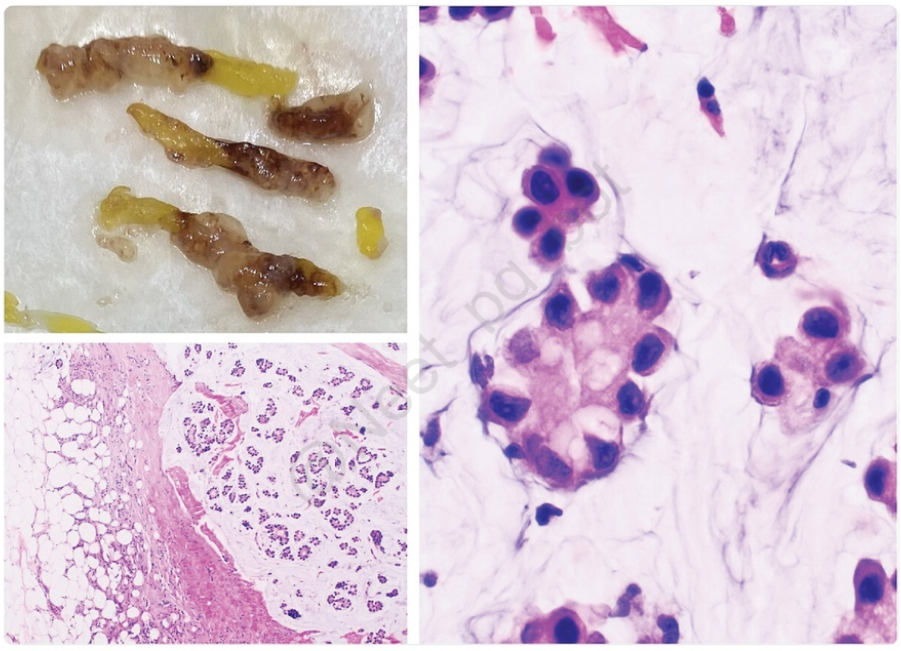
@Neet_pg_bot

Correct Answer: D. Mucinous carcinoma

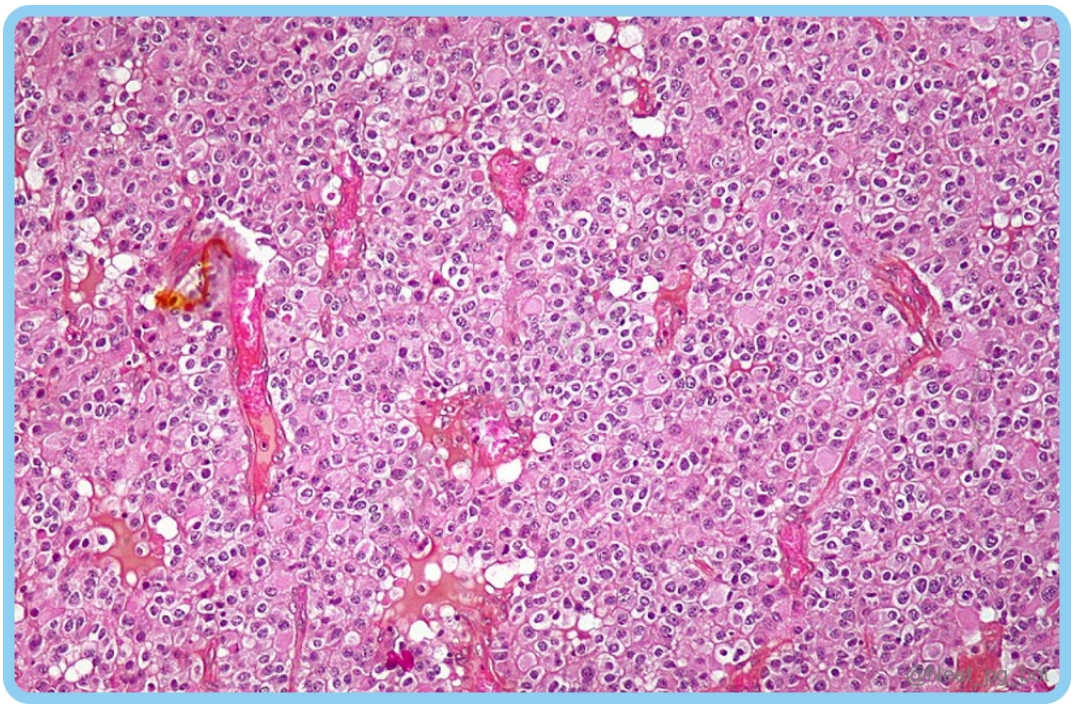
- *Listen (English)*
- *Listen (Hindi)*

Explanation: Mucinous or Colloid Carcinoma: A subtype of infiltrating ductal carcinoma with Excellent prognosis. Clinical findings: Soft to firm lump due to mucilage. It may be mistaken for a benign tumor.

Histopathology: Gross: Soft, shiny, rubbery texture with pale gelatinous/jelly consistency. Microscopy: Tumor cells arranged in clusters or islands with pools of mucin extracellularly and may be intracellularly (called signet ring cell). FNAC: Chicken wire blood vessels (blood vessels get entangled in FNAC needle because of presence of mucin) . Chicken wire blood vessels is also seen in Oligodendroglioma, which is a brain tumor showing fried egg appearance on biopsy and Chicken wire blood vessels. Lobular carcinoma (Option A): It is characterized by "single-file" (Indian file) rows of small, discohesive cells invading a fibrous stroma. It lacks extracellular mucin pools and typically doesn't form a well-circumscribed gelatinous mass. Ductal carcinoma in situ (Option B): Neoplastic cells are confined within the basement membrane of the ducts, often with a "comedo" (central necrosis) or cribriform (Swiss cheese) pattern. Medullary carcinoma (Option C): Characterized by large, pleomorphic cells growing in "syncytial" sheets with a prominent lymphoplasmacytic (white blood cell) infiltrate. Medullary carcinoma is "fleshy" and solid, not gelatinous



@Neet_pg_bot



References:

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 1053- 1058

↑ *Back to this question in Part A*

@Neet_pg_bot

Q23: A 45-year-old woman presented with a palpable breast lump detected during a routine self-examination. A biopsy confirmed the diagnosis of infiltrating ductal carcinoma (IDC). Which of the following is not a subtype of IDC? 1. Tubular carcinoma 2. Medullary carcinoma 3. Colloid carcinoma 4. Lobular carcinoma 5. Papillary carcinoma 6. Apocrine carcinoma 7. Secretory carcinoma 8. Myofibroblastoma 9. Angiosarcoma (Q845701)

A. 3, 4, 8, 9

B. 4, 6, 8

C. 2, 4, 7, 9

D. 4, 8, 9

Correct Answer: D. 4, 8, 9

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Lobular carcinoma, myofibroblastoma, and angiosarcoma are not subtypes of infiltrating ductal carcinoma (IDC). Carcinoma: Epithelial origin tumor Lobular carcinoma (Option 4) Myofibroblastoma (Option 8) : Mesenchymal tumor Angiosarcoma (Option 9) : Blood vessel cancer Infiltrating ductal carcinoma: Special Types of IDC: Tubular carcinoma: Good prognosis. Mucinous or Colloid Carcinoma- Signet ring cells on biopsy and FNAC: Chicken wire blood vessels. Medullary carcinoma- Lymphoplasmacytic infiltrate. Apocrine carcinoma. Metaplastic carcinoma. Papillary carcinoma Secretary carcinoma: Occurs in younger females. Inflammatory carcinoma- Peau d'orange appearance with Poor prognosis

References:

Robbins and Cotran Textbook of Pathology, 10th Edition, Page 1055-58

↑ *Back to this question in Part A*

@Neet_pg_bot

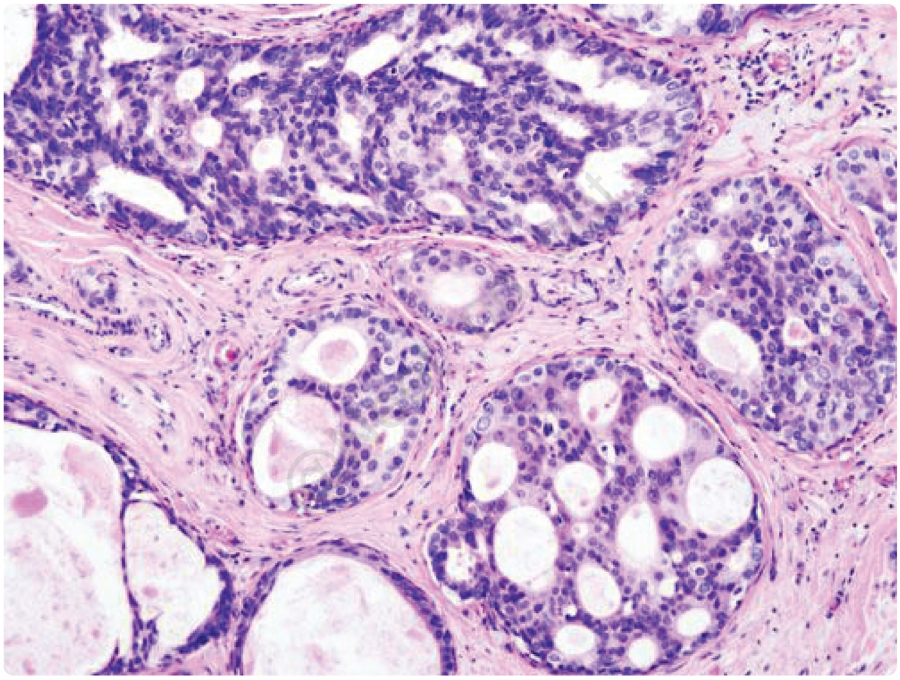
Q24: A 52-year-old woman presents for her routine mammogram, which reveals microcalcifications in the right breast. She has no significant family history of breast cancer and is asymptomatic. A core needle biopsy is performed, and the histopathological image is shown below. Based on histopathology, what is the most likely diagnosis? (Q845697)

A. Invasive Ductal Carcinoma

B. Lobular Carcinoma in Situ

C. Ductal Carcinoma in Situ

D. Fibroadenoma



@Neet_pg_bot

Correct Answer: C. Ductal Carcinoma in Situ

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The histopathological image shows features consistent with ductal carcinoma in situ (DCIS), including malignant cells confined within the ductal system without invasion into surrounding tissue. This correlates with the clinical scenario of microcalcifications detected on mammography, a common presentation of DCIS. The image shows cribriform variant of DCIS: In this duct, multiple small white spaces can be seen, which gives it the cribriform pattern . he most high-grade DCIS is comedo necrosis DCIS , because it has the highest chance of converting into invasive ductal carcinoma . Types of DCIS : Comedo It may occasionally produce a vague nodularity but is often detected as clustered or linear and branching areas of calcification. There is necrotic, dirty material inside the duct . Two features define it: Tumor cells with pleomorphic, high-grade nuclei. Areas of central necrosis. Cribriform It has rounded (cookie cutter–like) spaces, often filled with calcified secretory material. Micropapillary It produces complex bulbous protrusions without fibrovascular cores. Shows small papillary projections inside the duct. Papillary It produces true papillae with fibrovascular cores that lack a myoepithelial cell layer and shows proper finger-like papillary projections . Solid The duct is full of cells and becomes solid. Histological images of types of DCIS: Comedo DCIS: Cribriform DCIS: Micropapillary DCIS: Papillary DCIS:

[14_Breast Pathology] 061 Previous Year Questions — Quick Jump

Q1 (p. 2482) *Q2 (p. 2484)* *Q3 (p. 2485)* *Q4 (p. 2486)* *Q5 (p. 2487)* *Q6 (p. 2490)*

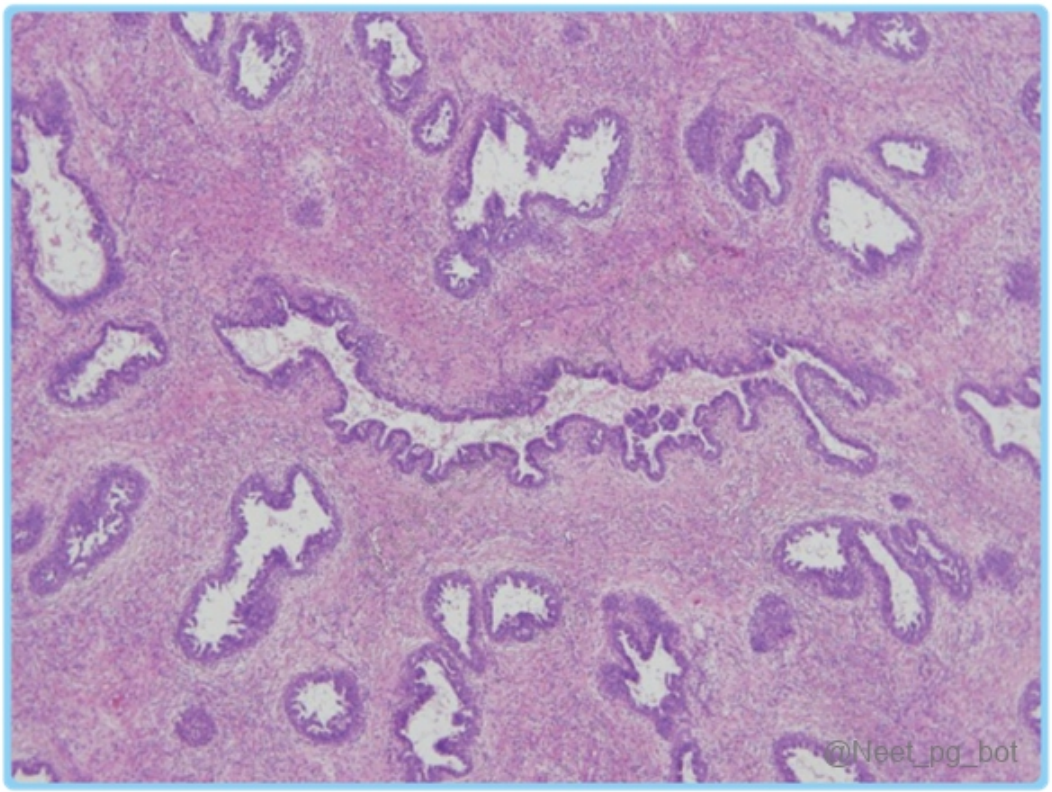
Q1: A 27-year-old woman discovers a well-defined mobile and rubbery breast lump measuring 4x7 cm on self-examination. The lesion is painless and has been stable over several months. What is the most likely diagnosis? (Q860560)

A. Acute mastitis

B. Fibroadenoma

C. Ductal ectasia

D. Sclerosing adenosis



Correct Answer: B. Fibroadenoma

Explanation: The clinical presentation along with histopathology showing epithelial ducts compressed and distorted by surrounding stroma, is characteristic of an intracanalicular Fibroadenoma. Fibroadenoma Definition Benign tumours arising from the proliferation of glandular tissue in the breast Prevalence Most common in women aged 15-25 years. Aetiology Believed to be influenced by hormonal fluctuations during reproductive years Molecular alteration: Alterations in MED12 gene. Clinical Presentation Painless, firm, rubbery, and mobile lumps Described as feeling like a "marble in the breast." Histopathology Well-defined borders due to a fibrous capsule, with proliferating stroma potentially compressing and distorting glandular components. The epithelium may be of 2 patterns: Pericanalicular Pattern: Surrounded by stroma Intracanalicular Pattern: Compressed and distorted by it. {{caption_text}} Mammogram Popcorn calcification on mammogram {{caption_text}} Diagnosis Triple Assessment: Clinical examination, radiological imaging (ultrasound), tissue sampling (core-needle biopsy) Ultrasound: Helps distinguish fibroadenomas from cysts Core-Needle Biopsy: Provides definitive diagnosis Treatment Conservative Management: Watchful waiting, regular monitoring Surgical Excision: For larger fibroadenomas, those causing symptoms, or uncertain diagnosis Giant Fibroadenomas: Over 5 cm, may require excision through submammary incision Prognosis Benign , does not increase the risk of breast cancer Growth can vary, influenced by hormonal changes Recurrence is uncommon Relationship to ANDI Categorised according to ANDI as: Normal: Small fibroadenomas (≤1 cm) Disorder: Larger fibroadenomas (≤3 cm) Disease: Giant fibroadenomas (>3 cm), multiple fibroadenomas Acute mastitis (Option A) is a breast infection, common in lactating women, presenting with pain, redness, swelling, and fever. It is caused by a bacterial infection but is unlikely here due to the absence of pain and inflammation. Ductal ectasia (Option C) is a benign condition in older women, causing nipple discharge, nipple retraction, and breast tenderness. It does not present as a well-defined, mobile, painless lump, making it an unlikely diagnosis here. Sclerosing adenosis (Option D) is a benign breast condition causing firm, palpable lumps, often associated with pain and calcifications. It is not typically mobile or rubbery, making it a less likely diagnosis.

@Neet_pg_bot

Q2: What does luminal type A tumour refer to? (Q857445)

A. ER+ / HER2 neu- ; mild to moderate proliferation

B. ER+ / HER2 neu+

C. ER- / HER2 neu-

D. ER+ / HER2 neu- ; high proliferation

Correct Answer: A. ER+ / HER2 neu- ; mild to moderate proliferation

Explanation: Luminal type A tumours refer to a subtype of breast cancer with ER-positive, HER2 neu negative and mild to moderate proliferation. These tumours tend to grow slowly and have a better prognosis compared to other

subtypes. Molecular classification of breast cancer is based on the results of receptor status such as ER, PR and HER2. Molecular classification of breast cancer Classification Hormone receptor HER2/Neu Others Luminal A Positive (either or both ER/PR) Negative Ki-67 low (mild to moderate proliferation) Luminal B (Options A & D ruled out) Positive (either or both ER/PR) Negative/ positive Ki-67 high (high proliferation) Basal type (triple -ve) (Option C ruled out) Negative Negative Ki-67 usually high HER2/neu enriched Negative Positive Ki-67 high Claudin low Negative Negative Claudin low

@Neet_pg_bot

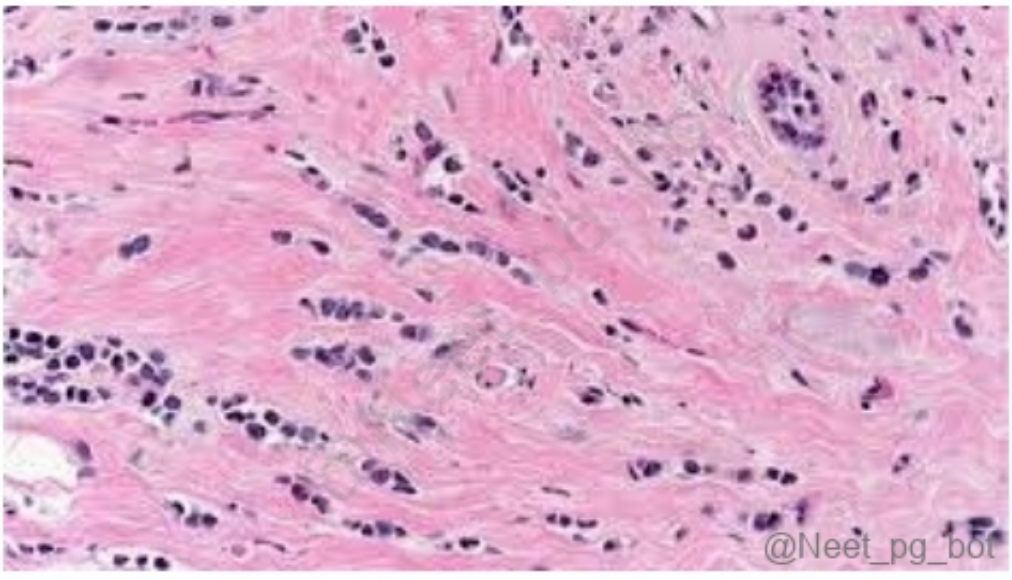
Q3: A woman presents with a firm and irregular lump in the upper outer quadrant of her breast. The histopathological slide of the mass sample is provided. What is the most likely diagnosis? f (Q830822)

A. Phyllodes tumor

B. Inflammatory breast carcinoma

C. Invasive lobular carcinoma

D. Fibroadenoma



Correct Answer: C. Invasive lobular carcinoma

Explanation: Correct Option C - Invasive lobular carcinoma: Invasive lobular carcinoma originates from the terminal duct lobular units and develops only in the female breast. It is mostly multicentric and bilateral Increased risk of cancer is in both breasts Calcifications associated with Invasive lobular carcinoma typically occur in adjacent tissues (neighborhood calcification) The histologic hallmark of Invasive lobular carcinoma is the tendency of tumor cells to invade in linear strands (Indian file pattern) Incorrect Options: Option A - Phyllodes tumor: It is mostly a benign tumor. It is characterized by Leaf-like (phyllode) epithelial pattern formed by an exaggerated intracanalicular pattern. Option B - Inflammatory breast carcinoma: It causes skin changes in the involved breast. It presents as a red and swollen breast, mimics mastitis. It is characterized by dermal lymphatic invasion by tumor cells on a skin punch biopsy of the affected breast. Option D - Fibroadenoma: It usually occurs in young women and regresses after menopause. The tumor consists of proliferating epithelial and mesenchymal components. Stroma proliferates around tubular ducts (pericanalicular pattern) or compressed cleft-like ducts (Intracanalicular pattern).

@Neet_pg_bot

Q4: Which of the following is NOT a favorable prognostic marker for a middle-aged woman diagnosed with breast carcinoma presenting with a lump in her right breast? (Q793798)

A. Luminal subtype

B. Low Ki67 /MIB 1 index

C. Her2 overexpression

D. Mucinous carcinoma

Correct Answer: C. Her2 overexpression

Explanation: HER2 overexpression is a biological phenomenon that occurs when there is an excessive expression of the human epidermal growth factor receptor 2 (HER2) protein on the surface of a cell. HER2 is a type of receptor that is involved in the regulation of cell growth and division. It is overexpressed in approximately 15-30% of breast cancer cases, as well as in other types of cancer. Incorrect choices: Option a. The Luminal subtype is a molecular classification of breast cancer, which is determined based on the genes expressed by the cancer cells. This subtype is defined by the presence of hormone receptors - estrogen receptors (ER) and/or progesterone receptors (PR). The Luminal subtype is further divided into two subtypes: Luminal A and Luminal B. Option b. Ki-67 is a protein that is associated with cell proliferation and is often used as a prognostic marker in breast cancer. A higher Ki-67 index is generally associated with a more aggressive form of cancer. Option d. Mucinous carcinoma is a type of cancer that starts in cells that produce mucus, called mucin. It is a relatively rare subtype of invasive cancer and can occur in many different organs or tissues, including the breast, colon, and ovaries. Mucinous carcinoma is defined by the presence of extracellular mucin that fills more than 50% of the tumor volume.

@Neet_pg_bot

Q5: A 35-year-old woman presents with a lump in the upper outer quadrant of her breast. Histopathological examination of the mass shows cells in mucin pools and faint nuclei. What is the most likely diagnosis? (Q858517)

A. Colloid carcinoma

B. Papillary carcinoma

C. Medullary carcinoma

D. Lobular carcinoma

Correct Answer: A. Colloid carcinoma

Explanation: Colloid carcinoma , also known as mucinous carcinoma , is characterised by malignant cells surrounded by mucin pools. Mucinous or Colloid Carcinoma: A subtype of infiltrating ductal carcinoma. Location: Upper outer quadrant (most common). Clinical findings: Soft to firm lump due to mucilage. It may be mistaken for a benign tumour. Histopathology: Gross: Soft, rubbery texture with pale gelatinous/jelly consistency. Microscopy: Tumour cells arranged in clusters or islands with pools of mucin extracellularly and may be intracellularly (called signet ring cell). FNAC: Chicken wire blood vessels. {{caption_text}} Gross pathology (upper left) of biopsies of

mucinous carcinoma shows gelatinous areas (which are transparent compared to normal yellow fatty tissue). Histopathology shows clusters or nests of tumour cells floating in pools of extracellular mucin. Excellent prognosis. Papillary carcinoma (Option B) is defined by the presence of papillary structures within the tumor. The tumour cells typically show elongated nuclei with nuclear grooves and intranuclear pseudo inclusions, which are distinct features not seen in colloid carcinoma. {{caption_text}} Medullary carcinoma (Option C) is a type of invasive breast carcinoma that presents with sheets of poorly differentiated tumour cells. These cells have large, pleomorphic nuclei and prominent nucleoli, which is different from the mucin-filled appearance in colloid carcinoma. {{caption_text}} Lobular carcinoma (Option D) originates from the lobular units of the breast and is characterised by tumour cells infiltrating in a single-file pattern, known as the Indian file pattern. The cells may exhibit signet ring morphology but do not form mucin pools, as seen in colloid carcinoma.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 1053-1058

↑ *Back to this question in Part A*

Q6: A 35-year-old female presents with a lump in the upper outer part of her breast. Histopathological analysis of the mass reveals a signet ring appearance. What is the probable diagnosis? (Q857606)

A. Colloid carcinoma

B. Papillary carcinoma

C. Medullary carcinoma

D. Phyllodes tumour

Correct Answer: A. Colloid carcinoma

Explanation: Colloid carcinoma, or mucinous carcinoma, is characterised by extracellular mucin and signet ring cells, where mucin pushes the nucleus to one side, creating a ring-like appearance. This carcinoma typically occurs in older women and presents as a soft, mobile mass. Mucinous or Colloid Carcinoma: A subtype of infiltrating ductal carcinoma. Location: Upper outer quadrant (most common). Clinical findings: Soft to firm lump due to mucilage. It may be mistaken for a benign tumour. Histopathology: Gross: Soft, rubbery texture with pale gelatinous/jelly consistency. Microscopy: Tumour cells arranged in clusters or islands with pools of mucin extracellularly and may be intracellularly (called signet ring cell). FNAC: Chicken wire blood vessels. Excellent prognosis. {{caption_text}} Source: Gross pathology (upper left) of biopsies of mucinous carcinoma shows gelatinous areas (which are transparent compared to normal yellow fatty tissue). Histopathology shows clusters or nests of tumour cells floating in pools of extracellular mucin. Papillary carcinoma (Option B) of the breast accounts for about 0.5% of all breast cancers, primarily affecting postmenopausal women aged 60 to 80. It generally has a favorable prognosis. Clinically, it may be asymptomatic or present with bloody nipple discharge or a palpable mass. On mammography, it appears as a high-density mass with circumscribed margins, sometimes accompanied by satellite nodules, microcalcifications, or a dilated ductal pattern. {{caption_text}} Medullary carcinoma (Option C) of the breast is typically well-circumscribed, moderately firm, and has a fleshy grey-tan cut surface, often appearing lobular or nodular with areas of haemorrhage, necrosis, or cystic degeneration. Tumours are usually smaller than 3 cm, with a median size of 2 to 3 cm. Patients commonly present with a palpable mass in the upper outer quadrant, which is well-defined clinically and on imaging. Axillary lymphadenopathy may also be present, indicating potential metastatic involvement. {{caption_text}} Phyllodes tumour (Option D) is a rare fibroepithelial neoplasm with a spectrum from benign to malignant, classified by the WHO based on nuclear atypia, stromal cellularity, mitotic activity, tumour margins, and stromal overgrowth. These tumours typically present as nodular masses with clear boundaries, although some may be ill-defined due to surrounding tissue invasion. The tumour is lobulated, solid, and firm, with a grey or grey-yellow colour, often containing narrow gaps or cavities filled with a clear, bloody, or jelly-like fluid. {{caption_text}}

Q1: Q1. A 40-year-old woman presents with headache and undergoes evaluation for a brain tumor/ cerebellopontine angle. Histopathological examination reveals a tumor composed of Antoni A and Antoni B areas. Which of the following is the most sensitive immunohistochemical marker for this tumor? (Q882188)

A. S-100 protein

B. Glial fibrillary acidic protein (GFAP)

C. Epithelial membrane antigen (EMA)

D. c-KIT

Correct Answer: A. S-100 protein

Explanation: Correct Option : A. Schwannomas characteristically show Antoni A (hypercellular) and Antoni B (hypocellular) areas on histology. These tumors arise from Schwann cells , which show strong and diffuse positivity for S-100 protein , making it the most sensitive immunohistochemical marker . Cerebellopontine angle location further supports this diagnosis. Incorrect Options: Opiton B: Glial fibrillary acidic protein (GFAP) GFAP is a marker of astrocytic and glial tumors, such as astrocytomas and glioblastomas, not Schwann cell tumors. Option C: Epithelial membrane antigen (EMA) EMA is typically positive in meningiomas, which can also occur at the cerebellopontine angle but lack Antoni A and B areas. Option D: c-KIT c-KIT (CD117) is commonly associated with gastrointestinal stromal tumors (GISTs) and some hematologic malignancies, not schwannomas.

@Neet_pg_bot

Q3: Which genetic mutation is associated with multiple bilateral renal cysts and cerebellar hemangioblastomas and a family history of renal cell carcinoma? (Q845175)

A. VHL gene mutation

B. TSC 1 gene mutation

C. APC gene mutation

D. PTCH gene mutation

Correct Answer: A. VHL gene mutation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Syndromes associated with CNS tumours : Syndrome Mutation CNS manifestation Von-Hippel Lindau (VHL) (Option A) VHL gene mutation on chromosome 3. Autosomal dominant disease. Hemangioblastomas of the CNS (cerebellum and retina) Cysts of the pancreas, liver, and kidneys Renal cell carcinomas Pheochromocytomas. Tuberous sclerosis (Option B) TSC1 (Hamartin) and TSC2 (Tuberin) gene mutations. Autosomal dominant disease. Brain-Subependymal nodules, cortical tubers, subependymal giant cell astrocytoma. Skin- Ash-leaf macules, Shagreen patches Renal-angiomyolipoma Heart-rhabdomyoma Lung-Lymphangioleiomyomatosis Turcot syndrome (Option C) APC gene mutation Medulloblastoma FAP Gorlin syndrome (Option D) Autosomal dominant disorder. PTCH gene mutation. Multiple basal cell carcinomas Medulloblastomas Ovarian fibromas Odontogenic keratocysts Neurofibromatosis Type I (NF-I) NF1 gene (Neurofibromin) on chromosome 17. Autosomal dominant. Skin: Café-au-lait spots, Lisch nodules (iris hamartomas), Neurofibromas. CNS: Optic pathway gliomas. Skeletal: Sphenoid dysplasia, pseudoarthrosis. Neurofibromatosis Type II (NF-II) NF2 gene (Merlin) on chromosome 22. Autosomal dominant. Classic: Bilateral vestibular schwannomas ("acoustic neuromas"). CNS: Multiple meningiomas, ependymomas. Eyes: Juvenile posterior subcapsular lenticular opacities. Cowden Syndrome PTEN gene mutation. Autosomal dominant. Skin: Trichilemmomas, papillomatous papules. Organs: High risk of Breast, Thyroid (follicular), and Endometrial cancers. CNS: Lhermitte-Duclos disease (dysplastic cerebellar gangliocytoma). Li-Fraumeni Syndrome TP53 gene mutation. Autosomal dominant. SBLA Syndrome: Sarcomas, Breast cancer, Leukemia, Adrenal cortical carcinoma. Early onset of various malignancies. Constitutional Mismatch Repair Deficiency (CMMRD) Biallelic MSH6/MLH1/PMS2/MSH2 ■ High-grade gliomas, medulloblastomas, supratentorial PNETs ■ Rhabdoid Tumor Predisposition SMARCB1/SMARCA4 (SWI/SNF chromatin remodeling, AD) ■ Atypical teratoid/rhabdoid tumors (ATRT)

@Neet_pg_bot

Q4: Which of the following is true regarding primary CNS lymphoma? (Q845174)

A. Caused by EB Virus (EBV)

B. Caused by underexpression of PDL1 gene

C. Leptomeningeal spread is common

D. Typically arises from meningeal layers.

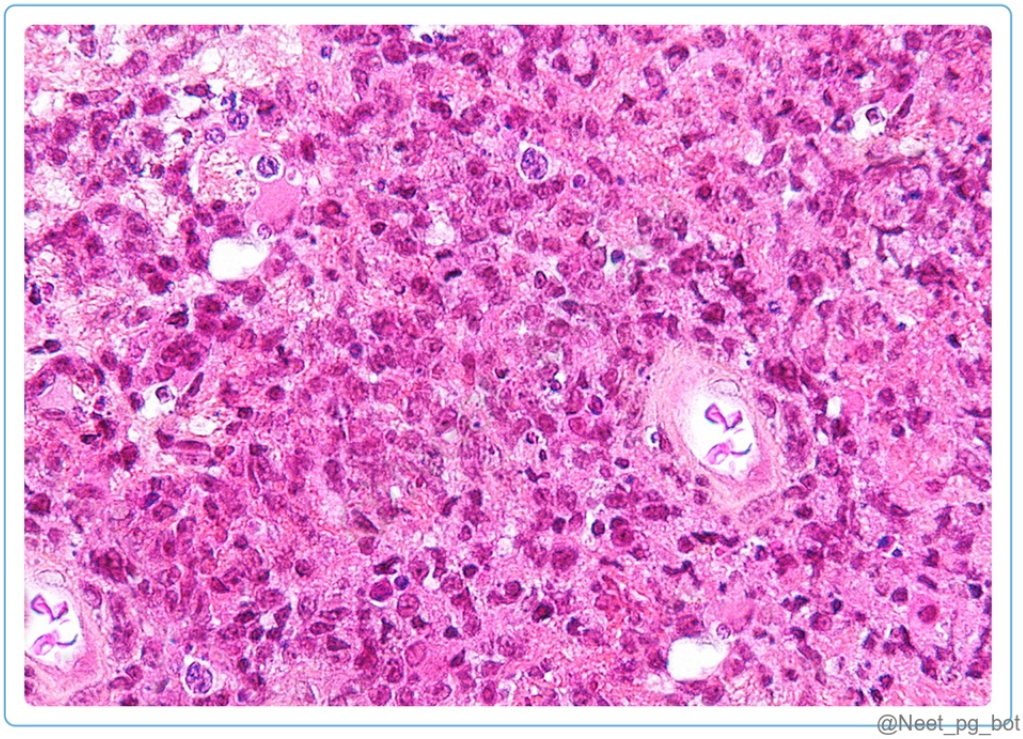
Correct Answer: A. Caused by EB Virus (EBV)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Primary CNS lymphoma It is caused by the Epstein-Barr virus in immunosuppressed cases and PDL1 gene overexpression in others. These diffuse large B-cell lymphomas present as multiple, aggressive, grey-white

masses in deep brain regions, often spreading in the periventricular areas . The cells are angiocentric and have areas of necrosis, expressing CD20. {{caption_text}} Primary CNS lymphoma where the malignant B cells show angiocentric hooping patterns.



References:

Robbin's and Cotran Pathologic Basis of Disease, 10th Edition, Pages 1299, 1300, 1237, 1296.

↑ *Back to this question in Part A*

@Neet_pg_bot

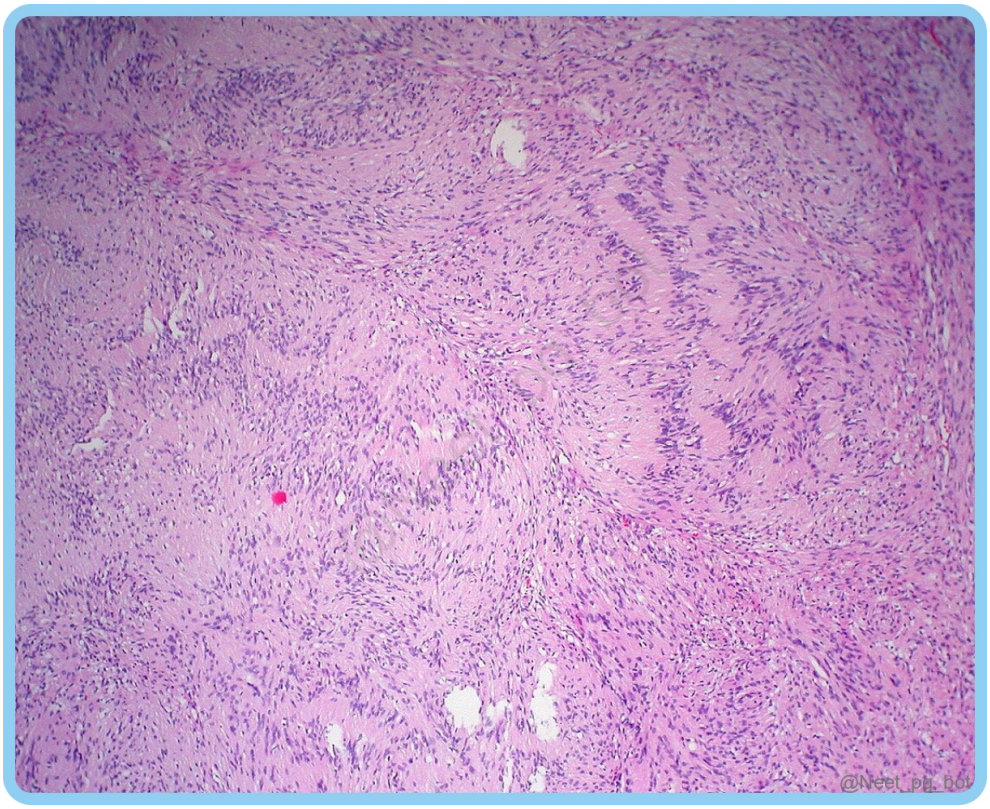
Q5: A 45-year-old woman with right-sided hearing loss, tinnitus, and vertigo has an MRI showing a mass at the right cerebellopontine angle from the vestibulocochlear nerve. Biopsy reveals encapsulated tissue with areas of dense cellularity and loose myxoid regions, as depicted in the image below. Which of the following statements is NOT true regarding this condition? (Q845173)

A. Associated with NF-1 gene mutation

B. Typically exhibit verocay bodies

C. Expresses Merlin

D. Immunoreactivity for S-100



Correct Answer: A. Associated with NF-1 gene mutation

- *Listen (English)*
- *Listen (Hindi)*

Explanation: NF1 (Neurofibromatosis type 1) Gene: NF1 gene on chromosome 17 Protein: Neurofibromin (tumor suppressor) Features: Multiple café-au-lait spots Cutaneous neurofibromas Lisch nodules (iris hamartomas) Optic gliomas Diagnostic Criteria (NIH, ≥2 required): ≥6 café-au-lait macules (>5 mm prepubertal). ≥2 neurofibromas or 1 plexiform neurofibroma. Axillary/inguinal freckling. Optic pathway glioma. ≥2 Lisch nodules (iris hamartomas). Distinctive bony lesion (sphenoid dysplasia, tibial pseudarthrosis). 1st-degree relative with NF1. Complications : Scoliosis, learning disability, hypertension (pheo/renal artery stenosis), MPNST (malignant transformation). Management : Annual ophthalmic exam, whole-body MRI for plexiform Nfs, MEK inhibitors (selumetinib) for inoperable plexiforms. NF2 (Neurofibromatosis type 2) Gene: NF2 gene on chromosome 22 Protein: Merlin (schwannomin) Inheritance : Autosomal Dominant Features: Bilateral vestibular (acoustic) schwannomas – 8th cranial nerve Meningiomas, ependymomas Diagnostic Criteria (Manchester): Bilateral vestibular schwannomas (classic), OR 1st-degree relative + unilateral VS, OR ≥2 meningiomas, OR ≥1 glioma/schwannoma/ependymoma, OR ≥2 CNS meningiomas. Histology : S100+ (neural crest marker); NF2 schwannomas show dense vs loose hypocellular areas (Antoni A/B). Complications : Hearing loss, balance issues, cataracts (juvenile posterior subcapsular), young age at tumor onset. Management : Serial MRI brain/spine, auditory evoked potentials, bevacizumab or HSCT for tumor control. Histology & IHC of Schwannoma Antoni A and B areas : dense cellular vs loose hypocellular regions Verocay bodies : parallel rows of palisaded nuclei with fibrillary processes between → characteristic of schwannoma S100 positivity : marker of neural crest origin (seen in schwannomas & neurofibromas

↑ *Back to this question in Part A*

@Neet_pg_bot

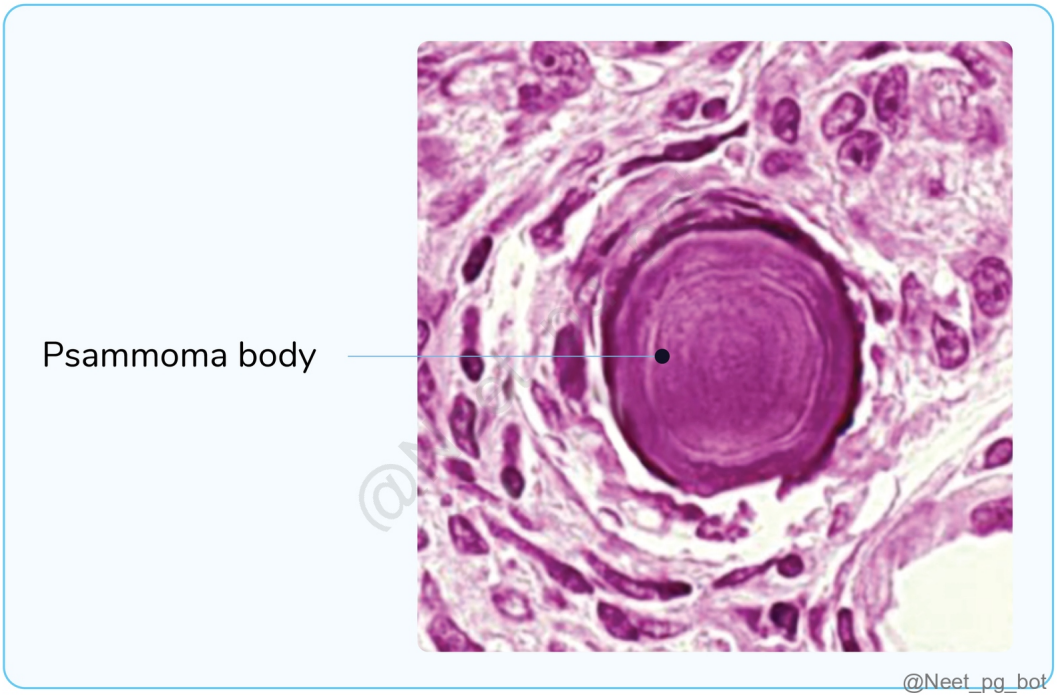
Q6: A 35-year-old female presents with persistent headaches and weakness in her right upper limbs. Imaging reveals a brain tumor that is PR+. Biopsy reveals psammoma bodies with necrosis, cellular atypia, mitosis >4/hpf, and invasion of brain parenchyma. What is the most likely diagnosis? {{caption_text}} (Q845172)

A. Typical meningioma

B. Atypical meningioma

C. Anaplastic meningioma

D. Papillary meningioma



Correct Answer: B. Atypical meningioma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and biopsy features suggest Atypical meningiomas characterized by the presence of psammoma bodies with areas of necrosis, cellular atypia, mitosis >4/hpf, and invasion of brain parenchyma. They arise from the meningothelial cells of the arachnoid and are attached to the dura. These PR+ tumors of adults are locally aggressive and are associated with higher recurrence rates. They are distinguished from lower-grade meningiomas by having Increased mitotic index (>4/hpf and <20/hpf) Brain invasion Cellular atypia Areas of necrosis Prominent nucleoli High N: C ratio Disorganised growth Typical Meningioma (Option A): A typical meningioma is characterized by slow growth, well-defined borders, and low mitotic activity. It is a benign dural masses that compress the underlying brain but are easily separated from it. They are PR+, non-aggressive, and do not invade the underlying brain parenchyma. Anaplastic meningioma (Option C): Anaplastic meningioma is a highly aggressive malignant tumor that often resembles a carcinoma or sarcoma. It's Mitotic index is >20/hpf. Papillary meningioma (Option D): Papillary meningioma is a variant of anaplastic meningioma and is also highly aggressive with a mitotic index of >20/hpf.

@Neet_pg_bot

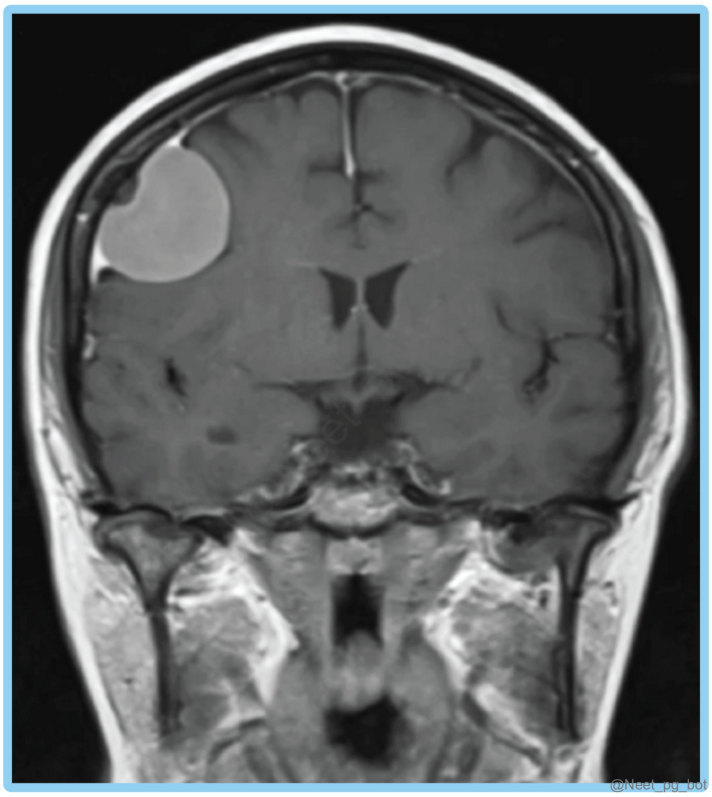
Q7: A 28-year-old gravid woman comes to the ODP due to a severe headache that started during her pregnancy. Investigations reveal the following. Which of the following statements is not true for the above condition? {{caption_text}} (Q845171)

A. Progesterone receptor-positive

B. Risk factors include exposure to radiation

C. Associated with NF2 gene mutation

D. HPE shows perivascular pseudorosettes



Correct Answer: D. HPE shows perivascular pseudorosettes

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Perivascular pseudo-rosette is seen in Ependymomas. The clinical presentation suggests Meningiomas, which are mostly benign tumors found in adults. They originate from meningothelial cells of the arachnoid layer and are typically connected to the dura mater. More common in women and has increased risk with pregnancy, exposure to radiation (Option B) , and NF2 gene mutation (Option C) . Tumors typically exhibit a rubbery dural mass, compressing the brain, yet easily separable. Histopathologically, they present with a whorled pattern of cells and psammoma bodies and are progesterone receptor-positive (Option A) . {{caption_text}} {{caption_text}}

@Neet_pg_bot

Correct Answer: B. 1- A, 2-C, 3-B, 4-E, 5-D

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Cells of the central nervous system Glial cells: Astrocytes Oligodendrocytes Ependymal cells Star-shaped cells. Immunohistochemistry stain: Glial Fibrillary Acidic Protein (GFAP) marker. Functions: Formation of the blood-brain barrier, structural support, and repair mechanism. Types: Fibrous astrocytes: Found in white matter and contain intermediate filaments. (A) Protoplasmic astrocytes: Found in grey matter and have granular cytoplasm. Maintain appropriate concentration of ions and neurotransmitters. (E) Form myelin on neighboring axons. Helps in the fast conduction of impulses in the CNS. (B) Associated diseases: Guillain–Barré syndrome. Multiple sclerosis. Charcot-MarieTooth disease. Myelin stain: Luxol fast blue. Present in ventricles of the brain. Production and circulation of CSF. (C) Astrocytes and their cell processes around capillaries (brown). {{caption_text}} Microglia: Scavenger cells arise from macrophages outside the nervous system. (D)

Ganong’s Review of Medical Physiology, 26th Edition, Pages 92-94

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 10-year-old child presents with a history of headaches and balance difficulties over the past few months. Histopathological examination of the biopsy shows bipolar cells with long, thin hairlike processes, dense fibrillary meshwork, and characteristic eosinophilic corkscrew-shaped inclusions. Which inclusion bodies are involved in this type of tumor? (Q845167)

A. Rosenthal fibers

B. Glomeruloid bodies

C. Negri bodies

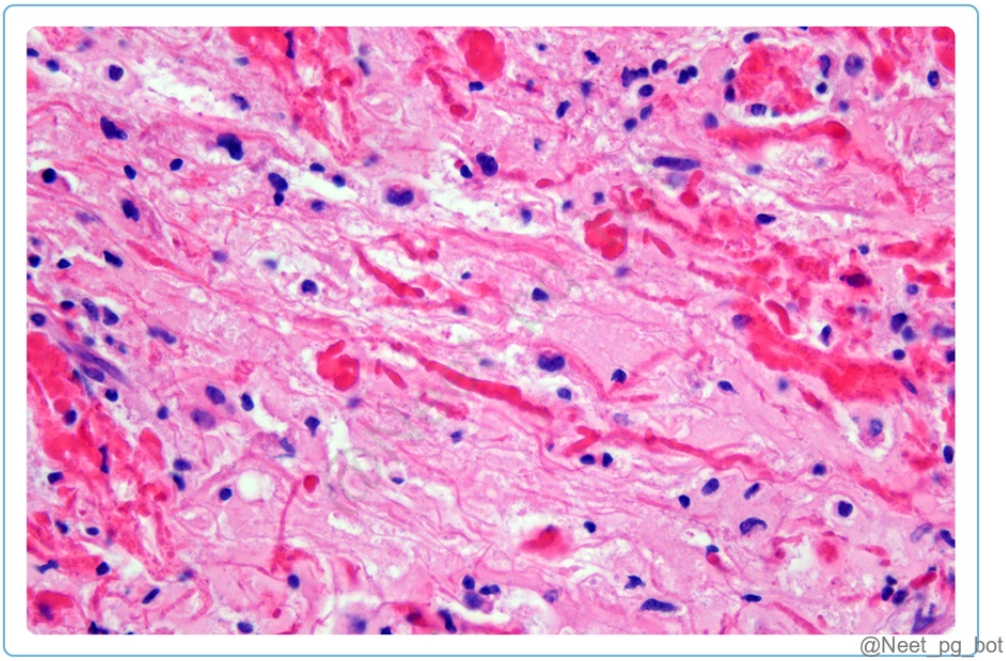
D. Lewy bodies

Correct Answer: A. Rosenthal fibers

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical scenario and histopathological findings point towards diagnosing Pilocytic astrocytoma, low-grade brain tumors commonly found in children and young adults. They are characterized by their slow growth and relatively benign behavior. The histopathology shows bipolar cells with elongated processes and characteristic eosinophilic inclusions like Rosenthal fibers and mulberry bodies (eosinophilic granular bodies) These tumors are often well-demarcated and cystic , with a contrast-enhancing mural nodule seen on imaging. {{caption_text}} Glomeruloid bodies (Option B) : Glomeruloid bodies are a characteristic feature of Glioblastoma multiforme (GBM). Negri bodies (Option C) : Negri bodies are eosinophilic, inclusion bodies typically found in neurons infected with the rabies virus Lewy bodies (Option D): Lewy bodies are eosinophilic cytoplasmic inclusions composed primarily of alpha-synuclein protein. They are characteristic pathological features of Parkinson's disease.



References:

Robbin’s and Cotran Pathologic Basis of Disease, 10th edition, Page 1296

@Neet_pg_bot

Q12: According to the Anne Mayo grading system, what grade would be assigned to the tumor showing hypercellularity, nuclear atypia, and mitotic activity but no evidence of microvascular proliferation or necrosis? (Q845166)

A. Grade 1

B. Grade 2

C. Grade 3

D. Grade 4

Correct Answer: C. Grade 3

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The St. Anne-Mayo grading system is a 4 tiered system and uses the presence of 4 morphologic criteria (AMEN) to assign a grade: Nuclear A typia M itosis E ndothelial proliferation - 'piled-up' endothelial cells. (NOT hypervascularity) N ecrosis The grade then depends on the accumulation of these criteria as follows: Grade 1 (Good prognosis): No AMEN Grade 2: Only atypia Grade 3: Atypia and mitosis Grade 4 (Poor prognosis): Atypia, mitosis, endothelial proliferation ± Necrosis Grade Tumor Types Characteristics Low grade Grade I Craniopharyngioma Chordomas Ganglioma Gangliocytoma Pilocytic astrocytoma Possibly curable via surgery alone Long-term survival Least malignant (benign) Non-infiltrative Grade II Pineocytoma "Diffuse" astrocytoma Pure oligodendroglioma Slight infiltrative Relatively slow-growing Can recur as a higher grade High grade Grade III Anaplastic ependymoma Anaplastic astrocytoma Anaplastic oligodendroglioma Malignant Infiltrative Tend to recur as higher grade. Grade IV Glioblastoma multiforme (GBM) Medulloblastoma Ependymoblastoma Pineoblastoma Most malignant Rapidly growing and aggressive Widely infiltrative Recurrence Tendency for necrosis

@Neet_pg_bot

Q15: Which of the following features are not seen in Alzheimer’s Disease? (Q845163)

A. Bunina bodies

B. Neuritic plaques

C. Neurofibrillary tangles

D. Hirano bodies

Correct Answer: A. Bunina bodies

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Bunina bodies are seen in amyotrophic lateral sclerosis (ALS). They are PAS-positive cytoplasmic inclusions , which appear to be remnants of autophagic vacuoles . They contain two proteins, cystatin, and transferrin , and are considered a hallmark of ALS. Histology of Alzheimer’s disease: Plaques Deposits of Aβ peptides in the neuropil. Neuritic plaques contain both Aβ 40 and Aβ 42. Tangles Aggregates of the microtubule-binding protein tau. Demonstrated by silver (Bielschowsky) staining. Hirano bodies Composed of Actin (intracellular inclusions) Granulovacuolar degeneration Formation of small, clear vacuoles within the neurons. {{caption_text}} Plaques {{caption_text}} Neurofibrillary tangles {{caption_text}} Hirano bodies {{caption_text}} Granulovacuolar degeneration

Robbin’s and Cotran Pathologic Basis of Disease, 10th Edition, Page 1278

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: Which of the following statements about Alzheimer’s Disease is/are correct? 1) Due to the mutation of the APP gene on Chromosome 21 2) Alpha and Gama secretase pathways are involved 3) APOE2 is a risk factor 4) Affects the frontal, parietal, and temporal lobes. (Q845162)

A. 2,3

B. 2,4

C. 1,3

D. 1,4

Correct Answer: D. 1,4

Explanation: Alzheimer's disease is a progressive neurological disorder causing memory loss, cognitive decline, and personality changes. Alzheimer's Disease is the most common cause of dementia in the elderly. It affects the frontal, parietal, and temporal lobes (Statement 4). It occurs due to the mutation of the APP gene on Chromosome 21 (Statement 1). If APP is processed by alpha and gamma-secretase pathways, products are soluble and do not deposit in the brain, and there is no disease. (Statement 2). If the beta-secretase pathway processes APP, it produces amyloid products, which are pathogenic. APOE2 is considered a protective factor for Alzheimer's Disease (Statement 3). Genetics of Alzheimer's Disease: Gene Chromosome Features APP 21 Trisomy 21 (Down's syndrome): ↑ APP → Presenile Alzheimer's disease Presenilin 1 14 γ-secretase complex generates increased amounts of Aβ, particularly Aβ42. Presenilin 2 1 APOE4 19 Early-onset Alzheimer's disease.

@Neet_pg_bot

Q17: A 65-year-old male presents with a 6-month history of resting tremor in his right hand, which improves with movement. He reports increasing slowness in daily activities and stiffness, particularly in the morning. He has had occasional falls due to unsteadiness while walking. Physical examination reveals a shuffling gait and cogwheel rigidity. All of the following are true statements regarding this condition except? (Q845161)

A. A key pathological feature in the substantia nigra neurons is observed.

B. This condition can occur due to mitochondrial dysfunction.

C. Mutations in LRRK2 are the most common cause of autosomal dominant disease.

D. Homozygous mutation of glucocerebrosidase is an important risk factor for this condition.

Correct Answer: D. Homozygous mutation of glucocerebrosidase is an important risk factor for this condition.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical vignette of resting tremors, early morning stiffness, unsteadiness, shuffling gait, and cogwheel rigidity is suggestive of Parkinson's disease. Homozygous mutations in glucocerebrosidase cause Gaucher's disease , a lysosomal storage disorder. Parkinson's Disease (PD): Autosomal dominant PD is SNCA , a gene that encodes α-synuclein . This protein is a major component of the Lewy body, which is the diagnostic hallmark of PD. Autosomal recessive forms of PD, are caused by gene mutations that encode the proteins DJ-1, PINK1, and parkin (Option B) . Mutations in the gene encoding LRRK2 (leucine-rich repeat kinase 2) are the most common cause of autosomal dominant PD (Option C) . Clinical Features: Triad of tremor, rigidity, and

bradykinesia. Morphology: A characteristic gross finding in PD is pallor of the substantia nigra Lewy bodies are usually single or multiple, cytoplasmic, eosinophilic, round to elongated inclusions. They have a dense core surrounded by a pale halo. Ultrastructurally, they are composed of fine filaments (composed of α-synuclein) {{caption_text}}

Robbin's and Cotran Pathologic Basis of Disease, 10th Edition, Pages 1282-1283

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 55-year-old male presented with behavioral changes and involuntary movements over the past several weeks. Neurological examination revealed ataxia and myoclonus. He passed away after 4 months, and biopsy findings of the brain tissue are shown below. Based on these findings, which of the following statements is false regarding this condition? Proteinaceous particles with single-stranded RNA cause it. It results from the misfolding of PrPsc to PrPc. Spongiform transformation is a characteristic histopathological feature It is associated with a good prognosis if diagnosed early. Familial forms are associated with specific genetic mutations.

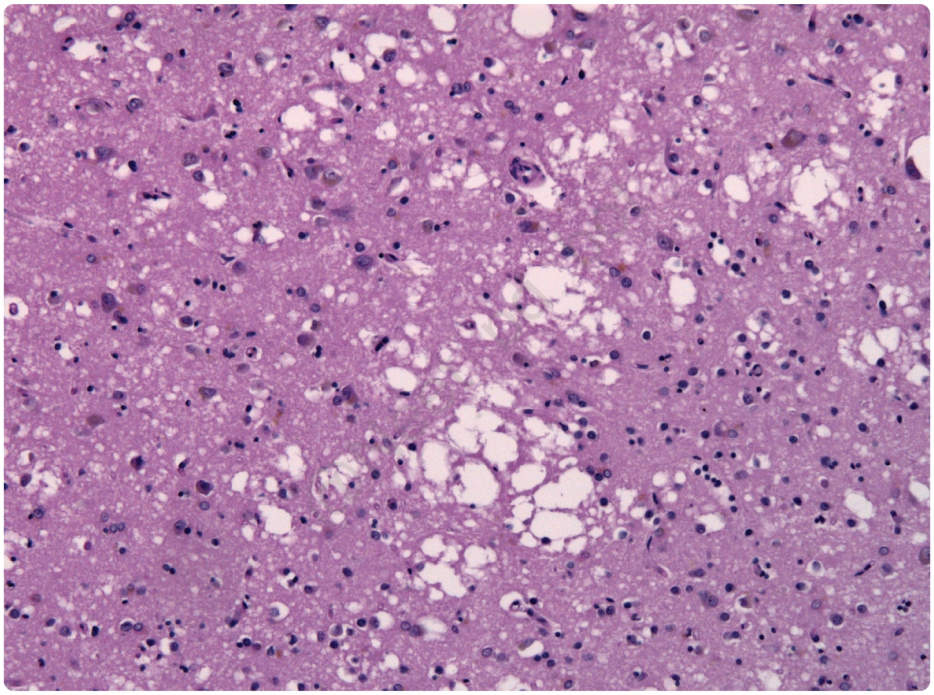
(Q845160)

A. 1, 2 and 4

B. 1, and 4

C. 2 and 4

D. 3, 4 and 5



Correct Answer: A. 1, 2 and 4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The most likely diagnosis in this clinical presentation is Creutzfeldt-Jakob disease (CJD), a prion disease. Prion Disease or Transmissible Spongiform Encephalopathy (TSE): Prions are proteinaceous infectious particles with no RNA/DNA . Pathogenesis: Misfolding of normal prion protein (PrPc) to form beta-pleated configuration (PrPSc). Common Symptoms: ■■■■■■■ Rapidly progressing dementia (memory loss, confusion). Ataxia (difficulty walking and loss of balance). Myoclonus (sudden, involuntary muscle jerks). Insomnia (specifically severe in the Fatal Familial Insomnia variant). Mood changes (depression, anxiety, or personality shifts). Histopathology: Spongiform vacuolisation inside the cell. Diagnosis: DWI (Diffusion-Weighted Imaging): Most sensitive sequence for early diagnosis. It identifies restricted diffusion as bright hyperintense signals. ADC Map (Apparent Diffusion Coefficient): Used to confirm "true" restricted diffusion. Affected areas in prion disease typically appear dark (hypointense) on the ADC map. FLAIR (Fluid-Attenuated Inversion Recovery): Shows hyperintensities in similar regions as DWI but is generally less

sensitive in the earliest stages. T1-weighted MRI: Usually appears normal or shows non-specific brain shrinkage (atrophy) as the disease reaches the end stage. Types of prion disease 1. Creutzfeldt-Jakob disease (M/C) Genetic: Familial form caused by PRNP mutation. Transmission: Iatrogenic Symptoms: Dementia. Associated pronounced involuntary jerking muscle contractions on sudden stimulation (startle myoclonus) and cerebellar dysfunction (ataxia). Histopathogenesis: Spongiform transformation of the cerebral cortex. Prognosis: Uniformly fatal with average survival < 7 months after the onset of symptoms. 2. Kuru disease PAS & Congo: red positive. Kuru plaques: Extracellular aggregated abnormal PrP. 3. Fatal familial insomnia 4. Bovine spongiform encephalopathy Comparison of radiological findings in different types of prions diseases: Feature Sporadic CJD (sCJD) Variant CJD (vCJD) Genetic Forms (FFI/GSS) Primary Location Cortex and Basal Ganglia Thalamus (Pulvinar/Dorsomedial) Thalamic atrophy (FFI); variable cortical/limbic signs Key Sign Cortical Ribboning Pulvinar/Hockey Stick Sign Thalamic degeneration DWI vs. FLAIR DWI > FLAIR FLAIR is highly sensitive Routine MRI is often normal

Q1: A 40-year-old female presents with frequent headaches. The investigation reveals raised intracranial pressure and the presence of a dural-based tumour. Which of the following histological findings correlates with the diagnosis? (Q858139)

A. Fried-egg appearance

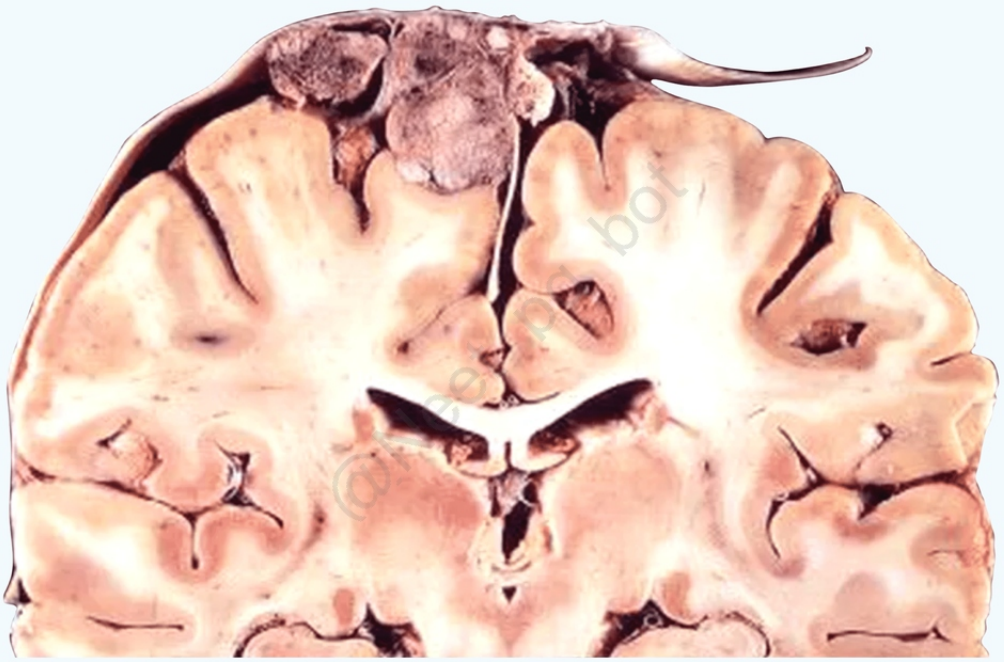
B. Flexner-Wintersteiner rosettes

C. Psammoma bodies with whorling of tumor cells

D. Homer-Wright rosettes

Correct Answer: C. Psammoma bodies with whorling of tumor cells

Explanation: The patient’s presentation of a dural-based tumour with raised intracranial pressure suggests a diagnosis of meningioma, and the histological feature of psammoma bodies with whorling of tumour cells is a characteristic finding. They originate from meningothelial cells of the arachnoid layer and are typically connected to the dura mater. More common in women and has increased risk with pregnancy , exposure to radiation and NF2 gene mutation. Tumours typically exhibit a rubbery dural mass, compressing the brain, yet easily separable. Histopathologically, they present with a whorled pattern of cells and psammoma bodies and are progesterone receptor-positive . {{caption_text}} {{caption_text}} Incorrect Options: Fried-egg appearance (Option A) is characteristic of oligodendrogliomas along with chicken wire vessels, calcification and perineuronal satellitosis. {{caption_text}} Flexner-Wintersteiner rosettes (Option B) are composed of an ‘empty’ lumen surrounded by columnar cells and are seen in retinoblastomas , along with Homer-Wright rosettes , undifferentiated tumour cells and areas of necrosis and calcification. {{caption_text}} Homer-Wright rosettes (Option D) are pseudo-rosettes and consist of cells surrounding a central lumen made up of their processes. They are commonly seen in neuroblastomas.



@Neet_pg_bot

Q2: What is the most common cause of berry aneurysm? (Q859895)

A. Endothelial injury of the vessel due to hypertension

B. Muscle intimal elastic lamina layer defect

C. Muscle and adventitial layer defect

D. Adventitia defect

Correct Answer: B. Muscle intimal elastic lamina layer defect

Explanation: Berry aneurysms , also known as saccular aneurysms or intracranial aneurysms, most commonly occur due to a defect in the muscle intimal elastic lamina layer of the blood vessel wall. This defect weakens the vessel wall, leading to the formation of a small outpouching or sac-like dilation. These aneurysms are frequently found in the arteries at the base of the brain, particularly at the branching points of the major cerebral arteries. Endothelial injury of vessels due to hypertension (Option A): While hypertension can contribute to the development and progression of aneurysms, it is not the most common cause of berry aneurysms. Muscle and adventitial layer defect (Option C) and Adventitia defect (Option D) : Berry aneurysms primarily involve the defect in the muscle intimal elastic lamina layer.

@Neet_pg_bot

Q3: Tau protein inclusions are involved in: (Q859856)

A. Alzheimer’s disease

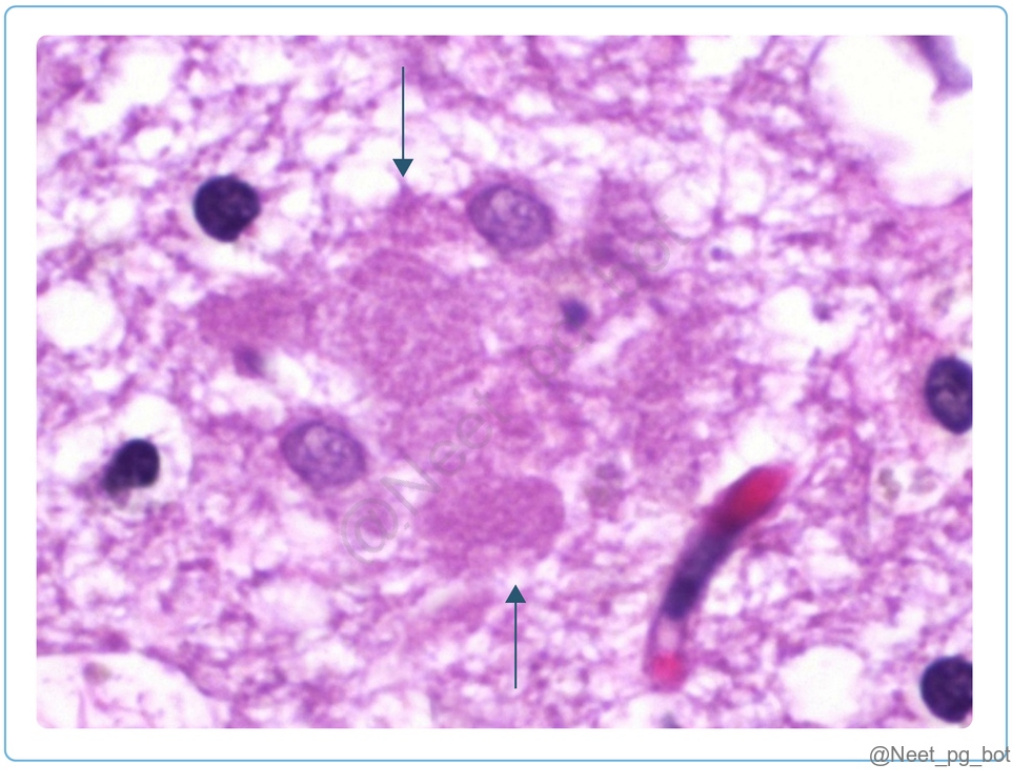
B. Huntington's disease

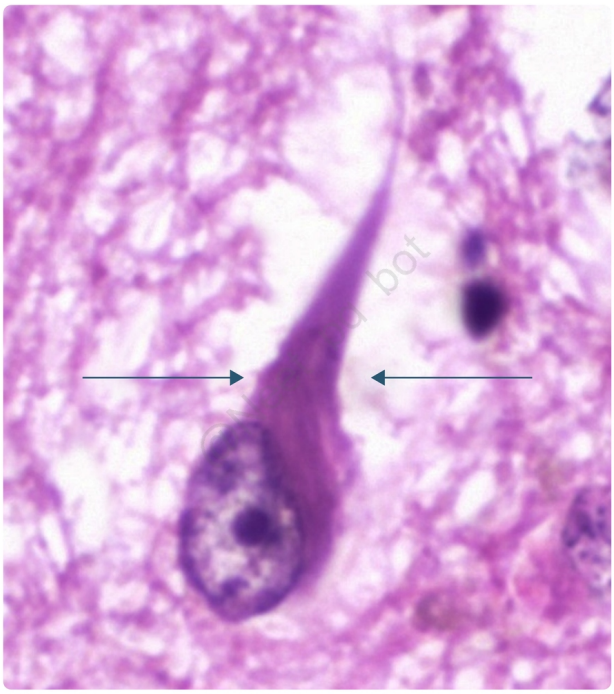
C. Amyotrophic lateral sclerosis

D. CNS lymphoma

Correct Answer: A. Alzheimer’s disease

Explanation: The fundamental abnormality in Alzheimer’s disease is the accumulation of two proteins (Aβ and tau) in specific brain regions in the form of plaques and tangles. Morphology of Alzheimer’s disease: Gross: Cortical atrophy (narrowed gyri and widened sulci) is predominant in the frontal, temporal, and parietal lobes. Histology: Plaques Deposits of Aβ peptides in the neuropil. They are of two types: Diffuse and neuritic (senile). Neuritic plaques contain both Aβ 40 and Aβ 42. Diffuse plaques are predominantly made up of Aβ 42 and seen in trisomy 21 patients. Tangles Aggregates of the microtubule-binding protein tau. Demonstrated by silver (Bielschowsky) staining. Commonly found in cortical neurons, especially in the entorhinal cortex, and in other sites such as pyramidal cells of the hippocampus, amygdala, basal forebrain, and raphe nuclei. Hirano bodies Intracellular eosinophilic inclusions are typically found in conditions like Alzheimer's disease and Creutzfeldt–Jakob disease. Granulovacuolar degeneration Formation of small, clear vacuoles within the neurons. {{caption_text}} Plaques {{caption_text}} Neurofibrillary tangles {{caption_text}} Hirano bodies {{caption_text}} Granulovacuolar degeneration Huntington's Disease (Option B) is characterised by toxic gain-of-function of mutant huntingtin protein and neuronal loss in the striatum. Amyotrophic Lateral Sclerosis (ALS) (Option C) involves the degeneration of motor neurons, often linked to superoxide dismutase 1 (SOD1) mutations or TDP-43 protein inclusions. CNS Lymphoma (Option D) is a type of brain tumour originating from lymphocytes (B cells) and is unrelated to tau protein.





@Neet_pg_bot

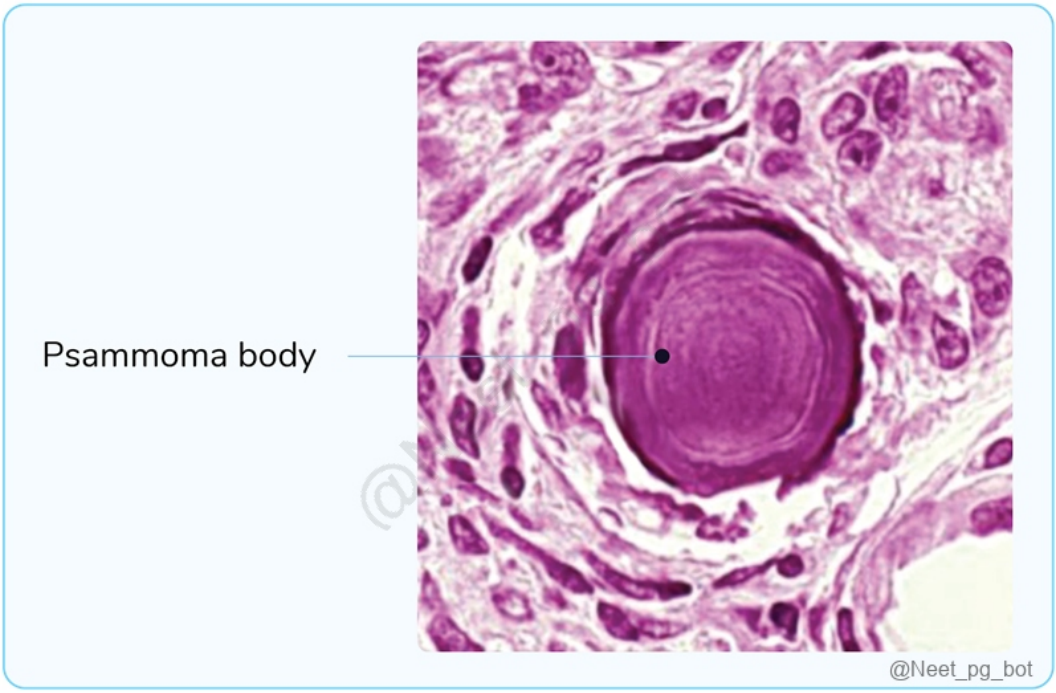
Q4: A 40-year-old female presents with the development of seizures, for which a CT-guided biopsy was done. The histopathological image showed the presence of psammoma bodies. What is the most likely diagnosis? (Q859262)

A. Astrocytoma

B. Medulloblastoma

C. Meningioma

D. Ependymoma



Correct Answer: C. Meningioma

Explanation: Meningiomas are tumours originating from the meninges , the protective membranes covering the brain and spinal cord. They are not derived from glial cells but rather from the arachnoid cap cells of the meninges . Incorrect Options: Astrocytoma (Option A) is a GFAP-positive glial cell tumour and the most common primary brain tumour in children. Histologically, it features densely packed elongated cells with round to oval nuclei and prominent nucleoli. Medulloblastoma (Option B) are embryonal tumours that develop from undifferentiated neuroepithelial cells in the cerebellum . They are not derived from glial cells but instead from primitive neuroectodermal cells . It is the most common malignant tumour in children. Ependymoma (Option D) arises from ependymal cells lining the ventricular system or spinal cord. It is commonly seen in the fourth ventricle in children and in the spinal cord in adults . Histologically, it is characterised by perivascular pseudorosettes , where tumour cells are arranged around blood vessels, and ependymal rosettes , where cells form true rosettes with a central lumen. {{caption_text}}

@Neet_pg_bot

Q5: A 24-year-old patient presented with swelling in the wrist joint. Histopathological examination of the swelling revealed spindle cells with palisading of the nuclei and Verocay bodies. Which of the following is the most likely condition? (Q854862)

A. Schwannoma

B. Neurofibroma

C. Neuroma

D. Glioma

Correct Answer: A. Schwannoma

Explanation: Schwannoma is a benign tumour of the peripheral nerve sheath, characterised by spindle-shaped cells with palisading nuclei and Verocay bodies, which are pathognomonic. Schwannomas are benign tumours originating from Schwann cells, often linked to mutations in the NF2 gene. These tumours are well-circumscribed, encapsulated, and typically attached loosely to nerves, allowing for surgical removal without damaging nerve function. They appear as firm, grey masses. Histology: Antoni A areas : Dense eosinophilic regions with spindle cells in intersecting fascicles. Antoni B areas : Looser, hypocellular regions with a myxoid extracellular matrix. Verocay bodies : Structures with central "nuclear-free zones" surrounded by palisading nuclei. Schwann cells show spindle-shaped nuclei and immunoreactivity for S-100. {{caption_text}} Degenerative changes: Nuclear pleomorphism, xanthomatous change, and necrosis can occur. Malignant transformation is rare, but large mitotically active schwannomas can resemble sarcomas. Other features: Schwannomas may recur if incompletely resected but rarely transform malignantly. They can arise from sensory nerves, including branches of the trigeminal nerve or dorsal roots, and can occur both within and outside the nerve trunk. Surgical removal is typically curative. Neurofibroma (Option B) are benign tumours that develop from peripheral nerves. They are composed of a mix of Schwann cells, fibroblasts, and other cellular components. Histologically, neurofibromas have a more varied appearance than schwannomas, with multiple cell types and no presence of Verocay bodies. Neuroma (Option C) is an abnormal growth of nerve tissue caused by nerve injury or trauma. They are characterised by disorganised nerve fibres and can lead to symptoms such as pain, tingling, and sensory disturbances. Glioma (Option D) are tumours that arise from glial cells in the central nervous system.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: All of the following conditions are related to the same core pathology, except: (Q856486)

A. Parkinson’s disease

B. Alzheimer’s disease

C. Lewy body dementia

D. Multisystem atrophy

Correct Answer: B. Alzheimer’s disease

Explanation: Parkinson's disease, Lewy body dementia, and multisystem atrophy are all associated with alpha-synuclein pathology, specifically the formation of Lewy bodies in the brain. In contrast, Alzheimer's disease

is primarily characterized by the accumulation of amyloid plaques and neurofibrillary tangles of tau protein, representing a different core pathology. Parkinson’s Disease (PD): Genetic Basis: Autosomal Dominant PD: Caused by mutations in SNCA, which encodes α-synuclein, the key component of Lewy bodies. Autosomal Recessive PD: Linked to mutations in DJ-1, PINK1, and Parkin. Most Common Autosomal Dominant Mutation: LRRK2 (Leucine-Rich Repeat Kinase 2). Clinical Features: Triad of Tremor, rigidity, and bradykinesia. Morphology: Gross pathology: Pallor of the substantia nigra due to neuronal loss. Microscopic features: Lewy bodies: Cytoplasmic, eosinophilic inclusions, either single or multiple. Structure: Dense core surrounded by a pale halo. Ultrastructure: Composed of fine filaments of α-synuclein. {{caption_text}} Protein Associated Disease(s) Aβ (Amyloid-beta) Alzheimer disease Tau Alzheimer's disease, Frontotemporal lobar degeneration LRRK2 mutations Parkinson disease α-synuclein Parkinson's disease, Multiple system atrophy TPD-43 Frontotemporal lobar degeneration, Amyotrophic lateral sclerosis FUS Frontotemporal lobar degeneration, Amyotrophic lateral sclerosis Polyglutamine aggregates Huntington's disease, Some forms of spinocerebellar ataxia, Spinal bulbar muscular atrophy Tau (with other symptoms) Progressive supranuclear palsy, Corticobasal degeneration, Chronic traumatic encephalopathy

@Neet_pg_bot

Q7: What is the most common cause of berry aneurysm? (Q857610)

A. Endothelial injury of the vessel due to hypertension

B. Muscle intimal elastic lamina layer defect

C. Muscle and adventitial layer defect

D. Adventitia defect

Correct Answer: B. Muscle intimal elastic lamina layer defect

Explanation: Berry aneurysms , also known as saccular aneurysms or intracranial aneurysms, most commonly occur due to a defect in the muscle intimal elastic lamina layer of the blood vessel wall. This defect weakens the vessel wall, leading to the formation of a small outpouching or sac-like dilation. These aneurysms are frequently found in the arteries at the base of the brain, particularly at the branching points of the major cerebral arteries. Endothelial injury of vessels due to hypertension (Option A): While hypertension can contribute to the development and progression of aneurysms, it is not the most common cause of berry aneurysms. Muscle and adventitial layer defect (Option C) and Adventitia defect (Option D) : Berry aneurysms primarily involve the defect in the muscle intimal elastic lamina layer.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A mutation in the SOD1 gene is most commonly associated with which of the following conditions? (Q866751)

A. Huntington's disease

B. Multiple sclerosis

C. Amyotrophic lateral sclerosis (ALS)

D. Parkinson's disease

Correct Answer: C. Amyotrophic lateral sclerosis (ALS)

Explanation: The SOD1 gene encodes superoxide dismutase 1, an enzyme responsible for breaking down harmful superoxide radicals into oxygen and hydrogen peroxide. This protects cells from oxidative damage. SOD1 and ALS: Condition: Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig’s disease. Type: SOD1 mutations account for about 20% of familial ALS cases (familial ALS ~10% of all ALS cases). Mechanism: Mutant SOD1 misfolds → gains toxic properties → causes oxidative stress and mitochondrial dysfunction. This leads to degeneration of both upper motor neurons (in motor cortex) and lower motor neurons (in brainstem and

spinal cord). Clinical Features of ALS: Mixed UMN and LMN signs: UMN: Spasticity, hyperreflexia, Babinski sign. LMN: Fasciculations, muscle atrophy, weakness. Progressive, usually fatal within 3–5 years (respiratory failure common). Sensation and cognition are usually preserved (helps differentiate from MS or other neuropathies). Huntington's disease (Option A): CAG trinucleotide repeat expansion in the HTT gene (chromosome 4). Multiple sclerosis (Option B): Autoimmune demyelination, not linked to SOD1. Parkinson's disease (Option C): Often linked to mutations in SNCA, LRRK2, PARK genes, not SOD1.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 45-year-old patient presents with severe headaches, seizures, and progressive neurological deficits. Imaging reveals a large mass with areas of necrosis and irregular borders in the brain. The biopsy confirms the diagnosis of a malignant tumor. Which of the following options represents the most common type of brain tumor in adults? (Q820559)

A. Medulloblastoma

B. Meningioma

C. Retinoblastoma

D. Glioblastoma

Correct Answer: D. Glioblastoma

Explanation: Correct Option D - Glioblastoma: Glioblastoma, also known as glioblastoma multiforme, is the most common and aggressive type of malignant brain tumor in adults. It originates from glial cells, which are supportive cells in the brain. Glioblastomas often have a rapid growth rate and infiltrative behavior and tend to be resistant to conventional treatments. The symptoms mentioned in the question, such as severe headaches, seizures, and progressive neurological deficits, are characteristic of glioblastoma due to its invasive nature and effect on brain function. Glioblastoma accounts for about 80% of primary brain tumors in adults. Incorrect Options: Option A - Medulloblastoma: Medulloblastoma is a type of malignant brain tumor, but it is more commonly found in children rather than adults. It usually arises in the cerebellum, which is the part of the brain responsible for coordinating movement. Option B - Meningioma: Meningiomas are generally benign tumors that arise from the meninges, which are the protective layers surrounding the brain and spinal cord. While they can occur in adults, they are usually slow-growing and tend to be less aggressive than glioblastomas. Option C - Retinoblastoma: Retinoblastoma is a rare type of eye cancer that primarily affects young children. It originates in the retina, which is the light-sensitive tissue at the back of the eye. It does not typically present as a brain tumor and is not commonly seen in adults

@Neet_pg_bot

Q10: A 70-year-old patient presents with progressive memory loss, cognitive decline, and behavioral changes. Imaging reveals characteristic amyloid plaques and neurofibrillary tangles in the brain. On further investigation, the accumulation of a specific protein is found to be a hallmark of this disease. What is the protein responsible for the amyloidosis seen in Alzheimer's disease? (Q820521)

A. Amyloid beta protein

B. ATTR

C. Amyloid beta 2 protein

D. Acal

Correct Answer: A. Amyloid beta protein

Explanation: Correct Option A - Amyloid beta protein: In Alzheimer's disease, there is an accumulation of abnormal proteins, including beta-amyloid plaques and tau protein neurofibrillary tangles, in the brain. These amyloid plaques are primarily composed of beta-amyloid protein, which is derived from the amyloid precursor protein (APP). The accumulation of beta-amyloid protein is a hallmark feature of Alzheimer's disease and is believed to play a role in the pathogenesis of the condition. Incorrect Options: Option B - ATTR (Transthyretin Amyloidosis): Transthyretin amyloidosis is a disease characterized by the buildup of abnormal transthyretin proteins, primarily in the nerves and heart, not in the brain. It is not associated with Alzheimer's disease. Option C - Amyloid Beta 2 Protein: Amyloid beta protein is typically referred to as amyloid beta (Aβ) or amyloid beta protein 1-42 (Aβ42) in the context of Alzheimer's disease. There isn't a commonly recognized "Amyloid beta 2" protein associated with Alzheimer's disease. Option D - Acal: Acal does not correspond to any known protein associated with Alzheimer's disease or amyloidosis.

@Neet_pg_bot

Q11: Which of the following is the disorder associated with hexanucleotide repeat? (Q860225)

A. Fragile X syndrome

B. Huntington disease

C. Myotonic dystrophy

D. Frontotemporal dementia

Correct Answer: D. Frontotemporal dementia

Explanation: The disorder associated with hexanucleotide repeat is Frontotemporal dementia or Frontotemporal Lobar Degeneration (FTLD). These are a heterogeneous group of disorders associated with focal degeneration of frontal and/or temporal lobes. They are associated with cellular inclusions comprised of specific proteins; the two most common patterns are: Features FTLD-tau FTLD-TDP Inclusions Cytoplasmic tau inclusions Inclusions contain TDP-43 (RNA-binding protein) Associated mutations Associated with mutations in the MAPT gene (encoding tau) Expansion of a hexanucleotide repeat in the 5′ region of C9orf72 . Mutations in the TARDBP gene (encoding TDP-43) Mutations in the GRN gene The below-mentioned disorders are Trinucleotide Repeat Disorders, where there is excessive repetition of trinucleotides. In Introns/Non-coding region: Fragile X syndrome: CGG (Option A ruled out) Friedreich ataxia: GAA Myotonic dystrophy: CTG (Option C ruled out) In Exons/ Coding region: Huntington's disease: CAG (Mnemonic- Hunter in a Cage) (Option B ruled out)

Robbins and Cotrans Pathological Basis of Diseases, 10th Edition, Page 174, 1280-1282.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 5-year-old child presents with a lesion in the right eye. Histopathology reveals the presence of Flexner-Wintersteiner rosettes. What is the likely diagnosis? (Q860515)

A. Retinoblastoma

B. Optic nerve glioma

C. Rhabdomyosarcoma

D. Ocular melanoma

Correct Answer: A. Retinoblastoma

Explanation: The presence of a lesion in the right eye and histopathological findings of Flexner-Wintersteiner rosettes strongly suggest a diagnosis of Retinoblastoma . Retinoblastoma It is caused by the inactivation of both alleles of the RB1 tumour suppressor gene. Types Heritable (germline): It frequently leads to bilateral retinoblastoma and is caused by a germline mutation in the RB1 gene in all cells, followed by a somatic mutation

in the retinal cells. Affected individuals are also at increased risk for developing non-ocular tumours, such as osteosarcoma. Non-heritable (sporadic): This form typically presents as a unilateral tumour and results from two somatic mutations in the retinal cells occurring after embryonic development, without a germline mutation. It is not inherited and does not carry an increased risk of developing non-ocular tumours. Clinical features Occurs in young children, usually before 5 years of age (most common ocular neoplasm in children). Leukocoria: White pupillary reflex (most common presenting sign of retinoblastoma). Strabismus Painful red eye Poor vision Asymptomatic Fundus examination A white, elevated mass in the retina is characteristic of retinoblastoma Genetic testing RB1 gene mutation on chromosome 13q14 Histopathology Flexner-Wintersteiner rosettes (highly specific) : These are composed of an ‘empty’ lumen surrounded by columnar cells. Homer-Wright rosettes : These are pseudo-rosettes and consist of cells surrounding a central lumen made up of their processes. Undifferentiated tumour cells. Areas of necrosis and calcification. {{caption_text}} Optic nerve glioma (Option B) is a benign tumour that arises from the glial cells of the optic nerve. It is most commonly seen in children and is often associated with neurofibromatosis type 1. Symptoms may include vision loss, proptosis, and visual field defects. It typically occurs along the optic nerve and does not exhibit Flexner-Wintersteiner rosettes. Rhabdomyosarcoma (Option C) is a malignant soft tissue sarcoma that originates from skeletal muscle cells or their precursors. It is most common in children and can occur in various locations, including the head and neck, genitourinary tract, and extremities. Symptoms depend on the tumour's location but often include a painless mass or swelling. It affects the eye but does not show these characteristic rosettes. Ocular melanoma (Option D) is a rare malignant tumour that develops in the pigment-producing cells (melanocytes) of the eye, most commonly in the choroid (part of the eye's vascular layer). It is more common in adults and can lead to symptoms like vision changes, dark spots in the field of vision, and proptosis.

@Neet_pg_bot

Q13: Which of the following is a marker of Alzheimer’s disease? (Q844213)

A. Synuclein

B. Aβ **40 and 42**

C. Polyglutamine

D. FUS

Correct Answer: B. Aβ **40 and 42**

Explanation: Correct Option B - Aβ 40 and 42: αβ 40 and 42 are amyloid-beta peptides that are deposited in the brains of patients with Alzheimer's disease, forming plaques. Incorrect Options: Option A - Synuclein: This is associated with Parkinson's disease and Lewy body dementia. Option C - Polyglutamine: This is associated with Huntington's disease. Option D - FUS: This is associated with frontotemporal lobar degeneration.

↑ *Back to this question in Part A*

@Neet_pg_bot

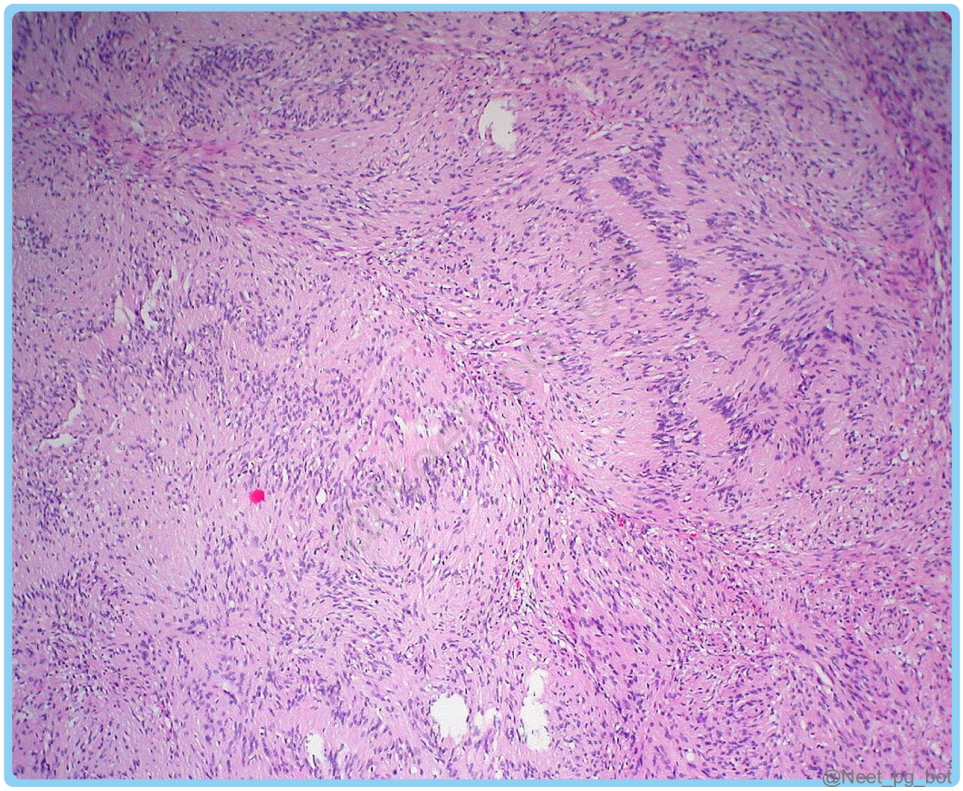
Q14: A patient presents with a hand lesion, and the histopathology of the lesion is provided. Which of the following statements is incorrect? (Q853372)

A. It originates from the peripheral nerve

B. Verrocay bodies are seen in light microscopy

C. Associated with neurofibromatosis

D. It is malignant and often metastasizes



Correct Answer: D. It is malignant and often metastasizes

Explanation: The described scenario, featuring a hand lesion and histopathological findings of encapsulated tissue with areas of dense cellularity and loose myxoid regions, suggests a diagnosis of Schwannoma . Schwannomas are benign tumours exhibiting Schwann cell differentiation and originate directly from peripheral nerves. (Option A) It is associated with NF2 mutations on chromosome 22 , producing merlin . (Option C) Most common location: Cerebellopontine angle Microscopically, they are comprised of: Antoni A area: Dense eosinophilic areas containing spindle cells are arranged into intersecting fascicles, leading to nuclei palisading. The resulting structures with central “nuclear-free zones” are called Verocay bodies . (Option B) Antoni B area: Loose, hypocellular areas where a myxoid extracellular matrix spreads apart the spindle cells. It typically shows immunoreactivity to S-100 . Clinical features: Cause symptoms by local compression of the involved nerve or adjacent structures (e.g., brainstem or spinal cord). Mostly occurs at the cerebellopontine angle (attached to the vestibular branch of the 8th nerve). Presents with tinnitus and hearing loss Sensory nerves are involved (trigeminal nerve and dorsal roots). They can arise in association with large nerve trunks or as soft tissue lesions (extradural) Management: Surgical removal is curative.

Robbin’s and Cotran Pathologic Basis of Disease, 10th Edition, Page 1237, 1297-1298.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: A child presents with visual disturbances and delayed growth. Imaging reveals a suprasellar mass, and histopathology shows the presence of "wet keratin" (compact, eosinophilic anucleate keratin). What is the most likely diagnosis? (Q866366)

A. Craniopharyngioma

B. Medulloblastoma

C. Glioma

D. Pituitary adenoma

Correct Answer: A. Craniopharyngioma

Explanation: The above history of a child presenting with visual disturbances and delayed growth with imaging features of a suprasellar mass, and histopathology showing the presence of "wet keratin" is suggestive of Craniopharyngioma. Rare, benign CNS tumour Often partly cystic in nature Occurs in the sellar/suprasellar region Pathophysiology: It can compress normal pituitary tissue and result in pituitary deficiencies, particularly of the anterior pituitary hormones. It can also compress the optic chiasm and also present with hydrocephalus secondary to third ventricle compression. Clinical Features: Headaches: Due to increased intracranial pressure or meningeal irritation. Visual Disturbances: Temporal hemianopsia is common due to optic chiasm compression. Endocrine Deficiencies: Growth hormone (GH) deficiency. Gonadotroph, ACTH, TSH, and vasopressin deficiencies. Other Symptoms: Hydrocephalus, nausea, vomiting, and possible cranial nerve palsies. Microscopic Examination: Adamantinomatous Craniopharyngioma (ACP): More common in children. Solid and cystic components. Characterised by squamous epithelium, "wet keratin," and calcifications. Papillary Craniopharyngioma (PCP): More common in adults. Predominantly solid, with well-differentiated squamous epithelium. Calcifications are rare. Imaging: MRI: Preferred modality for detailed evaluation. ACP: Heterogeneous with cystic areas and calcifications. PCP: Solid and less commonly cystic or calcified. CT: Best for identifying calcifications. Treatment: Surgery is the mainstay of treatment. Incorrect Options: Medulloblastoma (Option B): Typical location: Midline cerebellum (vermis) in children, not suprasellar. Presentation : Ataxia, gait disturbance, signs of increased intracranial pressure (due to 4th ventricle obstruction) like headache, vomiting, papilledema. Histology: Small, round, blue cells with Homer–Wright rosettes — no wet keratin. This child’s mass is suprasellar, causing visual and endocrine symptoms, which medulloblastomas do not. Glioma (Option C): Typical types relevant to the optic–hypothalamic region: Optic pathway gliomas, often in children (sometimes with NF1). Presentation: Progressive visual loss, proptosis, and sometimes endocrine dysfunction if the hypothalamus is involved. Histology: Glial fibrillary acidic protein (GFAP)–positive spindle cells, eosinophilic Rosenthal fibres (in pilocytic astrocytoma type) — no wet keratin. While location could overlap, the hallmark histologic finding is completely different. Pituitary Adenoma (Option D): Epidemiology: Very rare in children; it mostly affects adults. Presentation: Endocrine syndromes (hyperprolactinemia, Cushing’s disease, acromegaly), bitemporal hemianopia from optic chiasm compression. Histology: Uniform polygonal pituitary cells in nests or cords; no keratin debris. Age is atypical, histology doesn’t match, and pituitary adenomas don’t show “wet keratin.”

@Neet_pg_bot

Q16: In the WHO grading of astrocytoma, which grade does glioblastoma fall under? (Q793781)

A. I

B. II

C. III

D. IV

Correct Answer: D. IV

Explanation: Correct Option D - IV: In the WHO classification of astrocytoma, glioblastoma falls under Grade IV. This is the highest grade, and it means that the tumor is very bad and growing quickly. Glioblastoma is also called

a grade IV astrocytoma. Incorrect Options: Options A, B, and C are incorrect.

@Neet_pg_bot

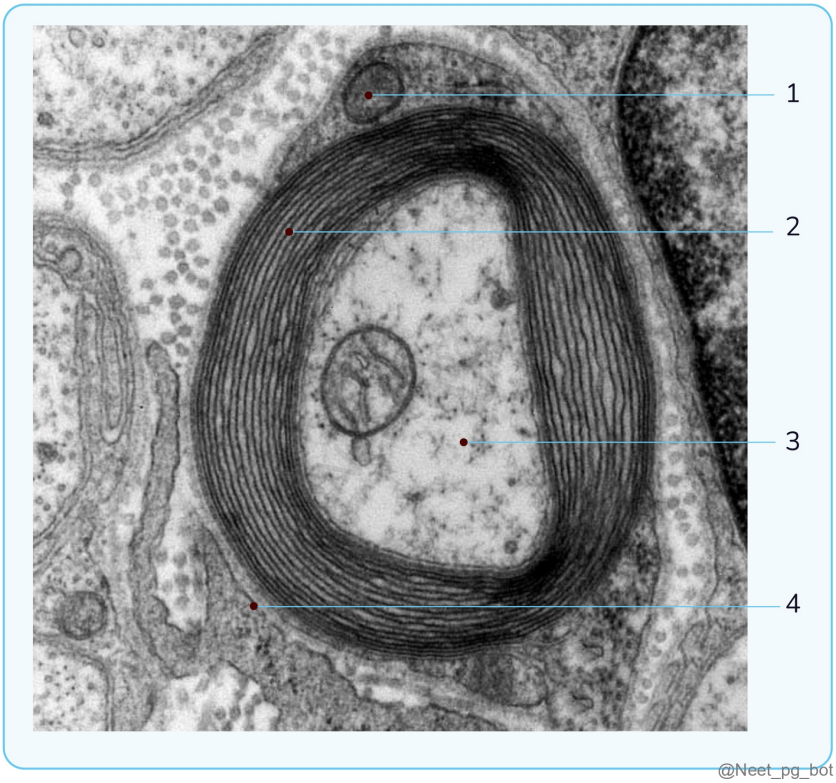
Q17: An electron microscopic picture of a cut section of a nerve fibre is given. Identify the area that will be affected by the most common variant of Guillain-Barre syndrome. (Q855395)

A. 1

B. 2

C. 3

D. 4



Correct Answer: B. 2

Explanation: The myelin sheath labelled "2" is the most common variant affected in Guillain-Barré Syndrome (GBS). Guillain-Barré Syndrome (GBS) A group of immune-mediated disorders causing acute paralysis, clinically characterized by weakness starting in the distal limbs and quickly progressing to involve proximal muscle function, resulting in "ascending paralysis". Variants Acute Inflammatory Demyelinating Polyneuropathy (AIDP) The most common variant is in Europe & North America. Patchy segmental demyelination of spinal cord and peripheral nerves Antibodies seen: IgG Anti GM1 IgG Anti GQ1b Axonal Variants Often associated with Campylobacter jejuni infection. More prevalent in China and Japan. Miller Fisher Syndrome Best-recognised variant. Associated with anti-GQ1b antibodies. Presents with internal and external ophthalmoplegia, ataxia, and areflexia Clinical features Motor Symptoms: Progressive ascending paralysis (distal to proximal) Areflexia Weakness in legs causing rubbery legs and instability to stand Truncal paralysis, quadriplegia, neck floppiness Bilateral 7th nerve palsy Bulbar palsy Difficulty in handling secretions leading to aspiration pneumonia A leading cause of death due to pulmonary involvement. Diaphragmatic paralysis Ventilatory support is required in 30% of cases. Increased carbon dioxide levels. Sensory Symptoms: Glove-and-stocking distribution paresthesias Proprioception loss Difficulty in climbing stairs Pain in the neck/arm/shoulder is similar to over-exercised muscle Sensory manifestations can occur before or along with motor manifestations. Autonomic Symptoms: Autonomic dysregulation (e.g., orthostatic hypotension, bladder/bowel sparing/transient involvement) Wide fluctuations of blood pressure, arrhythmias, postural hypotension Reduced heart rate and blood pressure, neurogenic shock. Investigations Lumbar Puncture CSF protein: 100-1000 mg/dL Elevated CSF protein but normal WBC count (albuminocytologic dissociation) CSF Study Timing Normal CSF findings (<48 hours) Maximum rise of protein seen by 7 days Electrodiagnostic Testing Prolonged F-wave latencies Earliest finding in AIDP (Acute Inflammatory Demyelinating Polyneuropathy) 1 (Option A) indicates Schwann cells, which are the supporting cells of the peripheral nervous system and play a crucial role in forming the myelin sheath around the axons. While Schwann cells can be involved in GBS, they are not the primary site of damage in the most common variant, acute inflammatory demyelinating polyradiculoneuropathy (AIDP). 3 (Option C) indicates an axon, whose damage can occur in GBS. It is more commonly associated with variants such as acute motor axonal neuropathy (AMAN) or acute motor-sensory axonal neuropathy (AMSAN). In the most common AIDP variant, the primary pathology is focused on the myelin sheath rather than the axon itself. 4 (Option D) indicates mesaxon, i.e., the region where the inner and outer layers of the Schwann cell membrane meet. It is involved in the formation of the myelin sheath. Although the mesaxon can be affected in GBS, it is not the primary area of damage in the most common AIDP variant.

Q7 (p. 2566) *Q8 (p. 2570)*

Q1: A child presents with skin eruptions upon exposure to sunlight and is diagnosed with a DNA repair defect. Which type of repair defect is most likely responsible? (Q844175)

A. Nucleotide excision repair defect

B. Base excision repair defect

C. Mismatch repair defect

D. Recombination repair defect

Correct Answer: A. Nucleotide excision repair defect

Explanation: Correct Option A - Nucleotide excision repair defect: Xeroderma pigmentosa is caused by a defect in nucleotide excision repair, leading to an inability to repair UV-induced DNA damage, which results in extreme sensitivity to sunlight and a high risk of skin cancers. Incorrect Options: Options B, C, and D do not cause xeroderma pigmentosa.

↑ *Back to this question in Part A*

@Neet_pg_bot

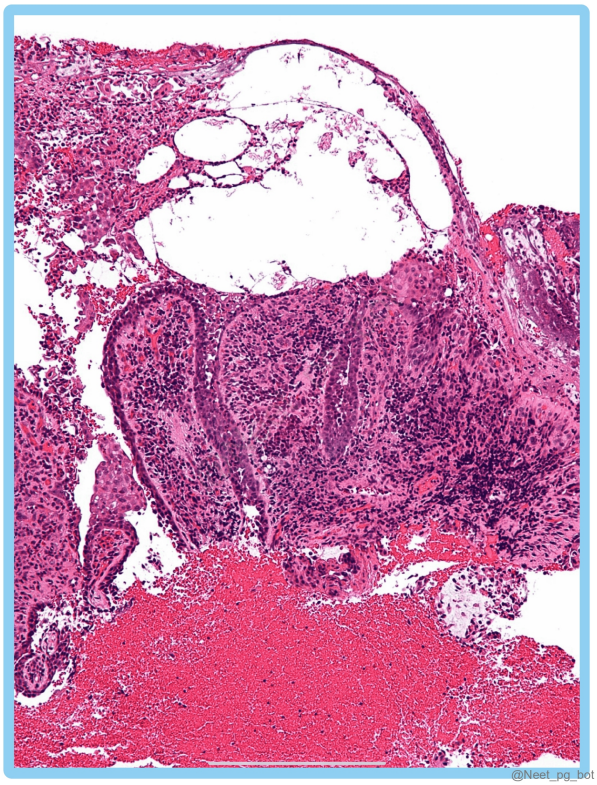
Q3: Identify the given condition. (Q856687)

A. Pemphigus Vulgaris

B. Leprosy

C. Mycosis fungoides

D. Visceral leishmaniasis



Correct Answer: A. Pemphigus Vulgaris

Explanation: The histopathological image shows Pemphigus Vulgaris (PV) , with intraepidermal cleavage and acantholysis in the suprabasal layer, along with a "row of tombstones" appearance due to the separation of basal keratinocytes at the basement membrane zone. It is the most common chronic autoimmune blistering disease caused by antibodies against desmosomal adhesion proteins. The target antigens for PV are most commonly Desmoglein 3 and sometimes Desmoglein 1. Clinical features: Flaccid blisters filled with clear fluid present on normal skin or an erythematous base. The blisters rupture, producing painful erosion. {{caption_text}} Mucosal involvement is a very important and one of the distinguishing features of PV. {{caption_text}} {{caption_text}} Histopathology: Intraepidermal cleavage with acantholysis (detached keratinocytes) primarily localized to the suprabasal region. Separation of basal keratinocytes along the basement membrane zone, resulting in an appearance that resembles a "row of tombstones". {{caption_text}} Leprosy (Option B) , also known as Hansen's disease , is a chronic infection caused by Mycobacterium leprae , affecting the skin, peripheral nerves, and mucous membranes. Tuberculous leprosy shows granulomatous lesions similar to tuberculosis, while lepromatous leprosy features lipid-laden macrophages (lepra cells) containing "globi" of acid-fast bacilli. {{caption_text}} {{caption_text}} Mycosis fungoides (Option C) is the most common type of cutaneous T-cell lymphoma. It presents with a variety of skin lesions, including patches, plaques, and tumours. Histologically, the epidermis and upper dermis are infiltrated by neoplastic T cells, which often have a cerebriform appearance due to marked infolding of the nuclear membrane. {{caption_text}} Visceral leishmaniasis (Option D) , also known as kala-azar, is a systemic parasitic infection caused by Leishmania species. It is characterized by granulomatous inflammation, phagocytosed parasites, hyperplasia of the reticuloendothelial system, necrosis with fibrosis, and hemophagocytosis, where macrophages engulf red blood cells, white blood cells, or platelets. {{caption_text}}

@Neet_pg_bot

Q4: A 5-year-old child who presented with proptosis of one of the eyes was found to have a desmin-positive tumour. What is the probable diagnosis? (Q856705)

A. Ewing’s sarcoma

B. Embryonal rhabdomyosarcoma

C. Leukaemia

D. Retinoblastoma

Correct Answer: B. Embryonal rhabdomyosarcoma

Explanation: The clinical presentation of a 5-year-old child with proptosis and a desmin-positive tumour suggests embryonal rhabdomyosarcoma (RMS). Desmin is a marker for muscle differentiation, and rhabdomyosarcoma, a malignant tumour of skeletal muscle origin, is common in children and can present with proptosis if it involves the orbit. Rhabdomyosarcoma (RMS) Origin A malignant tumour arising from skeletal muscle progenitors Types Embryonal rhabdomyosarcoma. Alveolar rhabdomyosarcoma. Pleomorphic rhabdomyosarcoma. Spindle cell/sclerosing rhabdomyosarcoma Clinical features It is the most common soft tissue sarcoma in children and adolescents. It commonly presents in the extremities. Pediatric rhabdomyosarcomas mostly arise in the sinuses, head and neck, and genitourinary tract. IHC Positive Markers Desmin Myogenin MyoD1 Muscle-specific actin Gross appearance The tumours are often large, soft, and infiltrative, with areas of necrosis and haemorrhage. Microscopy Small, round to spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm, sometimes with a myxoid stroma, are also seen. {{caption_text}} Ewing’s sarcoma (Option A) is a malignant tumour typically affecting bones or soft tissues, often seen in children and adolescents. It is characterized by a specific genetic translocation (t(11;22)) and is usually not associated with desmin positivity, which is more typical of rhabdomyosarcoma. Ewing's sarcoma may cause localized swelling or pain but rarely presents with proptosis unless it involves the orbit or surrounding tissues. It is composed of sheets of uniform, small, round cells with scant cytoplasm that may be clear due to abundant glycogen. Leukaemia (Option C) is a type of cancer that affects the blood and bone marrow, leading to the uncontrolled production of abnormal white blood cells. It typically doesn't present with localized tumours or proptosis. However, in cases of leukemic infiltration of the orbit, proptosis may occur, though it's relatively rare. Retinoblastoma (Option D) is a malignant eye tumour that primarily affects young children, often before the age of 5. While it can cause proptosis due to orbital involvement, it is typically not associated with a desmin-positive tumour. Retinoblastoma usually presents with a white reflex in the pupil (leukocoria) and can cause vision problems or strabismus.

@Neet_pg_bot

Q5: A patient underwent surgery for lipoma 5 weeks ago and now presents with a scar at the incision site, which is limited to the original wound boundaries. What is the most likely diagnosis? (Q857162)

A. Keloid

B. Exuberant granulation

C. Hypertrophic scar

D. Granulation tissue

Correct Answer: C. Hypertrophic scar

Explanation: The most likely diagnosis is a hypertrophic scar, characterised by a raised scar confined to the original wound boundaries, unlike keloids that extend beyond the wound. It is marked by excess collagen, rapid

growth, and the presence of myofibroblasts. Hypertrophic scars tend to regress over time and recur less frequently than keloids. {{caption_text}} Keloid: (Option A) Scar grows beyond the original wound boundaries and doesn’t regress. More common among African Americans. Develops after deep dermal injuries. {{caption_text}} Exuberant Granulation Tissue: (Option B) {{caption_text}} Excessive granulation tissue above skin level. Blocks reepithelialisation (also called "proud flesh"). Requires cauterisation or surgical excision for healing Contractures: {{caption_text}} Abnormal tightening of the wound and surrounding tissues. Common in palms, soles, and chest. Seen in severe burns, it may impair joint movement.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: An 8-year-old boy presents with progressive muscle weakness and walking difficulties. On examination, pseudohypertrophy of the calf muscles was noted. Which of the following is true regarding this condition? (Q858113)

A. Abnormal collagen

B. Absent dystrophin

C. Expansions of CAG triplet repeats

D. Defective fibrillin

Correct Answer: B. Absent dystrophin

Explanation: The patient described is likely suffering from Duchenne muscular dystrophy (DMD) , a genetic disorder characterised by progressive muscle weakness, particularly in the lower limbs, with pseudohypertrophy of the calf muscles . This condition is caused by a mutation in the dystrophin gene , resulting in the absence or severe deficiency of dystrophin , a protein that helps anchor the muscle cell membrane. Aspect Duchenne Muscular Dystrophy (DMD) Type of Mutation Frameshift mutations lead to a disrupted reading frame Dystrophin Protein Dystrophin deficient Truncated and unstable (< 3% of normal) Clinical Severity Severe, early onset, rapid progression Inheritance Pattern X-linked recessive. Age of onset Early childhood (Before 5 years) Incorrect Options: Abnormal collagen (Option A) would be more consistent with conditions like Ehlers-Danlos syndrome or osteogenesis imperfecta , which involve defective collagen synthesis. Dystrophinopathies, like DMD, do not primarily involve collagen. Expansion of CAG triplet repeats (Option C) can cause Huntington's disease or fragile X syndrome, but DMD is caused by a mutation in the dystrophin gene , not CAG repeats. Defective fibrillin (Option D) is the cause of Marfan syndrome , which affects connective tissue and is characterized by features like tall stature, long limbs, and aortic dissection, but it is not involved in muscle degeneration like DMD.

@Neet_pg_bot

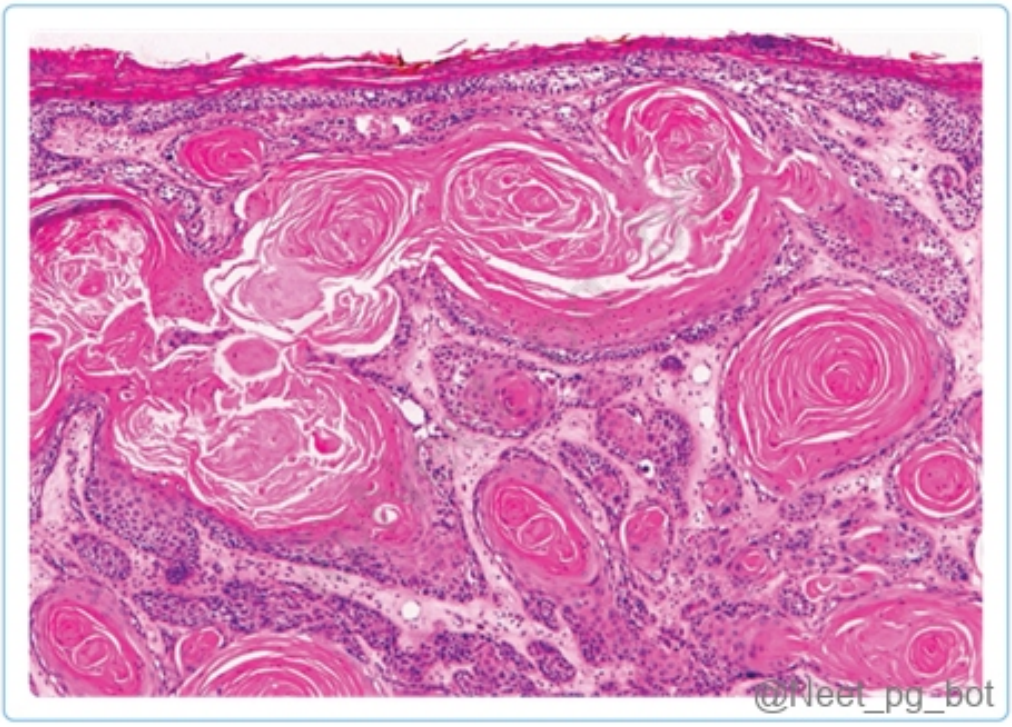
Q7: A farmer has a lesion on the shoulder. What is the most likely diagnosis based on the histopathological image of the lesion given below? (Q860532)

A. SCC

B. BCC

C. Molluscum contagiosum

D. Verrucous carcinoma



Correct Answer: A. SCC

Explanation: The histopathological image showing keratin pearls on histopathology is suggestive of Squamous Cell Carcinoma (SCC) . It is a malignant tumour originating from epidermal keratinocytes. It is the second most common skin tumour after basal cell carcinoma (BCC). SCC is notably the most common skin tumour in immunocompromised individuals . Predisposing factors include UV exposure, immunosuppression, and conditions like xeroderma pigmentosum, albinism, LP, and DLE, which can rarely progress into SCC. Clinical features: It typically exhibits a lower rate of local, regional, and distant spread compared to other skin malignancies. Associated with immunocompromised states such as HIV infection and renal transplant recipients. It presents as papules, nodules, or plaques with induration and signs of photodamage like crusting and scaling. {{caption_text}} Histopathological examination reveals characteristic keratin pearls . {{caption_text}} Treatment: Primary treatment involves wide surgical excision with margins. Advanced cases may require radiation or chemotherapy. BCC (Basal Cell Carcinoma) (Option B) is the most common type of skin cancer , originating from the basal cells in the epidermis. It is typically slow-growing, often appearing as a painless, pearly nodule with telangiectasias on sun-exposed areas like the face. Histologically, BCC is characterised by nests of basaloid cells with a palisading pattern at the periphery, fibrotic stroma, and clefting between the tumour and surrounding tissue. {{caption_text}} Molluscum contagiosum (Option C) is a viral skin infection causing small, flesh-coloured lesions with central umbilication, often in children and immunocompromised individuals. Histologically, it shows epidermal hyperplasia, ballooning keratinocytes, and Henderson-Patterson (HP) bodies in cup-shaped spaces. {{caption_text}} Verrucous carcinoma (Option D) is a rare, low-grade squamous cell carcinoma often found in areas with chronic irritation (e.g., oral cavity, genitals). It presents as a slow-growing, wart-like lesion and is associated with HPV infection. Histopathologically, it shows exophytic growth, thick keratinisation, well-differentiated squamous cells, and pushing borders with minimal atypia. {{caption_text}}

@Neet_pg_bot

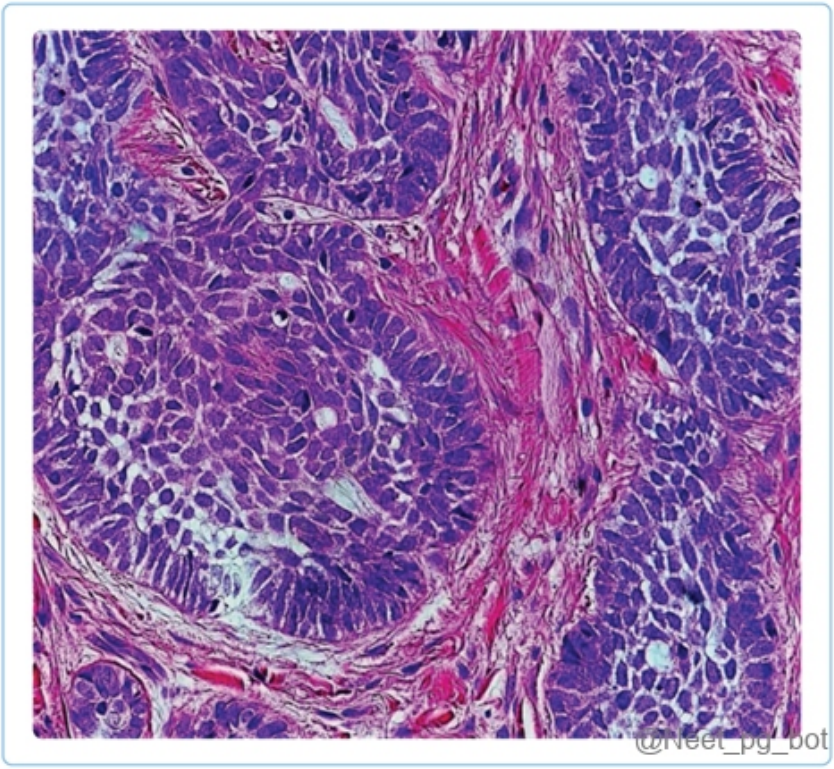
Q8: Identify the histopathological image. (Q860535)

A. Basal cell carcinoma

B. Squamous cell carcinoma

C. Adenocarcinoma

D. Malignant melanoma



Correct Answer: A. Basal cell carcinoma

Explanation: The histopathological image of the skin biopsy reveals nests of basaloid cells with peripheral palisading and a distinctive stromal retraction artefact, characteristic of Basal Cell Carcinoma (BCC), also known as Rodent Ulcer. It is the most common type of skin cancer and is typically seen in sun-exposed areas of the skin. It is a slow-growing, locally invasive tumour, and it rarely metastasises. Origin: Arises from pluripotent cells within the basal layer of the epidermis or follicular structures. Pathogenesis: Site: Face, Around eyes, Nose Clinical Features It presents initially small, scaly plaque. They present as pearly papules containing dilated blood vessels (telangiectasias) They may ulcerate locally and invade the underlying bone or facial sinuses (rodent ulcers). Slow progressive course of peripheral extension. {{caption_text}} Histologically: The tumour cells are basophilic cells with hyperchromatic nuclei (basaloid cells) arranged in clusters with a palisading pattern . The stroma sometimes retracts from the malignant cells. {{caption_text}} Treatment Medical: Imiquimod, 5-FU,Intralesional interferon α-2b Hedgehog pathway inhibitors:(Vismodegib) Surgical: Mohs micrographic surgery, Done in recurrent BCCs. Squamous cell Carcinoma (Option B) typically exhibits keratin pearls and intercellular bridges, features not present in the image provided. Additionally, the cells are generally larger and have more abundant cytoplasm, unlike the smaller basaloid cells seen in BCC. {{caption_text}} Adenocarcinoma (Option C) arises from glandular epithelium and shows glandular structures or mucin production. {{caption_text}} Malignant Melanoma (Option D) is characterised by atypical melanocytes, which can be seen in various configurations, such as nests or single cells within the epidermis and dermis. These cells often contain melanin pigment. {{caption_text}}

[17_Hematology_ Red Blood Cells] 065 Introduction To Hematology — Quick Jump

Q1 (p. 2575)	*Q2 (p. 2576)*	*Q3 (p. 2577)*	*Q4 (p. 2577)*	*Q5 (p. 2578)*	*Q6 (p. 2579)*
Q7 (p. 2579)	*Q8 (p. 2583)*	*Q9 (p. 2583)*	*Q10 (p. 2584)*	*Q11 (p. 2585)*	*Q12 (p. 2585)*
Q13 (p. 2586)	*Q14 (p. 2587)*	*Q15 (p. 2590)*	*Q16 (p. 2591)*	*Q17 (p. 2592)*	*Q18 (p. 2593)*
Q19 (p. 2594)	*Q20 (p. 2595)*				

Q1: What is the most common reason for an elevated reticulocyte count among the conditions? (Q846639)

A. Aplastic anemia

B. Hemolytic anemia

C. Megaloblastic anemia

D. Myelophthisic anemia

Correct Answer: B. Hemolytic anemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Normal reticulocyte count is 0.5–2.5%. When red blood cells are destroyed, as in hemolytic anemia, a signal is sent to the bone marrow to increase red blood cell production. In response, the bone marrow releases more reticulocytes into circulation, which explains the elevated reticulocyte count seen in hemolytic anemia. Aplastic anemia (Option A): This means bone marrow failure. If the bone marrow is not producing red blood cells, the reticulocyte count will be low. Megaloblastic anemia (Option C): This occurs due to vitamin B12 or folic acid deficiency, where nuclear-cytoplasmic asynchrony impairs proper cell maturation, resulting in a low reticulocyte count. Myelophthisic anemia (Option D): This situation arises when the bone marrow is infiltrated, such as by cancer metastasis or a tubercular granuloma. The infiltration disrupts normal cellular production and alters the types of cells produced, leading to a decreased reticulocyte count.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 636, 659, 661

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: What is the most likely interpretation if Hemoglobin is 9 g/dL, MCV is 104 fL, MCH is 22 pg, and MCHC is 31 g/dL? (Q846648)

A. Microcytic Hypochromic Anaemia

B. Normocytic Normochromic Anaemia

C. Macrocytic Hypochromic Anaemia

D. Microcytic Normochromic Anaemia

Correct Answer: C. Macrocytic Hypochromic Anaemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Parameter Values Normal Range Interpretation Haemoglobin (Hb) 9 g/dL 12-16 g/dL Low Mean Corpuscular Volume (MCV) 104 fL 80-100 fL High (Macrocytic) Mean Corpuscular Hemoglobin (MCH) 22 pg 27-32 pg Low (Hypochromic) Mean Corpuscular Hemoglobin Concentration (MCHC) 31 g/dL 32-36 g/dL Low (Hypochromic) Examples of Macrocytic anemia: Liver diseases Hypothyroidism Megaloblastic anemia (Vitamin B12 and folic acid deficiency) Chemotherapeutic drugs use

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 635 Dacie and Lewis Practical Haematology, 12th Edition, Page 35 https://www.ncbi.nlm.nih.gov/books/NBK470252/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: What is the Mean Corpuscular Hemoglobin Concentration (MCHC) using Hemoglobin (Hb) level is 15 g/dL and Hematocrit (Hct) is 45%? (Q846647)

A. 33.3 g/dL

B. 34.0 g/dL

C. 32.0 g/dL

D. 30.0 g/dL

Correct Answer: A. 33.3 g/dL

Explanation: MCHC indicates the amount of haemoglobin per unit volume. In contrast to MCH, MCHC correlates the haemoglobin content with the volume of the cells. It is expressed as g/dl of red blood cells or as a percentage value. MCHC (g/dl) = Hb x 100/ PCV or Hematocrit Given: Hemoglobin (Hb) = 15 g/dL; Hematocrit (Hct) = 45% Using the formula for MCHC: MCHC(g/dL)=Hemoglobin (g/dL)×100/Hematocrit (%) MCHC=15×100/45 MCHC=1500/45 MCHC=33.3 g/dL

References:

Dacie and Lewis Practical haematology 12th edition, Page 35 https://www.ncbi.nlm.nih.gov/books/NBK260/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 45-year-old male patient presents for a routine check-up. His laboratory results show that his Hemoglobin (Hb) level is 14 g/dL, and his RBC count is 4.7 million

cells/µL. Using these values, calculate the Mean Corpuscular Hemoglobin (MCH). (Q846646)

A. 29.8 pg

B. 29.0 pg

C. 30.0 pg

D. 28.5 pg

Correct Answer: A. 29.8 pg

Explanation: MCH (Mean Corpuscular Hemoglobin) measures the average hemoglobin amount per red blood cell, expressed in picograms (pg). It helps diagnose and classify anemia by assessing hemoglobin content in individual red blood cells. MCH (pg) = Hb x 10/ RBC count Given: Hemoglobin (Hb) = 14 g/dL; RBC count = 4.7 million cells/µL Using the formula for MCH: MCH(pg)=Hemoglobin (g/dL)×10/RBC count (millions/µL) MCH=14 ×10/4.7 MCH=140/4.7■ MCH=29.8 pg

References:

Dacie and Lewis Practical haematology 12th edition,pg 35 https://www.ncbi.nlm.nih.gov/books/NBK260/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Calculate MCV in a patient where RBC count is 4.5 million cells per microliter (cells/µL), Hb 9gm/dl and Hematocrit is 30% (Q846645)

A. 65.7 fL

B. 66.7 fL

C. 67.7 fL

D. 68.7 fL

Correct Answer: B. 66.7 fL

Explanation: Mean corpuscular volume (MCV) measures the average size of red blood cells in femtoliters (fL) and helps diagnose anemia. It is calculated by dividing the hematocrit (%) by the red blood cell count and multiplying by 10. MCV (fL) = PCV x 10/ RBC count Given: RBC count: 4.5 million cells/µL; Hematocrit/ PCV: 40% Using the formula for MCV: MCV (in fL) = (Hematocrit %)×10/(RBC×10 12 /L) MCV (fL) = Hematocrit(%)×10/RBC count(millions/µL) MCV = 30×10/4.5 MCV = 300/4.5■ MCV = 66.7 fL From the calculated MCV, the patient is likely to have Microcytic anaemia.

Dacie and Lewis Practical Haematology, 12th Edition, Page 35 https://pubmed.ncbi.nlm.nih.gov/31424859/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: RBC indices Definitions 1. MCV a) Indicates the variation in the size of red blood cells. 2. MCH b) Reflects the average volume of a red blood cell. 3. MCHC c) Measures the average amount of haemoglobin in a single red blood cell. 4. RDW d) Represents the amount of haemoglobin per unit volume of red blood cells. (Q846644)

A. 1-b, 2-c, 3-d, 4-a

B. 1-c, 2-a, 3-b, 4-d

C. 1-d, 2-a, 3-c, 4-b

D. 1-b, 2-d, 3-c, 4-a

Correct Answer: A. 1-b, 2-c, 3-d, 4-a

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: RBC INDICES DEFINITION MCV (Mean Corpuscular Volume) Reflects the average volume of a red blood cell (size of RBC) and is expressed as femtoliters (fl) or cubic microns (μm³). MCH (Mean Corpuscular Hemoglobin) Measures the average amount of haemoglobin in a single red blood cell, expressed in picograms (pg). MCHC (Mean Corpuscular Hemoglobin Concentration) Represents the average concentration of haemoglobin in a given volume of red blood cells, expressed as grams per deciliter (g/dl). RDW (Red Cell Distribution Width) Indicates the variation in the size of red blood cells (Anisocytosis) , expressed as a percentage.

@Neet_pg_bot

Q8: Which statement accurately describes ESR (Erythrocyte Sedimentation Rate)? (Q846642)

A. Non-specific marker of inflammation

B. Proportion of red blood cells in the total blood volume

C. Reflects the oxygen-carrying capacity of the blood

D. Reported in percentage

Correct Answer: A. Non-specific marker of inflammation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: ESR (Erythrocyte Sedimentation Rate) PCV (Packed Cell Volume) / Hematocrit Definition It measures the rate at which red blood cells (erythrocytes) settle at the bottom of a test tube over a specified period, usually one hour. PCV, also known as hematocrit, measures the proportion of blood volume occupied by red blood cells. (Option B) Significance Non-specific marker of inflammation No specific role in inflammation. Increases in Inflammation, fever, pregnancy, cancer Polycythemia Decreases in Sickle cell disease, polycythemia, hypoproteinemia Anemia Reported in Millimetre per hour percentage % (Option D) Reference range Male ≤15 mm/hr Female ≤ 20 mm/hr Child ≤10 mm/h Male = 40% to 54% Female = 36% to 48%.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 48-year-old man presents to the clinic with fatigue, palpitations, and shortness of breath. Examination reveals pallor. Using the following values, calculate the reticulocyte production index: Reticulocyte count: 5% Hemoglobin: 9 g/dL Hematocrit: 28% (Q846641)

A. 1.8

B. 1.5

C. 2.5

D. 2.0

Correct Answer: B. 1.5

Explanation: The reticulocyte production index (RPI) is a calculated value that adjusts the reticulocyte count for anemia severity and reticulocyte maturation time to assess bone marrow response. RPI = CRC / maturation time in peripheral blood in days CRC = Observed reticulocyte count x Patient's haemoglobin / standard haemoglobin. Reticulocyte maturation time: Hematocrit Maturation time ≥ 40% 1 Day 30-40% 1.5 Days 20-30% 2 Days < 20% 2.5 Days From the given Clinical scenario, Reticulocyte count: 5%; Hemoglobin: 9 g/dL; Hematocrit: 28% CRC = 5 x 9 / 15 = 3.0 RPI = CRC / 2= 1.5

References:

Wintrobes's Clinical Haematology, 13th Edition, Page 1367,1368

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 30-year-old man presents to the OPD with fatigue, weakness, and breathlessness. He shows pallor and icterus on examination. Given his hemogram results, reticulocyte count of 5%, haemoglobin of 9 g/dL, and hematocrit of 28%, calculate his corrected reticulocyte count. (Q846640)

A. 4.0

B. 5.1

C. 4.5

D. 3.0

Correct Answer: D. 3.0

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Normal reticulocyte count is 0.5-1.5%. Corrected reticulocyte count (CRC) is the correction for the degree of anaemia, and it's calculated using the following formula. Calculation of CRC using Haemoglobin: CRC= Observed reticulocyte count x Patient's haemoglobin / Standard haemoglobin Standard hemoglobin for men= 15g/dl; for women=13g/dl For the the above patient: CRC = 5 x 9 / 15 = 3.0 Calculation of CRC using Hematocrit: CRC= Observed reticulocyte count x Patient's hematocrit / Standard hematocrit Normal adult hematocrit= 45%

@Neet_pg_bot

Q11: At which site does erythropoiesis primarily occur in an adult human? (Q845922)

A. Bone marrow of long bones

B. Bone marrow of all bones

C. Yolk sac

D. Liver

Correct Answer: A. Bone marrow of long bones

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Primary Sites of Erythropoiesis 1st trimester: Yolksac (Option C) 2nd trimester onwards: Liver (Option D) Children: Bone marrow of almost all bones (Option B) After puberty and in adults: Only in the bone marrow of the long bones (e.g., femur, tibia), as well as in the pelvis, vertebrae, and sternum.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 28

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: What is the approximate maturation time for reticulocytes in the bloodstream to form mature red blood cells? (Q846637)

A. 1-2 days

B. 2-5 days

C. 6-7 days

D. 8-10 days

Correct Answer: A. 1-2 days

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Reticulocytes are the first cell in erythropoiesis that comes out of the bone marrow and starts circulating in the peripheral blood. Reticulocytes have a reticulum of RNA in them. Reticulocytes need 1-2 days to form mature red blood cells. Over 1–2 days, reticulocytes repeatedly pass through the spleen, where the spleen removes their extra RNA, thereby maturing them into mature red blood cells.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 584 Guyton and Hall Textbook of Medical Physiology, 14th Edition, Page 441

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: What is the normal range for reticulocyte count in adults? (Q846636)

A. 0.5-2%

B. 2-6%

C. 2-3%

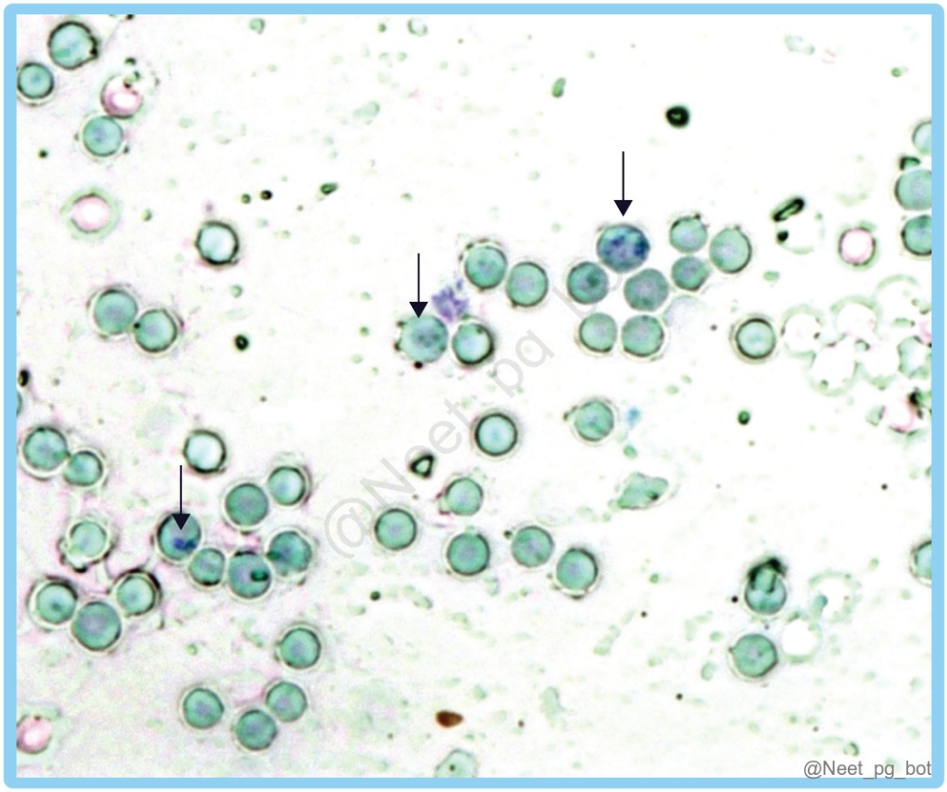
D. 0-0.1%

Correct Answer: A. 0.5-2%

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Reticulocytes are RBC precursors with no nucleus. 0.5-2.5% is the normal range of reticulocyte count in adults. In umbilical cord's blood sample, normal reticulocyte count is 2-6%



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 584 Guyton and Hall Textbook of Medical Physiology, 14th Edition, Page 441 https://emedicine.medscape.com/article/2086146-overview?form=fpf

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 25-year-old woman experiences ongoing fatigue and weakness, appearing pale upon examination. Laboratory investigations reveal low haemoglobin levels, and a peripheral blood smear is ordered. Which stain is most effective for visualising reticulocytes in peripheral blood smears? (Q846635)

A. Prussian Blue

B. New Methylene Blue

C. Periodic acid-Schiff (PAS) stain

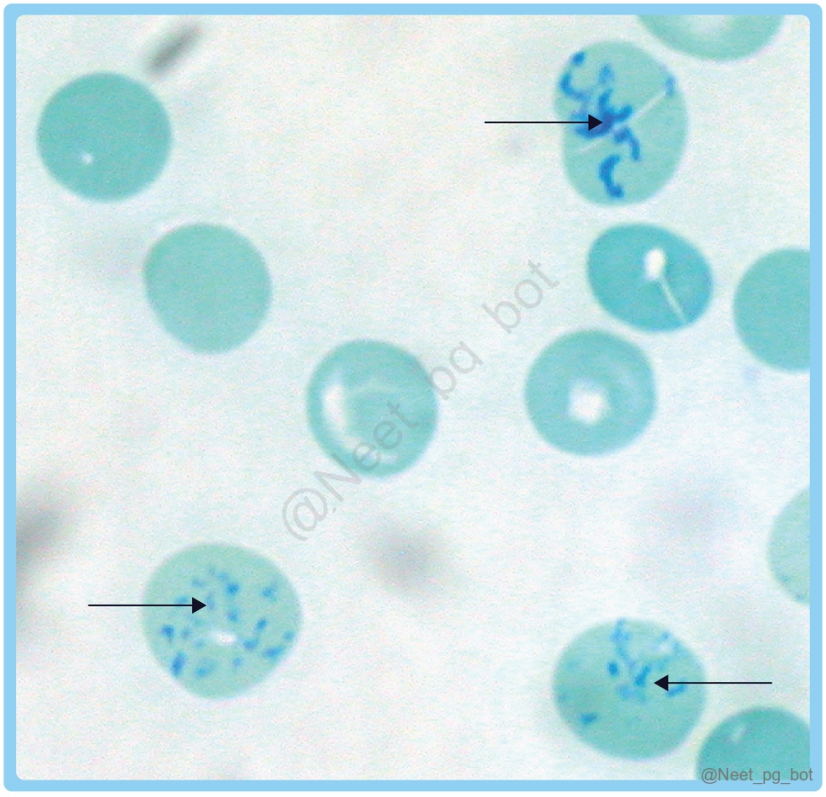
D. Wright stain

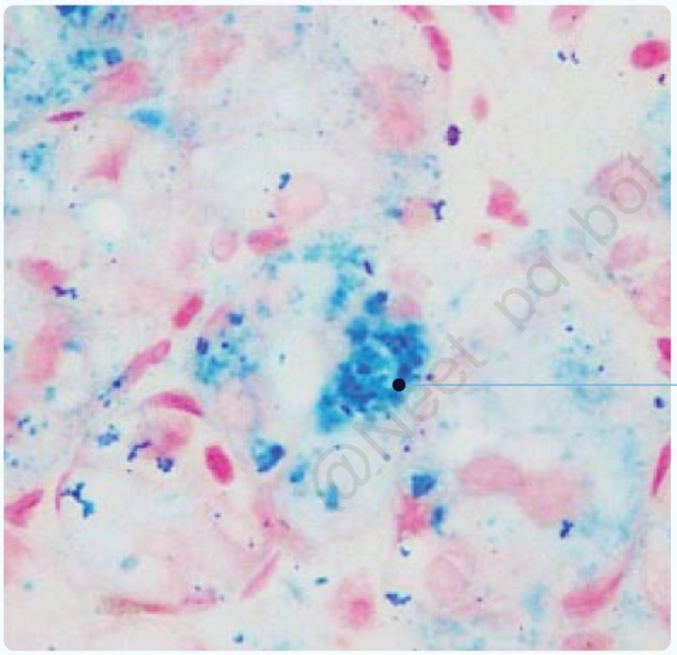
Correct Answer: B. New Methylene Blue

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The presence of anaemia typically triggers the body's response by increasing erythropoiesis, releasing reticulocytes into circulation early as part of the compensatory mechanism to replenish red blood cells and enhance tissue oxygenation. New Methylene blue is used to visualise reticulocytes in peripheral blood smears. It is a supravital stain that stains living states like the RNA in reticulocytes. Normal reticulocyte count in peripheral blood is 0.5% to 2.5% . Prussian blue (Option A): It is also known as Pearl stain and is used to stain iron. PAS Stain (Option C): It stains polysaccharides such as glycogen, glycoproteins, glycolipids, and mucin in tissues a pink color. Wright's stain (Option D): It comes under the Romanowsky stain family which is usual/routine stain used in haematology.





Hemosiderin containing cell

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which stage of erythropoiesis is characterised by the expulsion of the nucleus, resulting in a smaller, pyknotic cell with increased haemoglobin content? (Q846634)

A. Reticulocyte

B. Normoblast

C. Basophilic erythroblast

D. Proerythroblast

Correct Answer: A. Reticulocyte

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Reticulocytes are smaller pyknotic cells with increased haemoglobin content and have no nucleus. Stages of Erythropoiesis It starts with Hematopoietic stem cells(HSC)→Common Myeloid Progenitor cells(CMP)→Proerythroblasts. As the erythroid lineage progresses from the earliest precursor to the mature red blood cell, the overall cell size gradually decreases. In erythropoiesis, every stage that includes the term “blast” retains a nucleus, which applies to the proerythroblast, early normoblast, intermediate normoblast, and late normoblast stages. Reticulocyte: ■■■■■■■ It is the first cell in the erythropoietic lineage that does not have a nucleus . It is the first cell that comes out of the bone marrow and starts circulating in the peripheral blood . The normal reticulocyte count in peripheral blood is 0.5% to 2.5% .

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 584

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: Which condition is NOT typically associated with a dry tap during bone marrow aspiration? (Q846633)

A. Aplastic anaemia

B. Hairy cell leukemia

C. Myelofibrosis

D. Chronic Myeloid Leukemia

Correct Answer: D. Chronic Myeloid Leukemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Chronic Myeloid Leukemia (CML) is a myeloproliferative neoplasm characterised by the presence of the Philadelphia chromosome, resulting in the abnormal proliferation of myeloid cells. The marrow in CML is hypercellular due to increased numbers of matured cells. It typically does not cause significant fibrosis or hypocellularity, the primary factor contributing to dry taps. Causes of Dry Tap: Aplastic anaemia: Because of the bone marrow's failure, it is unable to produce new cells. Hairy cell Leukemia: Hairy cell's release mediators like TGF-β and PDGF which leads to bone marrow fibrosis and dry tap. Myelofibrosis: Marrow has undergone fibrosis, and on putting a needle, nothing will be aspirated. Myelophthisic anaemia AML-M7

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 622, 623, 660, 661

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: If a person is 45 years old, what would be the expected percentage of cellularity in their bone marrow biopsy? (Q845972)

A. 45%

B. 55%

C. 65%

D. 75%

Correct Answer: B. 55%

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The expected percentage of cellularity in a bone marrow biopsy can be estimated using the formula: Expected bone marrow cellularity =100 – age of the patient So, for a 45-year-old person: Cellularity = 100 – 45 = 55% Therefore, the expected percentage of cellularity in their bone marrow biopsy would be 55%. n a healthy adult, the expected bone marrow cellularity is about 1:1, meaning roughly 50% is composed of hematopoietic cells and the other 50% of fat (adipose) cells.

References:

https://clinicalgate.com/normal-bone-marrow-histology/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 35-year-old man undergoes a bone marrow biopsy, which shows a composition of cells and fat. What is the ratio of hematopoietic cells to fat cells expected in an adult? (Q845971)

A. 1:1

B. 1:3

C. 2:3

D. 3:1

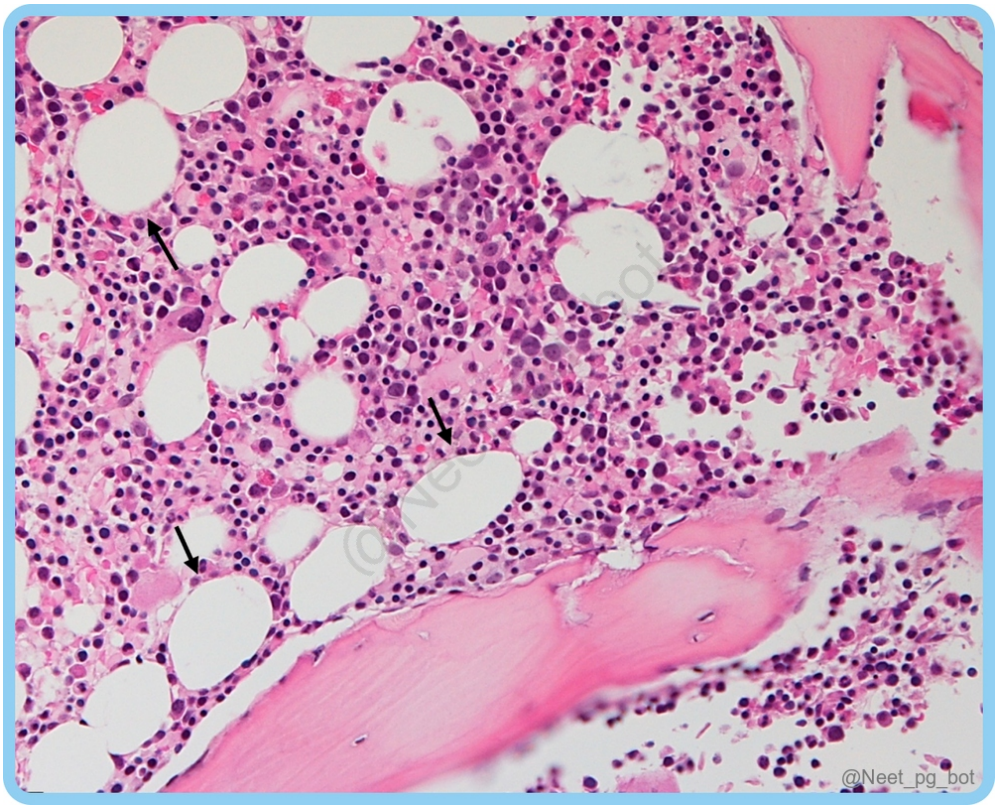
Correct Answer: A. 1:1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Two primary constituents within the bone marrow are hematopoietic cells and fat cells . This ratio tends to be more evenly distributed in adults , with around 50% of each cell type present. (1:1) (Option A) A child's marrow typically consists of 75% hematopoietic cells and 25% fat cells (3:1) for more production ability.

(Option D) An elderly individual's marrow cosists of 25% hematopoietic cells and 75% fat cells (1:3) because the production capability of body decreases with age (Option B)



References:

Atlas of Clinical Hematology, Chapter 4, Page 69

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 56-year-old male presents with pancytopenia and is scheduled for a bone marrow biopsy to determine the underlying cause. What is the most common site for performing a bone marrow biopsy in this patient? (Q845946)

A. Anterior Superior Iliac spine

B. Posterior Superior Iliac spine

C. Proximal femur

D. Proximal tibia

Correct Answer: B. Posterior Superior Iliac spine

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The posterior superior iliac spine (PSIS) is the preferred site for obtaining bone marrow in adults because it contains the most cellular marrow, there are no vital organs in close proximity, and it is a non-weight-bearing structure. If patient is obese and PSIS is difficult to palpate and locate then we can perform a bone marrow biopsy from Anterior Superior iliac spine (ASIS). In children, upper end of tibia is also commonly used for bone marrow biopsy.

References:

Atlas of Clinical Hematology Page 4

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: Identify the instrument shown in the image below. (Q845945)

A. Salah needle

B. Klima needle

C. Jamshidi needle

D. Quincke needle

Correct Answer: C. Jamshidi needle

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The Jamshidi Needle (T-shaped needle) is the most commonly used needle for bone marrow biopsy due to its design, which allows for minimal trauma and obtaining an intact core biopsy. The most common site for obtaining a sample for any bone marrow study is the Posterior superior iliac spine (PSIS). Salah needle (Option A) : This needle is used for only bone marrow aspiration and not for biopsy. Klima needle (Option B): The Klima needle is also used for bone marrow aspiration . It functions similarly to the Salah needle in aspirating bone marrow cells but is not the primary tool for obtaining a core biopsy Quincke needle (Option D): The Quincke needle is used primarily for lumbar puncture procedures (spinal taps) to collect cerebrospinal fluid (CSF). It is not used for bone marrow biopsies.

[17_Hematology_ Red Blood Cells] 066 Hemolytic Anemia-I — Quick Jump

Q1 (p. 2599) *Q2 (p. 2600)* *Q3 (p. 2601)* *Q4 (p. 2602)* *Q5 (p. 2607)* *Q6 (p. 2608)*
Q7 (p. 2609) *Q8 (p. 2610)* *Q9 (p. 2611)* *Q10 (p. 2613)* *Q11 (p. 2614)* *Q12 (p. 2616)*
Q13 (p. 2616) *Q14 (p. 2619)* *Q15 (p. 2620)* *Q16 (p. 2623)* *Q17 (p. 2624)*

Q1: A 30-year-old male presents with severe fatigue, shortness of breath, and dark urine after eating fava beans. He has a history of recurrent hemolytic anemia. On examination, he appears pale and jaundiced. Which statement correctly describes the pathogenesis of his condition? (Q845845)

A. Deficiency in an enzyme leads to oxidative stress-induced hemolysis.

B. Excessive production of glutathione leads to the destruction of red blood cells.

C. Decreased levels of reactive oxygen species (ROS) lead to decreased oxidative damage.

D. The severity is not influenced by environmental factors or dietary triggers like fava beans.

Correct Answer: A. Deficiency in an enzyme leads to oxidative stress-induced hemolysis.

■ *Listen to Audio 1*

Explanation: The clinical scenario is suggestive of glucose-6-phosphate dehydrogenase deficiency that leads to oxidative stress-induced hemolysis Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked recessive disorder characterised by a deficiency in the G6PD enzyme, which protects red blood cells from oxidative damage. This reduces the ability to generate NADPH via the pentose phosphate pathway and impairs glutathione regeneration, exacerbating oxidative stress and hemolysis. (Option B) When exposed to oxidative stressors, there is an imbalance between the production of reactive oxygen species (ROS) and antioxidants that neutralize them. This leads to oxidative damage to red blood cell membranes and proteins, resulting in hemolysis. (Option C) It presents with episodes of acute hemolytic anemia triggered by oxidative stressors such as infections, certain medications (e.g., antimalarials, sulfonamides), or ingestion of certain foods (e.g., fava beans). (Option D) Clinical manifestations include fatigue, pallor, jaundice, and dark urine (due to hemoglobinuria). The severity of hemolysis varies depending on the degree of enzyme deficiency and the magnitude of the oxidative insult, with some individuals experiencing life-threatening hemolytic crises. G6PD deficiency causes both intra and extravascular hemolysis.

@Neet_pg_bot

Q2: Which investigation is considered the most definitive for confirming the diagnosis of paroxysmal nocturnal hemoglobinuria (PNH)? (Q890597)

A. Ham’s acid hemolysis test

B. Bone marrow biopsy

C. High-performance liquid chromatography (HPLC)

D. Flow cytometry

Correct Answer: D. Flow cytometry

Explanation: Flow cytometry detects the absence or deficiency of GPI-anchored proteins (CD55, CD59) on RBCs and WBCs, providing a highly sensitive and specific diagnosis of PNH. It is considered the gold standard test.

Ham’s acid hemolysis test (Option A): This older test detects complement-mediated lysis and is not as sensitive or specific. Bone marrow biopsy (Option B): Useful to evaluate marrow failure or exclude other causes, but not diagnostic of PNH. High-performance liquid chromatography (HPLC) (Option C): Used for hemoglobinopathies, not PNH diagnosis.

@Neet_pg_bot

Q3: A 12-year-old girl presents for a regular health maintenance visit. There are no active complaints, and she has been feeling well. She has no chronic medical conditions and does not take any medications. She has a positive family history of thalassemia. Which of the following best confirms the diagnosis of thalassemia trait? (Q882123)

A. Elevated HbA2

B. Reticulocytosis

C. NESTROFT

D. Peripheral smear

Correct Answer: A. Elevated HbA2

Explanation: Option A: Elevated HbA 2 Elevated levels of HbA 2 are a specific feature of the thalassemia trait. The levels of HbF are relatively normal. Prominently increased levels of HbF are a particular feature of thalassemia major . Option B: Reticulocytosis Increased formation of reticulocytes occurs secondary to almost all hemolytic anaemias and is a very non-specific sign. It has no role in confirming the diagnosis of thalassemia trait. Option C: NESTROFT NESTROFT [Naked Eye Single Tube Red Cell Osmotic Fragility Test] is useful in screening thalassemia trait. Option D: Peripheral smear The peripheral smear findings can sometimes be used for screening purposes But these have no role in the confirmation of the thalassemia trait.

@Neet_pg_bot

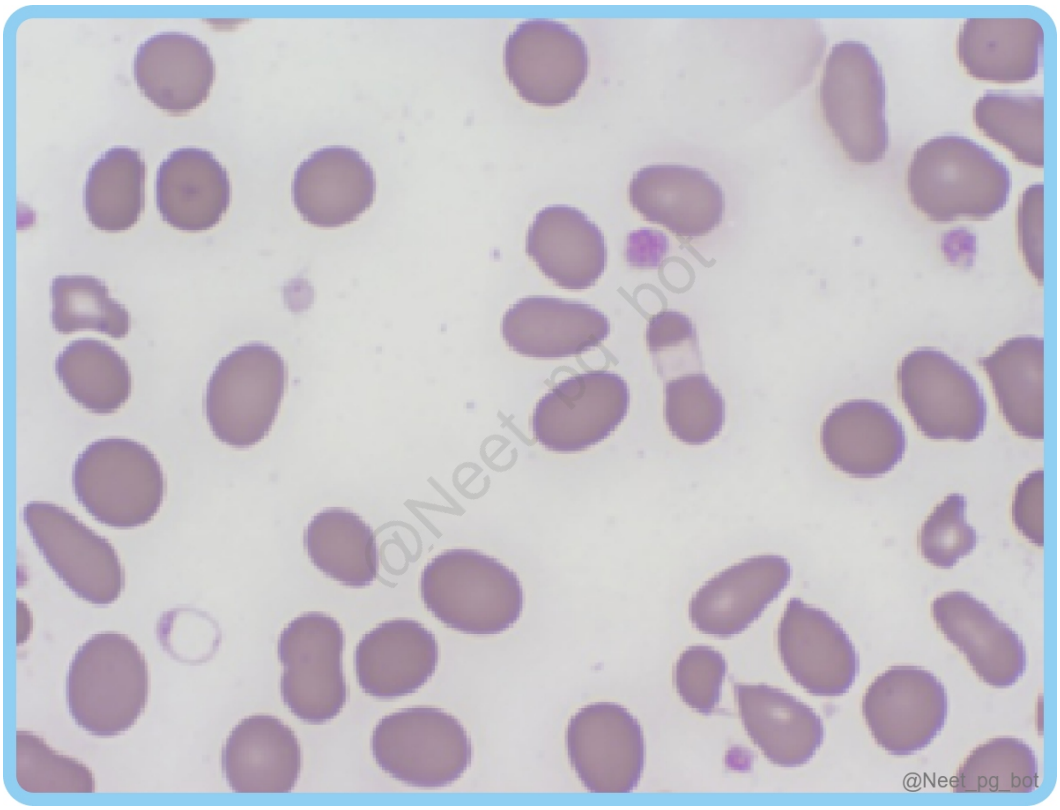
Q4: Match the following histopathological findings with their correct diagnosis: 1. A. Sickle Cell Anemia 2. B. Hereditary Spherocytosis 3. C. G6PD deficiency 4. D. Thalassemia (Q845892)

A. 1-C, 2-D, 3-A, 4-B

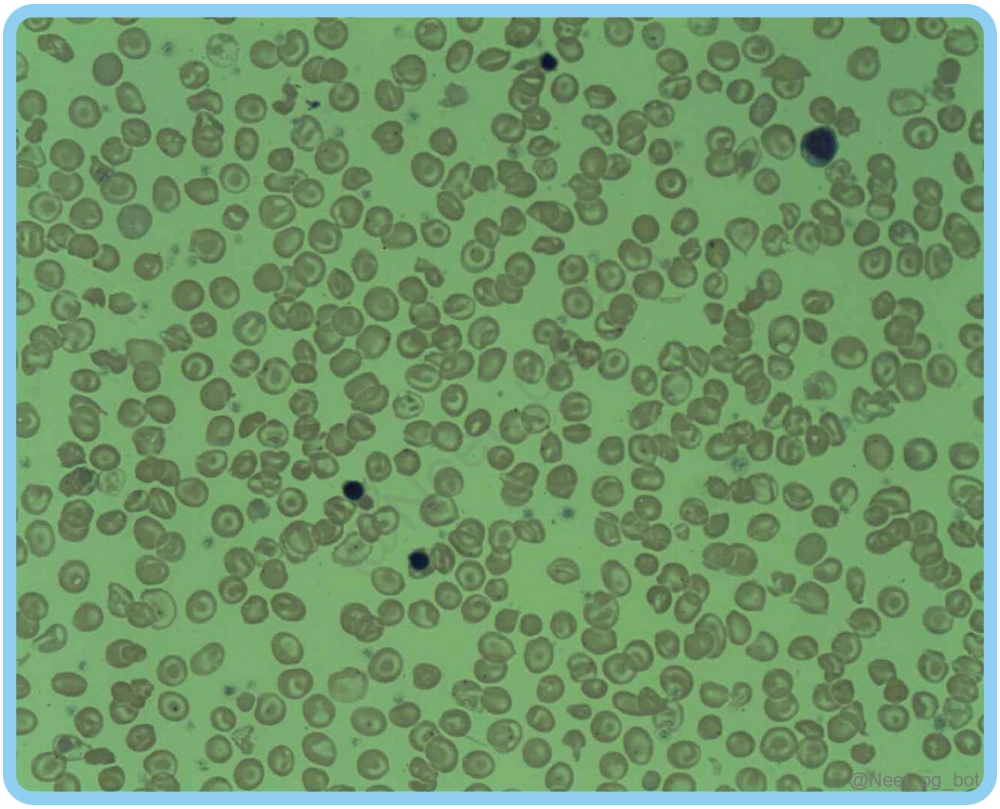
B. 1-D, 2-C, 3-B, 4-A

C. 1-B, 2-A, 3-D, 4-C

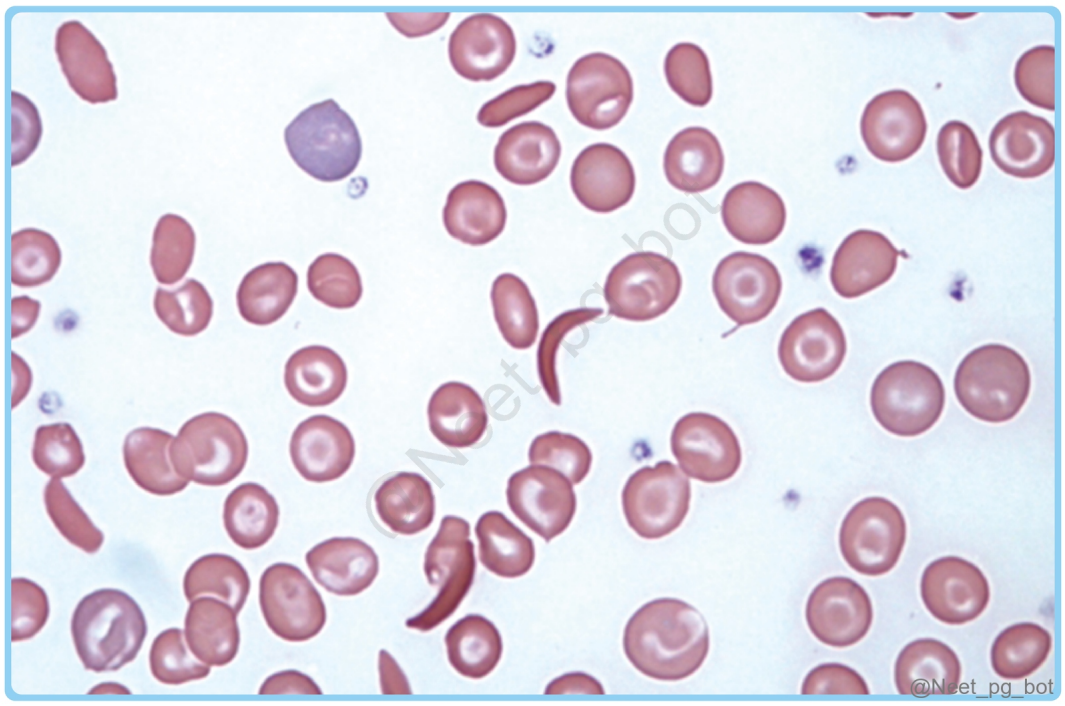
D. 1-A, 2-B, 3-C, 4-D

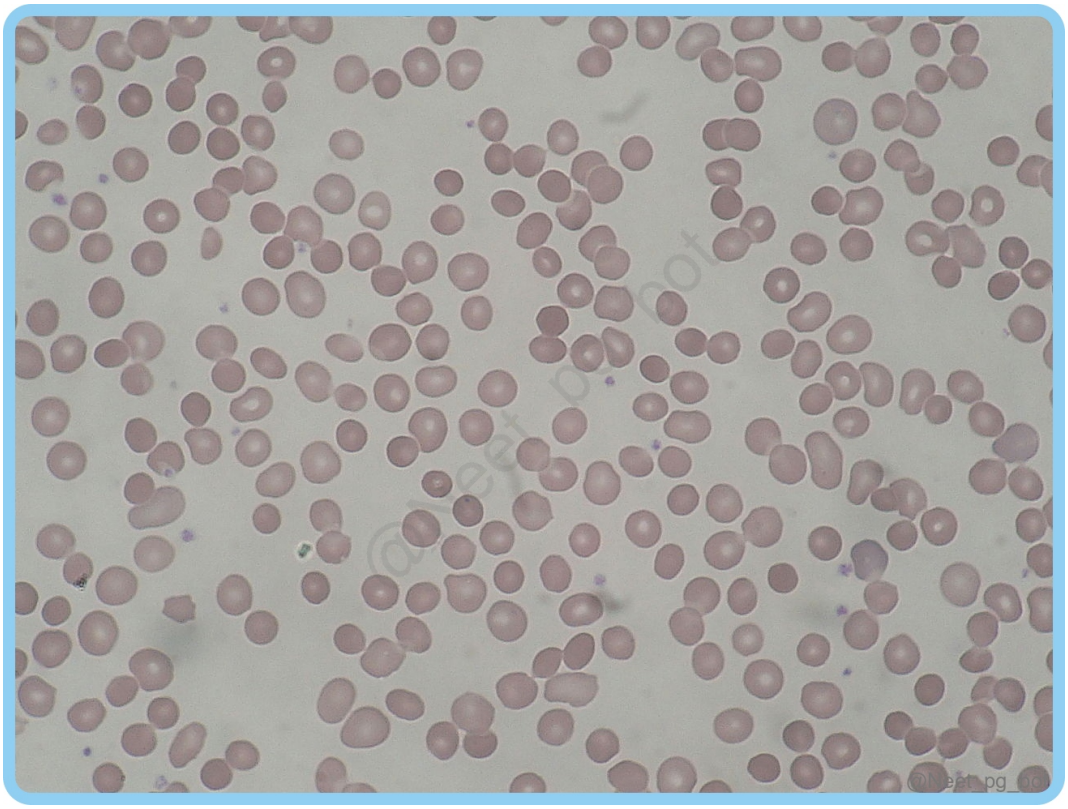


@Neet_pg_bot



@Neet_pg_bot



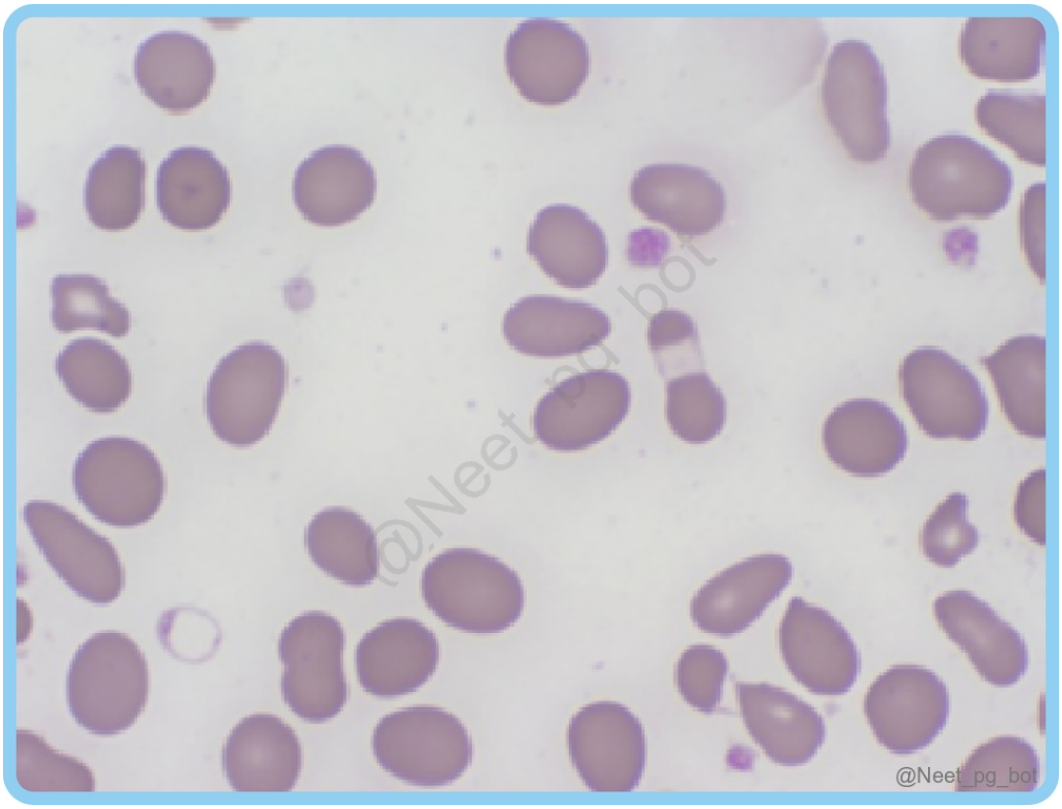


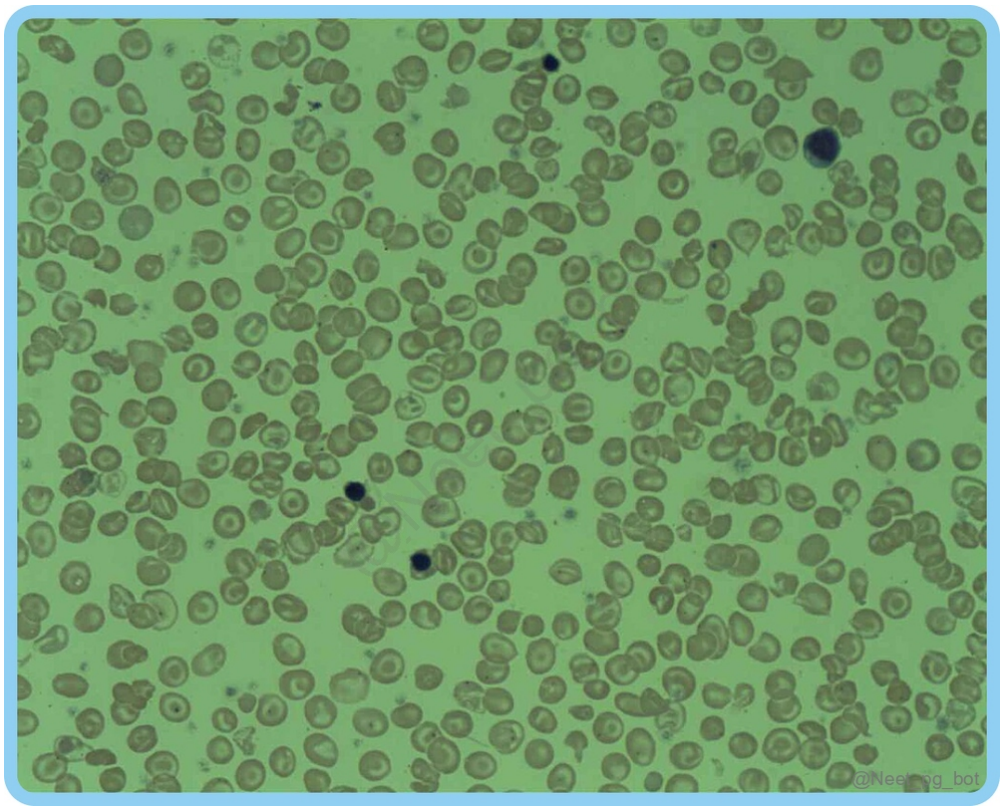
Correct Answer: A. 1-C, 2-D, 3-A, 4-B

■ *Listen to Audio 1*

Explanation: Red Blood Cell Abnormality Condition Reason 1. Bite cells C. G6PD deficiency Oxidative stress leads to denaturation of hemoglobin → Heinz bodies 2. Target cells D. Thalassemia ↓ Hemoglobin content in

RBCs → ↓ RBC volume → Surface area relatively unchanged → ↑ Surface area to volume ratio→ Altered lipid composition → ↑ Formation of membrane protrusions→ ↑ Membrane instability → ↓ Hemoglobin accumulation in certain membrane areas → Central area with hemoglobin, clear zone, outer ring Uneven distribution of hemoglobin and lipids → Characteristic "bull's-eye" appearance of Target cells 3. Sickle-shaped red blood cells A. Sickle Cell Anemia Abnormal Hemoglobin (HbS) →HbS molecules polymerize under low oxygen→RBCs become rigid and assume a sickle shape. 4. Spherocytes B. Hereditary Spherocytosis Genetic defect in RBC membrane protein(spectrin) ■ Loss of membrane surface area ■ RBCs become spherical





@Neet_pg_bot

Q5: Which of the following treatments is commonly used for Paroxysmal Nocturnal Hemoglobinuria? (Q845891)

A. Rituximab

B. Bevacizumab

C. Eculizumab

D. Trastuzumab

Correct Answer: C. Eculizumab

Explanation: Monoclonal antibody-Eculizumab is commonly used for Paroxysmal Nocturnal Hemoglobinuria. Mechanism of action: By binding to C5, eculizumab blocks the enzymatic activity of the C5 convertase, which is

responsible for cleaving C5 into two fragments, C5a and C5b. Inhibition of C5 cleavage prevents the formation of (Membrane Attack Complex), which is involved in cell lysis. It also lowers the risk of thrombosis by up to 90% Drawback: Increased risk of serious or fatal meningococcal infection The only cure is hematopoietic stem cell transplantation. Monoclonal Antibody Disorders Mechanism of Action Eculizumab Paroxysmal Nocturnal Hemoglobinuria (PNH) Inhibits complement protein C5, preventing terminal complement activation and reducing hemolysis. Rituximab (Option A) Non-Hodgkin lymphoma Chronic lymphocytic leukemia (CLL) Rheumatoid arthritis Idiopathic thrombocytopenic purpura (ITP) Targets CD20 antigen on B cells, leading to B cell depletion and modulation of immune response. Bevacizumab (Option B) Colorectal cancer Lung cancer Renal cell carcinoma Age-related macular degeneration Targets vascular endothelial growth factor (VEGF), inhibiting angiogenesis and tumor growth. Trastuzumab (Option D) Breast cancer Gastric cancer Targets HER2/neu receptor on cancer cells, inhibiting cell proliferation and promoting antibody-dependent cellular cytotoxicity.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which of the following is the most common cause of death in Paroxysmal Nocturnal Hemoglobinuria? (Q845890)

A. Pancytopenia

B. Acute Myeloid Leukemia

C. Hepatic vein thrombosis

D. Myelodysplastic syndrome

Correct Answer: C. Hepatic vein thrombosis

Explanation: Hepatic vein thrombosis is the most common cause of death in PNH. Paroxysmal nocturnal hemoglobinuria (PNH) is a disease that results from acquired mutations in the phosphatidylinositol glycan complementation group A gene (PIGA), an enzyme that is essential for the synthesis of certain membrane-associated complement regulatory proteins. PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: (1) decay-accelerating factor, or CD55; (2) membrane inhibitor of reactive lysis, or CD59; and (3) C8-binding protein Of these factors, the most important is CD59, a potent inhibitor of C3 convertase that prevents the spontaneous activation of the alternative complement pathway. Clinical Features: Hemolysis at night (slight decrease in blood pH during sleep, which increases the activity of complement) Anemia - usually mild to moderate in severity. Complications: Thrombosis is the leading cause of disease-related death in individuals with PNH. About 40% of patients suffer from venous thrombosis, often involving the hepatic, portal, or cerebral veins. Diagnosis: Flow cytometry - for detecting red cells that are deficient in GPI-linked proteins such as CD59. Treatment: Eculizumab (prevents the conversion of C5 to C5a) Drawbacks: high cost and an increased

risk of serious or fatal meningococcal infection Definitive treatment: Hematopoietic stem cell transplantation Complications of PNH Bone marrow failure Pancytopenia (Option A) Aplastic anemia Thrombosis (Most common cause of death in PNH) Cerebral vein thrombosis Hepatic and portal vein thrombosis - Budd Chiari Syndrome Clonal expansion Acute Myeloid Leukemia(AML). (Option B) Myelodysplastic syndrome (Option D)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following defects is seen in paroxysmal nocturnal hemoglobinuria? (Q845889)

A. Spectrin

B. CD 45 and CD 95

C. G6PD enzyme

D. PIGA gene

Correct Answer: D. PIGA gene

Explanation: Paroxysmal nocturnal hemoglobinuria is due to a mutation in the PIGA gene. Pathogenesis of PNH: PNH is caused by an acquired mutation in the PIGA gene leading to defective synthesis of (GPI) anchors. GPI anchors are essential for attaching certain proteins to the cell surface, including CD55 (decay-accelerating factor), CD59 (membrane inhibitor of reactive lysis), and C8-binding protein. (Option B) These proteins regulate the complement system and inhibit the formation of the membrane attack complex (MAC) that leads to cell lysis. In PNH, the deficiency of these regulators increases susceptibility to complement-mediated hemolysis. Subsequent lysis by the MAC leads to intravascular hemolysis Hemoglobin from lysed RBCs appears in the urine (hemoglobinuria) and is more pronounced during periods of increased complement activation, such as at night (Nocturnal) or stress. Clinical manifestations: Fatigue, weakness, dyspnea Pallor due to anemia Hemoglobinuria may cause urine to appear dark or cola-colored. Abdominal pain, thrombosis (due to platelet activation and endothelial injury)

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 638, 640, 648.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following statements regarding Paroxysmal Nocturnal Hemoglobinuria (PNH) is true? (Q845888)

A. Causes extravascular hemolysis

B. Splenectomy would be beneficial

C. Causes hemolysis only at night

D. Acquired intracorpuscular defect

Correct Answer: D. Acquired intracorpuscular defect

Explanation: The true statement regarding PNH is that it is an acquired intracorpuscular defect. PNH is the "ONLY" acquired intracorpuscular defect (defect within the RBCs) among hemolytic anemia, making them susceptible to destruction by the complement system. It causes intravascular hemolysis due to complement activation that attacks RBCs. (Option A) Hence, splenectomy, which would be beneficial in some cases of extravascular hemolysis, would not be of any use in PNH. (Option B) Contrary to the name, only 25% of cases show paroxysmal and nocturnal hemolysis. (Option C) Red cell lysis at night is explained by a slight decrease in blood pH during sleep, which increases complement activation. Chronic hemolysis without dramatic

hemoglobinuria is more typical.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 636, 648

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 45-year-old male presents to the emergency department with symptoms of acute hemolytic anemia. A methemoglobin reduction test is performed, revealing a delayed rate of methemoglobin reduction. What is the underlying principle of the above-mentioned screening test used to diagnose G6PD deficiency? (Q845846)

A. Measures the levels of methemoglobin in red blood cells.

B. Evaluates the ability of red blood cells to reduce methemoglobin back to haemoglobin.

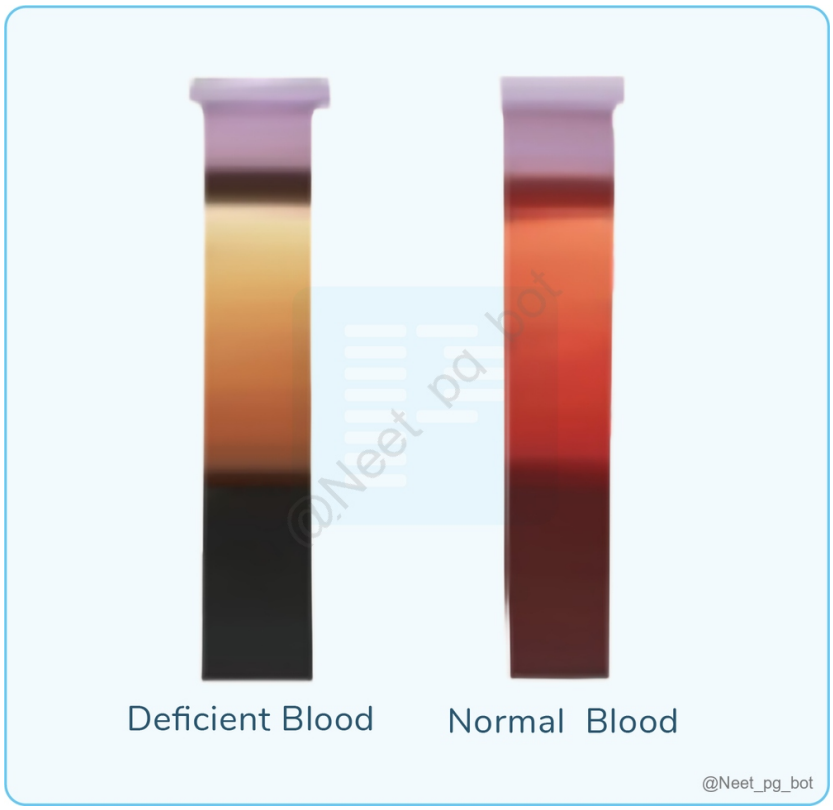
C. Detects G6PD activity by measuring the rate of reduction of a fluorescent dye.

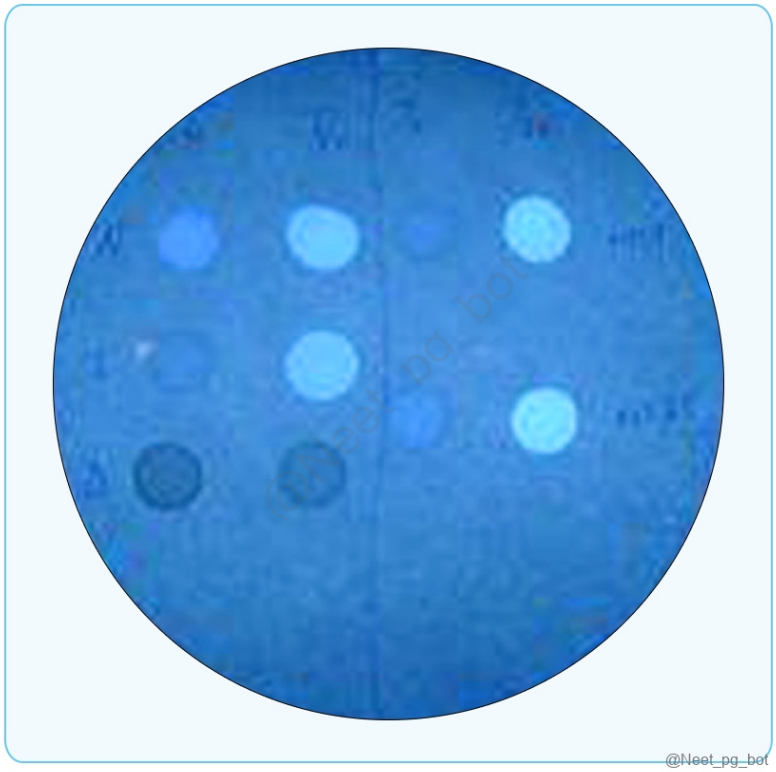
D. Measures the actual activity levels of the G6PD enzyme.

Correct Answer: B. Evaluates the ability of red blood cells to reduce methemoglobin back to haemoglobin.

■ *Listen to Audio 1*

Explanation: Purpose of Methemoglobin Reduction Test : Used to detect glucose-6-phosphate dehydrogenase (G6PD) deficiency. Measures the ability of red blood cells to convert methemoglobin back to hemoglobin. Helps assess the enzymatic activity crucial for protecting cells from oxidative stress. Mechanism in G6PD Deficiency : Individuals with G6PD deficiency have reduced enzyme activity. Red blood cells are more vulnerable to oxidative damage. Impaired reduction of methemoglobin indicates decreased G6PD function. Testing Procedure : The blood sample is exposed to a chemical that induces methemoglobin formation. The rate of reduction back to hemoglobin is measured. The slower reduction compared to normal suggests G6PD deficiency. Clinical Application : Used to confirm diagnosis in patients suspected of having G6PD deficiency. Helps guide management decisions in conditions where oxidative stress can trigger hemolysis. Provides insight into the enzymatic function critical for maintaining red blood cell integrity. Other tests used for screening include: Fluorescent Spot Test (FST): This is a quick screening test that detects G6PD activity by measuring the rate of reduction of a fluorescent dye. (Option C) NADPH is autofluorescent In normal cases: fluorescence is seen. In G6PD deficiency: Fluorescence not seen Quantitative Enzyme Assays: These tests measure the actual activity levels of G6PD enzyme in the blood. They provide a more accurate assessment but are often more expensive and time-consuming. (Option D)





References:

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2555344/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following sequences correctly represents the progression of hemoglobin handling in the body during intravascular hemolysis (IVH)? A. Hemoglobin binds to albumin, forming meth albuminemia B. Hemoglobin combines with haptoglobin C. Haptoglobin saturation and hemoglobin binding to hemopexin. D. RBC lysis causes hemoglobin to leak out. (Q845837)

A. D → B → C→ A

B. D → B → A → C

C. D → C → A → B

D. D → C → B → A

Correct Answer: A. D → B → C→ A

■ *Listen to Audio 1*

Explanation: Intravascular hemolysis involves the destruction of RBCs within blood vessels. Hemoglobin(Hb) is released and free Hb in the blood is toxic. Several mechanisms come into play to sequester this free Hb as shown below. Clinical and laboratory findings include: Hemoglobinemia Hemoglobinuria Hemosiderinuria - Hemoglobin filtered into the urine → absorbed by renal tubular cells → broken down to iron→ accumulated as hemosiderin→ shedding of tubular cells → hemosiderinuria. Decreased serum haptoglobin Increased LDH

@Neet_pg_bot

Q11: A 6-year-old child presents with a history of recurrent episodes of jaundice, fatigue, and abdominal pain. Physical examination reveals splenomegaly. The child's blood work shows the presence of spherocytes on the peripheral blood smear. An osmotic fragility test is performed. Identify the correct statement about this test. (Q845844)

A. It is a diagnostic test.

B. In thalassemia patients, low osmotic fragility leads to a right shift on the graph.

C. In HS patients, high osmotic fragility leads to a right shift on the graph.

D. Normally, RBC lysis begins at 0.7% NaCl.

Correct Answer: C. In HS patients, high osmotic fragility leads to a right shift on the graph.

■ *Listen to Audio 1*

Explanation: The correct statement regarding the osmotic fragility test is high osmotic fragility leads to a right shift on the graph in patients with HS. Osmotic Fragility Test : The osmotic fragility test measures the resistance of RBCs to hemolysis in hypotonic saline . It is mainly used to diagnose membrane disorders , especially Hereditary spherocytosis . Principle: When RBCs are placed in hypotonic saline , water enters → cells swell → burst (hemolysis). Spherocytes → burst early → ↑ osmotic fragility Target cells / thalassemia → burst late → ↓ osmotic fragility Steps of an osmotic fragility test: Prepare serial dilutions of NaCl (0.85% → 0.0%) Add equal amount of patient blood to each tube Incubate ~30 minutes Centrifuge tubes Measure hemolysis (supernatant Hb color / spectrophotometer) Plot graph: % hemolysis vs NaCl concentration In the osmotic fragility curve, the x-axis represents NaCl concentration and the y-axis represents % Hemolysis Normal Curve: Hemolysis starts at 0.45% NaCl and completes at 0.30% NaCl (OptionD) Right Shift (Increased Fragility): Cells lyse earlier (at higher NaCl concentration) due to decreased RBC surface area Seen in Hereditary spherocytosis (Option C) , Autoimmune hemolytic anemia Left Shift (Decreased Fragility): Cells lyse later (at lower NaCl concentration) due to increased RBC surface area Seen in Thalassemia (Option B) , Iron deficiency anemia, Sickle cell anemia and Liver disease However, this test is just a screening method, and the Eosin-5-maleimide (EMA) binding test is the gold standard for diagnosing hereditary spherocytosis. (Option A)

https://www.sciencedirect.com/topics/immunology-and-microbiology/osmotic-fragility

https://emedicine.medscape.com/article/2085814

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following is not a typical change in blood indices in patients with hereditary spherocytosis? (Q845843)

A. MCV decreases

B. MCHC increases

C. RDW decreases

D. Hemoglobin decreases

Correct Answer: C. RDW decreases

■ *Listen to Audio 1*

Explanation: The RDW (red cell distribution width) increases, not decreases, in hereditary spherocytosis due to anisocytosis- a heterogeneous population of red blood cells, including both normal-sized and smaller, denser spherocytes. The MCV decreases due to the presence of smaller, more dense red blood cells (spherocytes). (Option A) The MCHC increases due to dehydration of RBCs, leading to a higher concentration of hemoglobin per unit volume of the cell. (Option B) Hemoglobin levels may decrease in hereditary spherocytosis due to the hemolysis, but they do not increase. (Option D) Blood indices in hereditary spherocytosis: Reduced Hemoglobin Reduced MCV Normal or increased MCH Increased MCHC due to water loss Increased RDW (variation in size) Increased reticulocyte count

@Neet_pg_bot

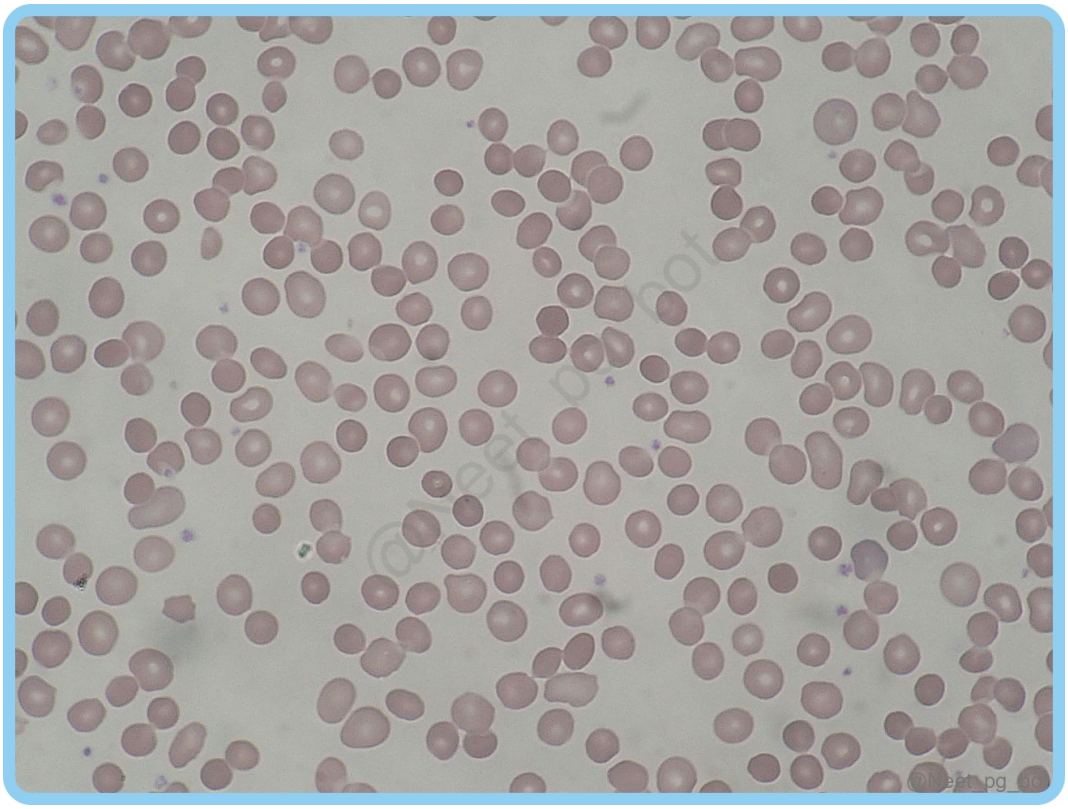
Q13: A 10-year-old child presents with a history of recurrent episodes of jaundice, fatigue, and abdominal pain. Physical examination reveals splenomegaly, and peripheral blood smear shows the following picture. Coomb's test is negative. What is the most likely diagnosis? (Q845842)

A. Hereditary spherocytosis

B. Autoimmune hemolytic anemia

C. Glucose-6-phosphate dehydrogenase (G6PD) deficiency

D. Thalassemia



Correct Answer: A. Hereditary spherocytosis

Listen to Audio 1

Explanation: The given clinical scenario and peripheral smear showing spherocytes most likely suggest a diagnosis of hereditary spherocytosis. Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. It has an autosomal dominant inheritance(75%) characterized by ankyrin mutation and an autosomal recessive inheritance characterized by spectrin mutation. Pathophysiology of hereditary spherocytosis: The most specific morphologic finding is spherocytosis: Dark-staining (hyperchromic) spherocytes lacking the central zone of pallor. Other features include reticulocytosis. The characteristic clinical features are anemia, splenomegaly, jaundice, and an increased risk of gallstones. Severity ranges from asymptomatic to severe hemolytic anemia requiring transfusions. Early complications include neonatal jaundice and hemolytic crises. Late complications include gallstones and rarely iron overload. Autoimmune hemolytic anemia (AIHA) (Option B): AIHA involves antibodies targeting red blood cells and typically has a positive Coombs test, which is not mentioned. It usually presents with acute rather than recurrent hemolysis. Glucose-6-phosphate dehydrogenase (G6PD) deficiency (Option C): It is characterized by bite cells, not hyperchromic spherocytes lacking a central pallor. Thalassemia (Option D): It is characterized by target cells rather than sperocytes on peripheral smear.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 638-639

↑ *Back to this question in Part A*

@Neet_pg_bot

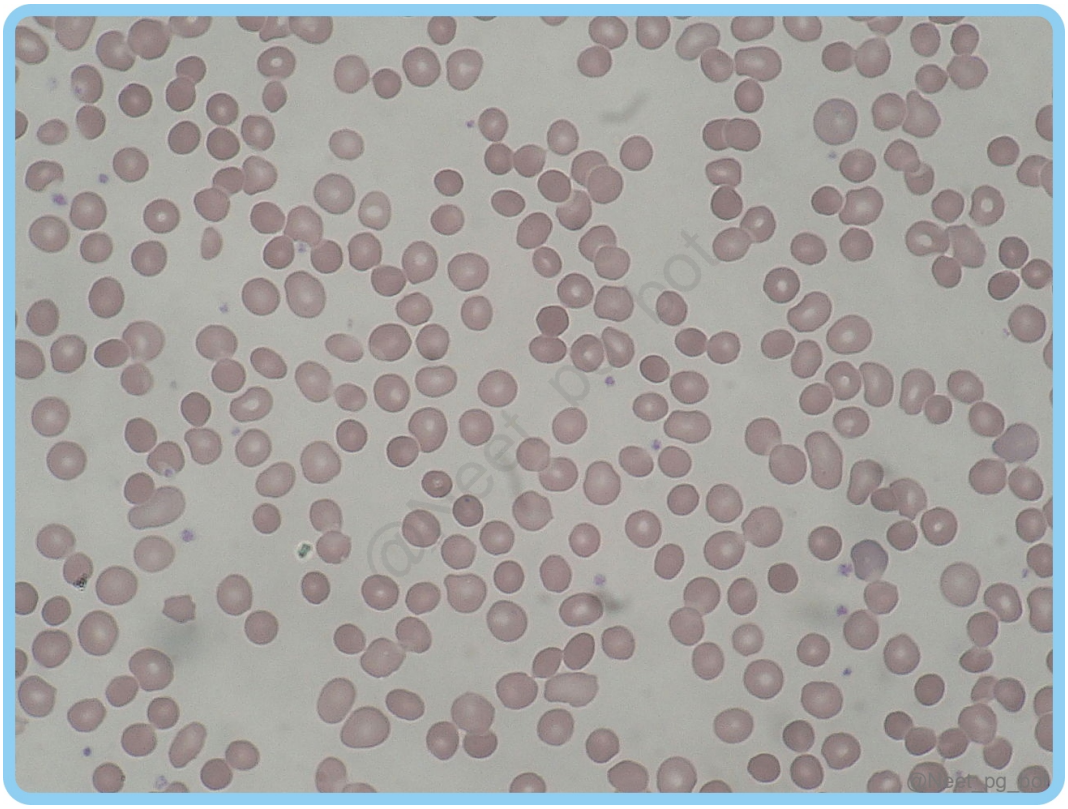
Q14: A 28-year-old male presents with fatigue, jaundice, splenomegaly, and anemia with elevated MCHC. A peripheral smear is done which is shown below. What is the most common protein defect in this condition? (Q845841)

A. Spectrin

B. Band 3 protein

C. Ankyrin

D. Glycophorin A



Correct Answer: C. Ankyrin

■ *Listen to Audio 1*

Explanation: The peripheral smear in this scenario indicates hereditary spherocytosis, and ankyrin is the most common or important protein defective in hereditary spherocytosis. IMPORTANT PROTEINS IN RBC MEMBRANE: Spectrin: Responsible for RBC stability and biconcave shape (Option A) Ankyrin: The most important or common protein defective in hereditary spherocytosis. Band 3 protein (Option B) Glycophorin A:

The most abundant protein present in the RBC membrane , rarely(almost never) undergoes mutation in hereditary spherocytosis (Option D) Actin, Band 4.1, and Band 4.2 Proteins present at the head end of spectrin: Ankyrin, Band 4.2, Band 3 Proteins present at the tail end of spectrin: Actin, Band 4.1, Glycophorin A

[17_Hematology_ Red Blood Cells] 067 Hemolytic Anemia-Ii — Quick Jump

Q1 (p. 2626)	*Q2 (p. 2627)*	*Q3 (p. 2627)*	*Q4 (p. 2628)*	*Q5 (p. 2630)*	*Q6 (p. 2630)*
Q7 (p. 2632)	*Q8 (p. 2633)*	*Q9 (p. 2634)*	*Q10 (p. 2635)*	*Q11 (p. 2636)*	*Q12 (p. 2639)*
Q13 (p. 2639)	*Q14 (p. 2641)*	*Q15 (p. 2642)*	*Q16 (p. 2643)*		

Q1: A 1-year-old boy, previously healthy until five months ago, presents with a three-hour history of severe swelling and tenderness of hands and feet. The family history is significant for an older brother who had transfusion-dependent anaemia and died of pneumococcal sepsis at the age of 6. Which haemoglobin molecule composition protected him from developing symptoms until recently? (Q845914)

A. α2γ2

B. α2β2

C. α2δ2

D. α2ε2

Correct Answer: A. α2γ2

■ *Listen to Audio 1*

Explanation: The given scenario is most likely suggestive of sickle cell anaemia. This child did not present with the disease earlier because of the presence of fetal haemoglobin (HbF) containing α2γ2 HbF has a high oxygen affinity, which helps maintain oxygen concentration and prevent hypoxia. (Sickle cells are formed during hypoxia) HbF inhibits the polymerisation of HbS more effectively than HbA , so infants with sickle cell disease typically remain asymptomatic until 5 or 6 months of age when HbF levels naturally decline. Normal Adult Hemoglobin: HbA (α■β■): ~95% of total Hb HbA■ (α■δ■): <3% of total Hb HbF (α■γ■): Fetal hemoglobin, normally <1% in adults Hydrops fetalis (Hb Barts) – α■-thalassemia: Cause: Deletion of all four α-globin genes → no α chains. Effect: Fetal hemoglobin (α■γ■) cannot form. Compensation: Excess γ chains form γ■ tetramer (Hb Barts) . Consequence: High oxygen affinity → poor tissue oxygen delivery → hydrops fetalis. α■β■ & α■δ■: Variants of normal adult Hb (Options B & C) α■ε■ (Hb Gower-1) & ζ■ε■ (Hb Gower-2): Embryonal hemoglobins (Option D)

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 645
https://www.sciencedirect.com/topics/neuroscience/hemoglobin-chain

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Which of the following points best describes the pathogenesis of sickle cell disease (SCD)? Select all that apply. Nonsense point mutation in 6th position of β-globin chain Mutation promotes the polymerization of oxygenated hemoglobin Glutamic acid is changed to valine at the 6th position of β-globin chain Presence of HbF and HbS is protective against SCD. Patients heterozygous for HbS have more severe diseases than homozygous HbS. Individuals with coexistent α-thalassemia have less severe disease. (Q845915)

A. 1, 5, 4, and 6

B. 3, 4, and 6

C. 2, 5, and 6

D. 1, 2, 5, and 6

Correct Answer: B. 3, 4, and 6

Explanation: Sickle cell disease is caused by a missense mutation in the 6th position of the β-globin chain. This mutation replaces glutamic acid with valine, promoting polymerization of deoxygenated hemoglobin. Heterozygous individuals (HbAS) have about 40% HbS and the rest HbA, reducing polymerization and disease severity. Homozygous individuals have more HbS and more severe disease. HbF inhibits HbS polymerization better than HbA, keeping infants asymptomatic until 5-6 months of age. Intracellular parasites consume oxygen and lower pH, promoting sickling and rapid clearance of infected HbAS cells, reducing parasite load. Coexistent α-thalassemia reduces Hb synthesis, resulting in milder disease.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 641- 642

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following conditions does not lead to sickling of RBCs in patients with sickle cell disease? (Q845917)

A. Dehydration

B. Hypoxia

C. Increased pH

D. Decreased HbF

Correct Answer: C. Increased pH

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Among the given options, increased pH/alkalosis does not lead to sickling, but rather decreased pH or acidosis. Factors affecting sickling: Dehydration - Higher HbS concentrations and increased MCHC due to intracellular dehydration enhance the likelihood of HbS aggregation and polymerization during deoxygenation, facilitating sickling. Hypoxia - Hypoxia induces sickling of cells Less pH (acidic environment) : A decrease in pH reduces hemoglobin's oxygen affinity, increasing deoxygenated HbS and enhancing the tendency for sickling. Decreased fetal hemoglobin (HbF) - HbF has high affinity for oxygen. Decrease in HbF will cause hypoxia, leading to sickling. Amount of HbS : Homozygous>heterozygous Interaction of HbS with the other types of hemoglobin : HbSC> HbSA/HbSA2 > HbSF (Fetal hemoglobin has more affinity towards oxygen, thus reducing sickling)

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 641 - 642

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 28-year-old man who has received blood transfusions on some occasions and has experienced severe pain in his hands and legs came to follow up. He is currently fine with no complaints and has been receiving treatment that has increased his HbF levels for the past 5 years. Which of the following would be seen in the peripheral smear of this patient? (Q845919)

A. Bite cells

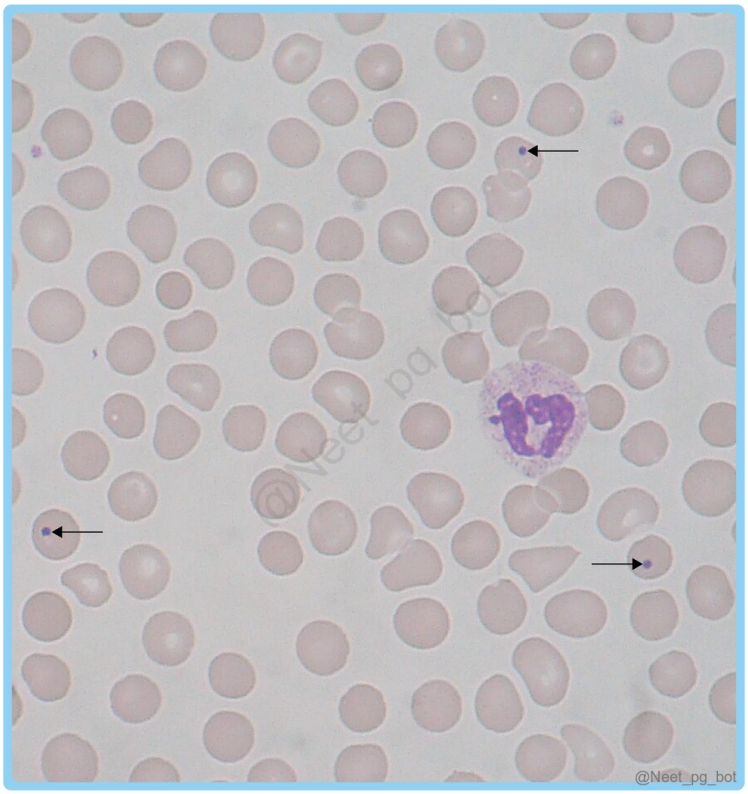
B. Heinz bodies

C. Howell-Jolly bodies

D. Spherocytes

Correct Answer: C. Howell-Jolly bodies

Explanation: Howell-Jolly bodies are nuclear remnants seen in red cells when the spleen is nonfunctional or absent, as in sickle cell disease with autosplenectomy caused by repeated infarctions. Bite cells and Heinz bodies indicate G6PD deficiency, not sickle cell disease. (Options A and B) . Spherocytes are typical of autoimmune hemolytic anemia or hereditary spherocytosis. (Option D) . RBC Shape Defects (Poikilocytosis): RBC Shape Morphology Associated Conditions Spherocytes Small, round, no central pallor Hereditary spherocytosis, Autoimmune hemolytic anemia Elliptocytes / Ovalocytes Elliptical/oval cells Hereditary elliptocytosis, Iron deficiency anemia Target cells (Codocytes) Central Hb with ring Thalassemia, Liver disease, Sickle cell disease Sickle cells Crescent-shaped Sickle cell disease Schistocytes Fragmented RBCs Disseminated intravascular coagulation, Thrombotic thrombocytopenic purpura, Hemolytic uremic syndrome Acanthocytes (spur cells) Irregular spiky projections Liver disease, Abetalipoproteinemia Echinocytes (burr cells) Regular projections Uremia, CKD Tear drop cells (Dacrocytes) Tear-shaped Myelofibrosis, marrow infiltration Bite cells “Bite-like” defects Glucose-6-phosphate dehydrogenase deficiency Helmet cells RBC fragments Microangiopathic hemolysis Stomatocytes Slit-like central pallor Hereditary stomatocytosis, liver disease Rouleaux formation Stacked RBCs Multiple myeloma, chronic inflammation WBC Disorders (Morphology and Functional Abnormalities): Disorder Morphology Associated Condition Hypersegmented neutrophils >5 lobes Megaloblastic anemia Hyposegmented neutrophils (Pelger-Huët anomaly) Bilobed nucleus Congenital or acquired (MDS) Toxic granulation Prominent granules Severe infection Döhle bodies Blue cytoplasmic inclusions Infection, burns Leukemoid reaction Marked neutrophilia Severe infection Neutropenia ↓ neutrophils Drugs, infections, aplastic anemia



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 642

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Match the complications of sickle cell disease (SCD) with their corresponding crises: Complications Crises 1. Acute chest syndrome A. Vaso-occlusive crises 2. Parvovirus B19 infection B. Aplastic crises 3. Splenic enlargement C. Sequestration crisis 4. Splenic fibrosis (Q845921)

A. 1-A, 2-B, 3-C, 4-C

B. 1-A, 2-B, 3-C, 4-A

C. 1-A, 2-A, 3-B, 4-C

D. 1-A, 2-C, 3-B, 4-A

Correct Answer: B. 1-A, 2-B, 3-C, 4-A

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Vaso-occlusive crises include: Splenic fibrosis: Because the blood supply is hampered by sickle cells, the spleen undergoes repeated infarctions. Over time, this causes progressive shrinkage of the spleen (autosplenectomy), with normal splenic tissue being replaced by fibrosis. Acute chest syndrome: Affecting the lungs, it presents with fever, cough, chest pain, and pulmonary infiltrates, potentially leading to life-threatening hypoxemia. Bone crises Renal papillary necrosis Cerebrovascular accident Priapism Autosplenectomy Aplastic crisis in SCD Cause: Parvovirus B19 infects erythroid precursors → temporarily halts RBC production Occurs in: Patients with pre-existing hemolytic anemia (HS, sickle cell, thalassemia) Lab features: Severe anemia, reticulocytopenia , WBC/platelets normal or slightly low, peripheral smear shows underlying hemolysis Sequestration crisis in SCD - Sequestration crisis affects children with intact spleens, characterized by significant trapping of sickled red cells, resulting in swift splenic enlargement , hypovolemia, and occasionally shock.

↑ *Back to this question in Part A*

@Neet_pg_bot

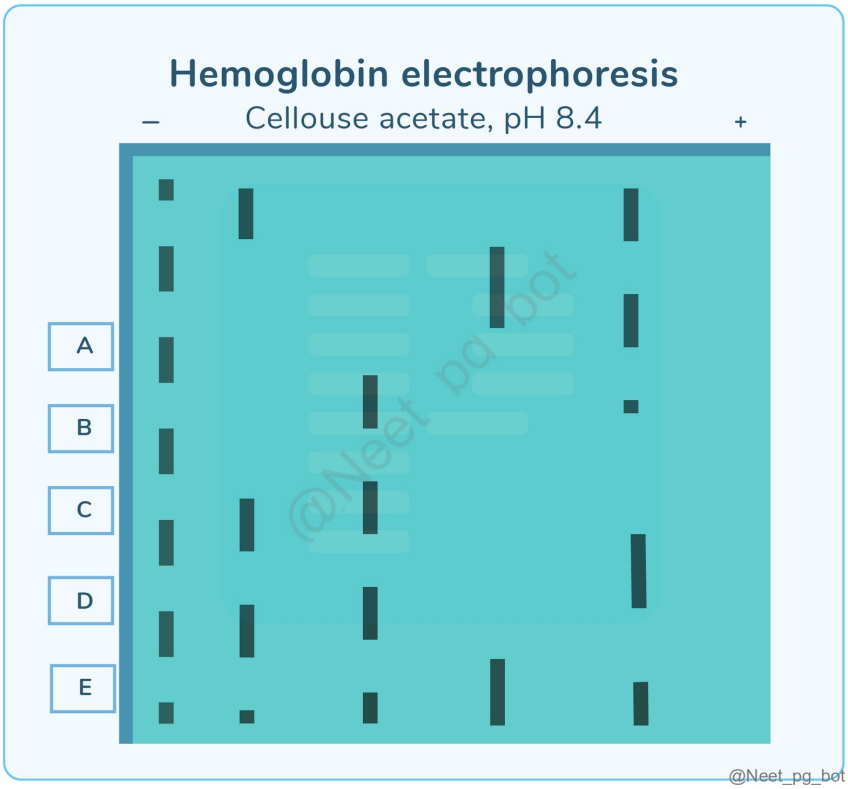
Q6: A 12-year-old girl presents to her primary care physician with complaints of fatigue, pallor, and jaundice. Peripheral smear showed sickling of RBCs. What is the most likely electrophoretic pattern seen in this patient? (Q845923)

A. A

B. B

C. C

D. D



Correct Answer: B. B

Explanation: The patient's clinical presentation with fatigue, pallor, jaundice, and the presence of sickle cells on peripheral blood smear are consistent with sickle cell anemia . The electrophoretic pattern seen in this patient would be B. Electrophoresis is a technique that separates hemoglobin variants based on their electric charge and solubility in different media. It is performed using cellulose acetate at alkaline pH (8.4) and citrate agar at acidic pH (6.0–6.2). High-performance liquid chromatography (HPLC) is the gold standard for diagnosing hemoglobinopathies.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: Which of the following statements regarding the different types of thalassemia is correct? Thalassemia major - mutations in both alleles of the HBB gene - impaired production of beta-globin chains. Beta-thalassemia trait - mutations in one allele of the HBB gene - reduced beta-globin chain synthesis. Alpha-thalassemia trait - deletions in one or more alpha-globin genes - decreased production of alpha-globin chains. Thalassemia intermedia - mutations affecting both alpha and beta-globin genes - severe anemia requiring regular blood transfusions (Q845925)

A. 1, 2, and 4

B. 2, 3, and 4

C. 1, 3 and 4

D. 1, 2, and 3

Correct Answer: D. 1, 2, and 3

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Statements 1, 2, & 3 are correct. Statement 4 is wrong as thalassemia intermedia does not require regular blood transfusions. A thalassemia is a group of inherited blood disorders characterized by abnormal hemoglobin production, leading to anemia. Genetic defects in thalassemia involve mutations, insertions, or deletions in the genes responsible for producing hemoglobin chains This results in either decreased or absent production of alpha or beta-globin chains. These defects are inherited in an autosomal recessive manner. There are two main types: alpha-thalassemia and beta-thalassemia. 1. Alpha-thalassemia: Deletion of one or more genes out of the total four genes, which leads to decreased production of alpha-globin chains. 2. Beta-thalassemia: Arising from mutations in the beta-globin gene located on chromosome 11. Subtypes include: Beta-thalassemia minor (trait): Reduced beta-globin chain production due to mutations in one allele of the HBB gene. Beta-thalassemia major: Mutations in both alleles of the HBB gene, leading to severe anemia requiring lifelong transfusions and treatment. Thalassemia intermedia: Milder variants and unusual forms of β-thalassemia, also include alpha globin defects in some cases. But the cases does not require regular blood transfusions

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 644-647

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 25-year-old male presents with fatigue, jaundice, and splenomegaly. Laboratory investigations reveal microcytic hypochromic anemia with increased levels of serum iron and ferritin. Further genetic analysis reveals a mutation in the HBB gene. Upon histopathological examination of the bone marrow, there is evidence of erythroid hyperplasia with ineffective erythropoiesis. Which mutation in the HBB gene is most likely responsible for the patient's presentation? (Q845927)

A. Substitution of cytosine for guanine at position 8 in the promoter region of the HBB gene.

B. Substitution of one nucleotide at position +8 in the coding region of the HBB gene.

C. Splicing mutation resulting in the removal of intervening sequence-IVS1-5 G-> C in the HBB gene.

D. Insertion of a nucleotide at position 54 in the coding region of the HBB gene

Correct Answer: C. Splicing mutation resulting in the removal of intervening sequence-IVS1-5 G-> C in the HBB gene.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Among the given options, Splicing mutation resulting in the removal of intervening sequence-IVS1-5 G-> C in the HBB gene leads to β-thalassemia: This mutation affects the splicing process by altering the consensus splice site, leading to aberrant splicing and abnormal mRNA transcripts, contributing to β-thalassemia. Beta-thalassemia mutations are diverse and can occur throughout the HBB gene, which encodes the beta-globin subunit of hemoglobin. These mutations can affect various aspects of beta-globin production, including transcription, splicing (most common) , mRNA stability, and translation. Splicing is removal of non-coding part or intron (intervening sequence) from gene. Most common splicing mutation resulting in beta thalassemia is IVS1-5 G-> C. (IVS = Intervening sequence) These mutations disrupt normal hemoglobin synthesis, leading to reduced or absent beta-globin production and the characteristic clinical features of beta-thalassemia. 3-types of beta thalassemia: FEATURE THALASSEMIA MAJOR THALASSEMIA INTERMEDIA THALASSEMIA MINOR Beta chain production No beta chain production. Little chains present. One beta chain is normal. Others are defective. Clinically Pallor Jaundice Splenomegaly Pallor Jaundice Splenomegaly Asymptomatic Hb (gm/dl) 3 to 5 (more severe) 5 to 8 >8 Iron profile Increased Normal Normal

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 646-648
https://www.ncbi.nlm.nih.gov/pmc/articles/PMC10147086/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 35-year-old woman with beta-thalassemia major presents to the cardiology clinic with complaints of increasing shortness of breath on exertion and swelling in her ankles. She has been undergoing regular blood transfusions since childhood. She dies after a few days of hospitalization. What is the most common condition leading to her death? (Q845930)

A. Anemia

B. Liver disease

C. Infections

D. Heart failure

Correct Answer: D. Heart failure

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above scenario of heart failure is the most common cause of death in beta-thalassemia major. Cardiac disease resulting from progressive iron overload and secondary hemochromatosis is the most common cause of death in patients with beta-thalassemia major They must be treated with iron chelators to prevent this complication. Other complications include growth retardation, splenomegaly, leg ulcers, hepatic disease, lung disease/pulmonary hypertension, thromboembolism, endocrinopathies, and bone disease. Hematopoietic stem cell transplantation is the only therapy offering a cure in these patients.

References:

Harrison's Principles of Internal Medicine, 21st Edition, Page 763

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 25-year-old woman presents to the clinic for routine prenatal care. She has no significant past medical history. Her initial lab work reveals a microcytic, hypochromic anemia. Which of the following statements is most accurate in differentiating between iron deficiency anemia (IDA) and beta-thalassemia minor in this patient? (Q845932)

A. RDW is typically elevated in IDA compared to beta-thalassemia minor

B. RDW is typically lower in IDA compared to beta-thalassemia minor

C. Mentzer index is >13 in beta-thalassemia minor

D. RDW is typically normal in both IDA and beta-thalassemia minor

Correct Answer: A. RDW is typically elevated in IDA compared to beta-thalassemia minor

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: RDW is significantly higher in patients with IDA compared to those with beta-thalassemia minor or coexistent IDA and beta-thalassemia traits. This is because in IDA, the erythropoiesis process is disrupted, leading to a more varied size of red blood cells and thus an increased RDW (Red cell distribution width). Normal RDW = 11.5 to 14.5% In contrast, RDW tends to be lower in beta-thalassemia minor as most cells are just microcytic and hypochromic due to uniformly reduced hemoglobin synthesis. The Mentzer index, which is the MCV divided by the RBC count, is more useful in distinguishing between IDA and beta-thalassemia minor, with a lower Mentzer index (<13) indicating beta-thalassemia minor. Therefore, an elevated RDW favors a diagnosis of IDA over beta-thalassemia minor in this patient with microcytic, hypochromic anemia. Confirmatory testing with hemoglobin electrophoresis to detect elevated HbA2 levels (>3.5%) is required to diagnose beta-thalassemia minor. Feature Iron Deficiency Anemia Beta Thalassemia Minor Type Microcytic hypochromic anemia Microcytic hypochromic anemia RBC Less More MCV Normal to low Low RDW(size variance) More Normal Mentzer index: MCV/RBC >13 <13 Reticulocyte count Low Normal to slightly increased HbA2 - confirmatory

test <3.5% >3.5%

↑ *Back to this question in Part A*

@Neet_pg_bot

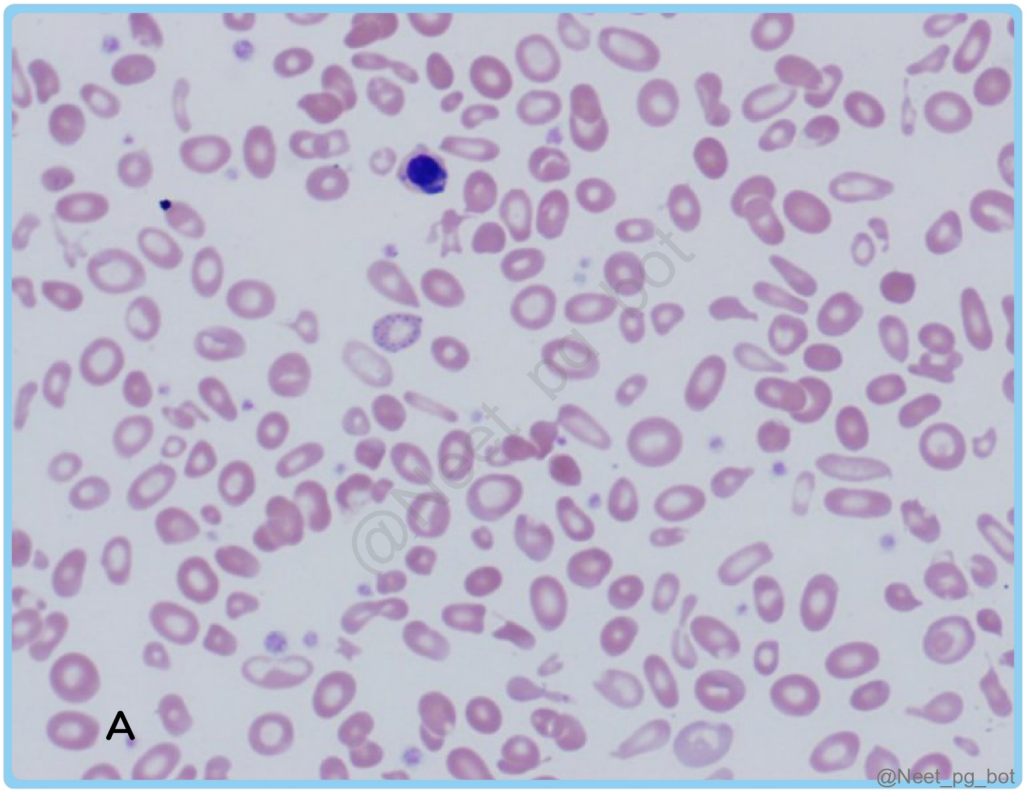
Q11: A hematologist is reviewing the peripheral blood smears of three patients diagnosed with different types of thalassemia. Patient A has severe anemia, target cells, and nucleated red blood cells (NRBCs). Patient B has mild anemia with microcytosis and hypochromia but no NRBCs. Patient C has mild anemia with microcytosis and hypochromia but also shows a small number of NRBCs and some hemoglobin H inclusions. Based on the peripheral smear findings, which of the following correctly matches the patients with their thalassemia types? (Q845933)

A. Patient A: β-thalassemia major, Patient B: β-thalassemia minor, Patient C: α-thalassemia

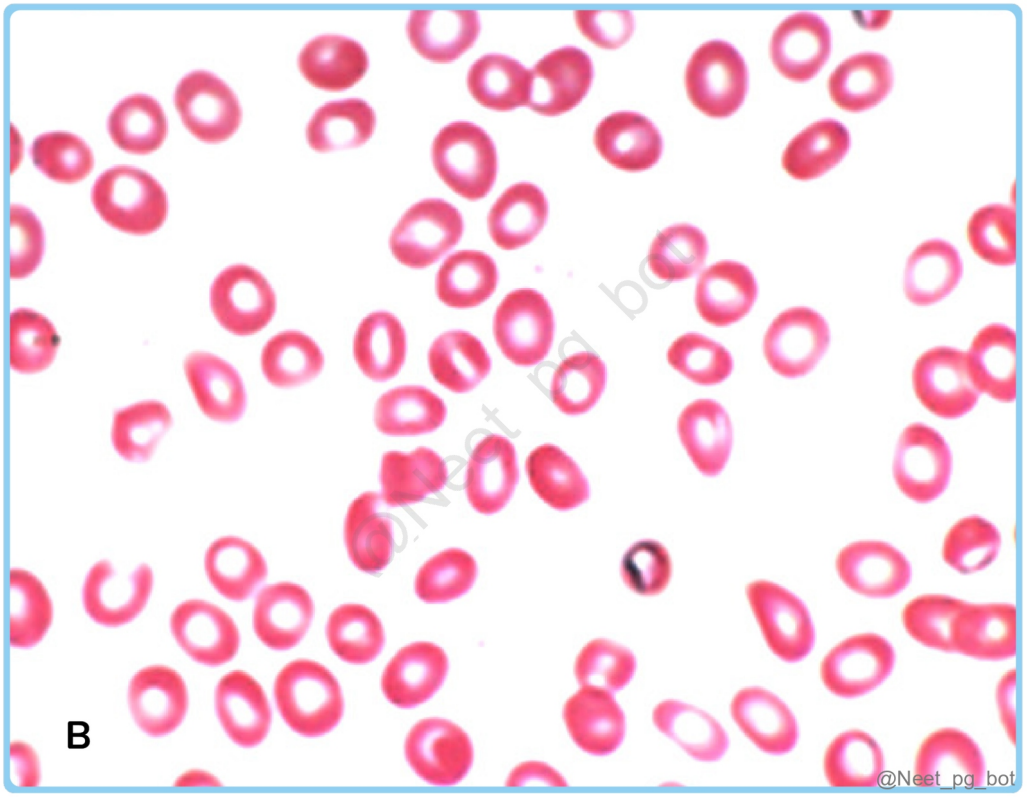
B. Patient A: β-thalassemia minor, Patient B: α-thalassemia, Patient C: β-thalassemia major

C. Patient A: α-thalassemia, Patient B: β-thalassemia minor, Patient C: β-thalassemia major

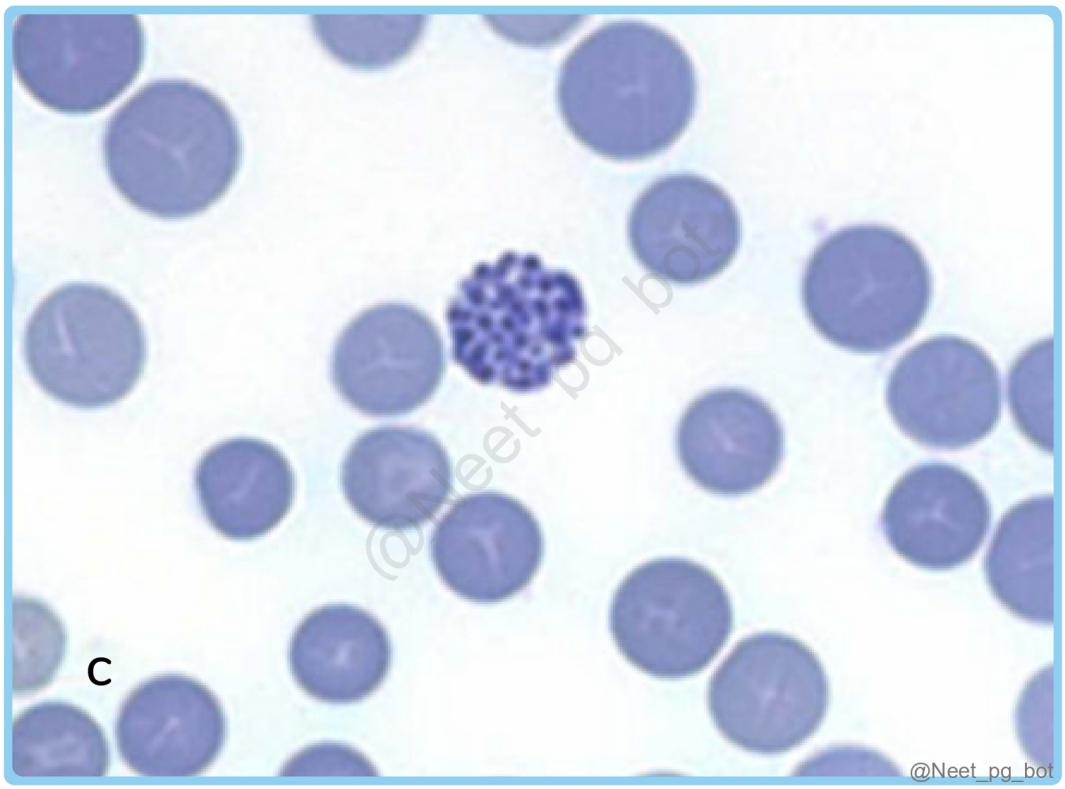
D. Patient A: β-thalassemia major, Patient B: α-thalassemia, Patient C: β-thalassemia minor



A
@Neet_pg_bot



B
@Neet_pg_bot



Correct Answer: A. Patient A: β-thalassemia major, Patient B: β-thalassemia minor, Patient C: α-thalassemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The peripheral smear findings can help distinguish between different types of thalassemia: β-thalassemia major (Patient A): This condition is characterized by severe anemia . The peripheral smear typically shows significant abnormalities, including target cells , nucleated red blood cells (NRBCs) , microcytosis, hypochromia, and anisopoikilocytosis. These findings are consistent with the severe hemolytic anemia and ineffective erythropoiesis seen in β-thalassemia major. β-thalassemia minor/β-thalassemia trait (Patient B): This condition usually presents with mild anemia. The peripheral smear shows microcytosis and hypochromia but generally lacks significant numbers of NRBCs. α-thalassemia (Patient C): This condition can vary in severity. The peripheral smear of a patient with α-thalassemia trait may show mild anemia , microcytosis, and hypochromia. In cases of HbH disease (a form of α-thalassemia), the smear can also show NRBCs and hemoglobin H inclusions (golf ball cells), which are not seen in β-thalassemia minor. Hemoglobin H inclusions are seen in α-thalassemia patients when there are 3 out of 4 alpha genes deletions.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 647.

https://www.ncbi.nlm.nih.gov/books/NBK545151/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following findings is most consistent with β thalassemia major when compared to β thalassemia minor? (Q845934)

A. Decrease in HbA, slight increase in HbA2, and normal HbF; HPLC: HbA2: 6%, HbF: 2%

B. Decrease in HbA, increase in HbA2, and marked increase in HbF; HPLC: HbA2: 6%, HbF: 90%

C. Absent HbA, slight increase in HbA2, and moderate increase in HbF; HPLC: HbA2: 4%, HbF: 20%

D. Decrease in HbA, normal HbA2, and normal HbF; HPLC: HbA2: 2%, HbF: 2%

Correct Answer: B. Decrease in HbA, increase in HbA2, and marked increase in HbF; HPLC: HbA2: 6%, HbF: 90%

Explanation: β thalassemia major is characterised by decrease in HbA, increase in HbA2, and marked increase in HbF; HPLC: HbA2: 6%, HbF: 90% In β-thalassemia major, adult hemoglobin (HbA) is severely reduced, often to 0–5%. Fetal hemoglobin (HbF) compensates, rising above 90%. HbA2 may be normal or slightly elevated around 5%. Decrease in HbA, slight increase in HbA2, and normal HbF; HPLC: HbA2: 6%, HbF: 2% (Option A): These findings indicate β-thalassemia trait, characterized by decreased adult hemoglobin (HbA), normal HbF, and increased HbA2 levels. Absent HbA, slight increase in HbA2, and moderate increase in HbF; HPLC: HbA2: 4%, HbF: 20% (Option C): This is seen in sickle cell anemia with absent HbA, presence of sickle hemoglobin HbS >75%, HbA2: 4% and HbF: 20% Decrease in HbA, normal HbA2, and normal HbF; HPLC: HbA2: 2%, HbF: 2% (Option D): These findings indicate sickle cell trait, with HbA levels around 60-70%, HbS about 30%, and normal HbA2 and HbF levels.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 647 Harrison's Principles of Internal Medicine, 21st edition, Page 757, 762 https://www.ncbi.nlm.nih.gov/books/NBK545151/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A pregnant woman is a silent carrier for α-thalassemia (α-/αα) and is concerned about the risk of her child inheriting α-thalassemia. Her partner has the α-thalassemia trait (αα/--). What is the probability that their child will have Hemoglobin H (HbH) disease? (Q845937)

A. 0%

B. 25%

C. 50%

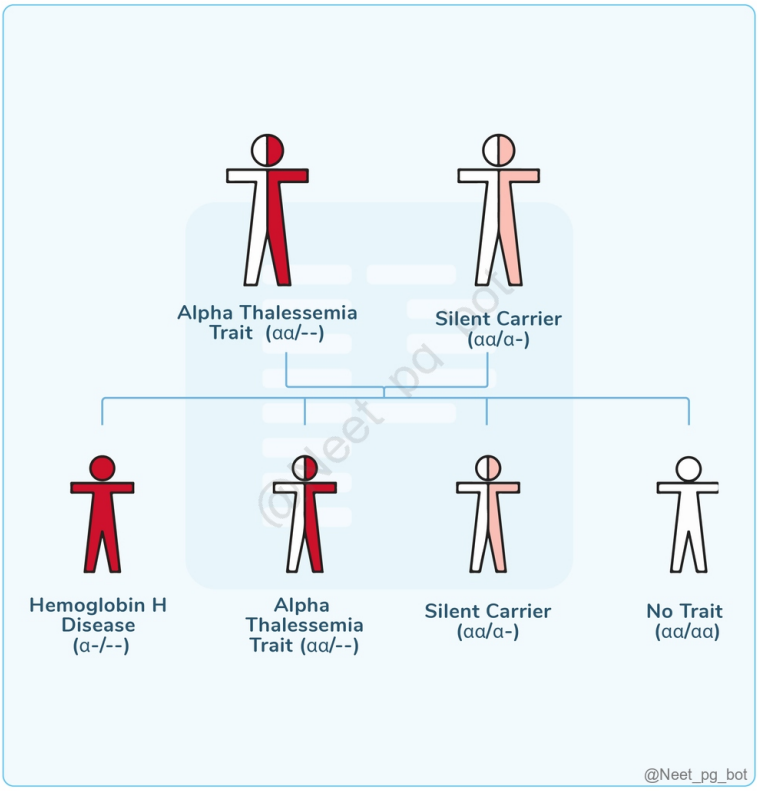
D. 75%

Correct Answer: B. 25%

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This couple will have a 25% chance of their child being affected with Hemoglobin H Disease. α-Thalassemia: Autosomal recessive condition, caused by deletions of 1–4 α-globin genes Severity of disease correlates with the number of genes deleted – more deletions lead to more severe clinical manifestations Hemoglobin H (HbH) disease is caused by α-thalassemia, with the deletion of 3 α-globin genes, leaving only 1 α-gene remaining. Effect: Insufficient α chains; excess β chains form β■ tetramers (HbH) . Pathophysiology: HbH is unstable → extravascular hemolysis → inclusion bodies on brilliant cresyl blue staining . Clinical features: Anemia, jaundice, splenomegaly, mild hemolysis. The α-globin gene is located on chromosome 16, and each individual has two copies of this gene on each chromosome, for a total of four α-globin genes (αα/αα). Parent Genotypes: Mother (Silent carrier): α-/αα Father (α-thalassemia trait): αα/– Interpretation of Results: α-/αα (Silent carrier)- 25% αα/αα (Normal)- 25% α-/-- (HbH disease)- 25% αα/-- (α-thalassemia trait)- 25% When 2 carriers get married: Chance of child having the disease = 25% Chance of child of being a carrier = 50%



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 646, 647.
https://www.stjude.org/treatment/disease/sickle-cell-disease/diagnosing-sickle-cell/alpha-thalassemia-trait.html

↑ *Back to this question in Part A*

@Neet_pg_bot

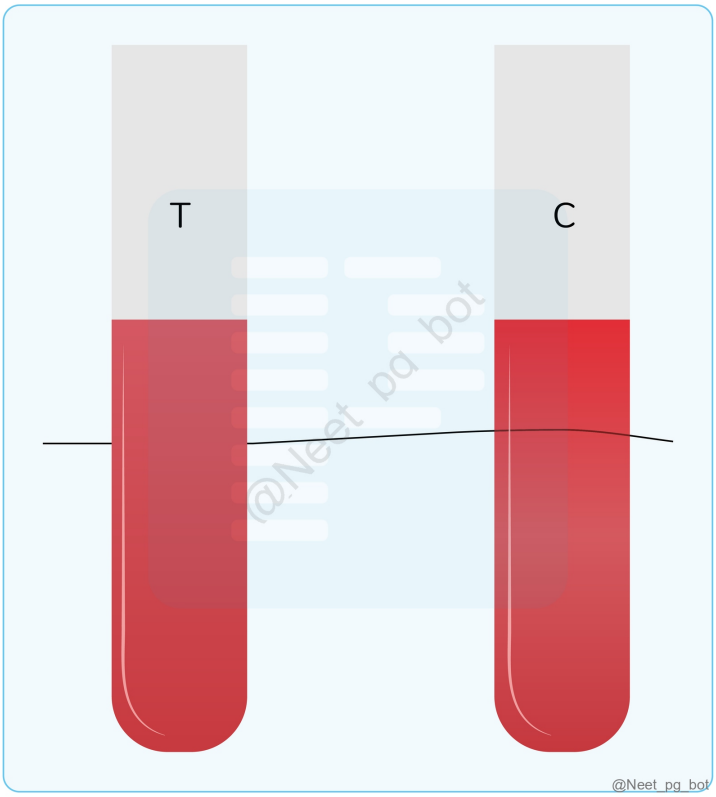
Q14: The medical team, aware of the prevalence of genetic disorders in the village decides to implement a screening process using NESTROFT for beta thalassemia. They plan to test the result by observing the solution turning clear by checking the visibility of a black line behind the test and control tubes. Which of the following on Nestrof test would be indicative of a positive result? (Q845940)

A. Black line visible in both tubes

B. Black line visible in only control tubes

C. Black line not visible in only test tubes

D. No black line visible in any of the tubes



Correct Answer: C. Black line not visible in only test tubes

Explanation: A black line not visible only in the test tubes containing blood sample mixed with a 0.36 buffered solution is suggestive of a positive Nestrof test. NESTROFT (Naked Eye Single Tube Red Cell Osmotic Fragility Test) Screening test for beta thalassemia and sickle cell trait carriers. Take 5 ml of 0.35% hypotonic saline in two tubes Add patient's blood (test) and a normal person's blood (control) A white paper with black lines is placed behind both tubes after half an hour RBCs of a normal person's blood break due to hypotonic saline - black line is visible Thalassemia cells do not break - line is not visible

https://pediatrics.medresearch.in/index.php/ijpr/article/view/142/281

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Match the following diseases with their respective antibodies and target antigens on red blood cells (RBCs): 1. Cold Agglutinin Disease 2. Cold Hemolytic Disease Antibody Target Antigen on RBCs A IgM I antigen B IgG P antigen C IgG I antigen D IgM P antigen Select the correct matching pairs: (Q845943)

A. 1-A, 2-C

B. 1-C, 2-D

C. 1-A, 2-B

D. 1-B, 2-D

Correct Answer: C. 1-A, 2-B

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Cold Agglutinin Disease is associated with IgM antibodies against the I antigen on RBCs. Cold Hemolytic Disease involves IgG Donath-Landsteiner antibodies against the P antigen on RBCs. Feature Cold Agglutinin Disease (CAD) Cold Hemolytic Disease (CHD) / Paroxysmal Cold Haemoglobinuria(PCH) Antibody Type IgM antibodies against the I antigen on RBCs. IgG Donath-Landsteiner antibodies against the P antigen on RBCs. Temperature Sensitivity Bind avidly at low temperatures (0°C to 4°C), but not at 37°C Bind in cool peripheral regions, but complement-mediated lysis occurs at warm core Causes Associated with certain infections (Mycoplasma pneumoniae, Epstein-Barr virus, cytomegalovirus, influenza virus, HIV), B-cell neoplasms, or idiopathic Often seen in children following viral infections Hemolysis Intravascular hemolysis is usually not seen; extravascular hemolysis due to phagocytosis after release of IgM Complement-mediated intravascular hemolysis and hemoglobinuria Clinical Symptoms Pallor, cyanosis, Raynaud phenomenon in cold-exposed body parts Hemoglobinuria, intravascular hemolysis

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 650

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: Which of the following statements is false regarding warm antibody-mediated autoimmune hemolytic anemia (AIHA)? (Q845944)

A. It is commonly mediated by IgG antibodies active at 37°C.

B. It can be associated with the intake of drugs like alpha-methyldopa and quinine.

C. It typically involves the destruction of red blood cells primarily in the liver.

D. A positive direct Coombs test is often used to confirm the diagnosis.

Correct Answer: C. It typically involves the destruction of red blood cells primarily in the liver.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The incorrect statement regarding warm AIHA is that it involves the destruction of red blood cells primarily in the liver, rather than in the spleen. Warm Antibody-Mediated Autoimmune Hemolytic Anemia (AIHA): Feature Description Antibody Type IgG Optimal Temperature for Activity 37°C (body temperature) (Option A) Common Symptoms Fatigue, pallor, jaundice, shortness of breath, dark urine, splenomegaly Mechanism of Hemolysis IgG antibodies bind to RBCs, leading to phagocytosis primarily in the spleen (Option C) Diagnosis Positive direct Coombs test (direct antiglobulin test) (Option D) Hemolysis Location Primarily in the spleen Associated Conditions Autoimmune diseases (e.g., SLE), lymphoproliferative disorders (e.g., CLL), infections Drug-Induced Causes Alpha-methyldopa, quinine, penicillin, and cephalosporins (Option B) Laboratory Findings Anemia, elevated reticulocyte count, increased LDH, Decreased haptoglobin, spherocytes on blood smear Type of AIHA Warm AIHA (WAIHA) Cold AIHA (CAIHA) Most Common Antibody Ig G Ig M Frequency Most common type (approx. 70-80% of cases) Less common Optimal Reaction Temperature 37°C (Body temperature) Below 37°C (usually 4°C)

Q1: Which of the following conditions is least likely to result in iron deficiency anemia? (Q880000)

A. A young 5-year-old suffering from hookworm infection

B. An elderly 60-year-old male diagnosed with carcinoma of the cecum

C. A middle-aged 54-year-old woman who has undergone Billroth II gastrectomy

D. A 25-year-old female consuming a diet predominantly based on maize

Correct Answer: D. A 25-year-old female consuming a diet predominantly based on maize

Explanation: Maize-based diets are least likely to cause iron deficiency anemia on their own. While maize is low in bioavailable iron and contains absorption inhibitors, iron deficiency anemia usually requires other risk factors, such as poor overall nutrition or blood loss. Iron fortification may also lessen deficiency risk. Condition Likelihood of Iron Deficiency Anemia Reason Hookworm infection (5 years old) High (Ruled out Option A) Blood loss from intestinal parasites Carcinoma of the cecum (60-year-old male) High (Ruled out Option B) Chronic gastrointestinal bleeding Billroth II gastrectomy (54-year-old woman) High (Ruled out Option C) Malabsorption from altered GI anatomy and acid secretion Maize-based diet (25-year-old female) Least Likely (Option D) Iron bioavailability is low, but anemia is less likely without additional causes

@Neet_pg_bot

Q2: In the human body, where is the majority of biologically active iron located? (Q879988)

A. Hemoglobin

B. Myoglobin

C. Catalase enzymes

D. Ferritin

Correct Answer: A. Hemoglobin

Explanation: About 70% of total body iron is bound in hemoglobin within red blood cells, responsible for oxygen transport. Incorrect Options: Myoglobin (Option B): Myoglobin contains iron but represents a small fraction compared to hemoglobin. Catalase enzymes (Option C): Catalase enzymes contain iron but constitute a minor portion. Ferritin (Option D): Ferritin is an iron storage protein that stores iron in an inactive form, not the most biologically active iron.

References:

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 59.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A patient is found to have a mean corpuscular volume (MCV) of 109 fL. Which of the following conditions is least commonly associated with this laboratory finding? (Q879982)

A. Hypothyroidism

B. Vitamin B12 deficiency

C. Orotic aciduria

D. Anemia of chronic disease

Correct Answer: D. Anemia of chronic disease

Explanation: Anemia of chronic disease usually causes normocytic or mildly microcytic anemia. Macrocytosis is uncommon in this condition. Incorrect Options: Hypothyroidism (Option A): Hypothyroidism frequently causes mild macrocytosis due to decreased erythropoiesis. Vitamin B12 deficiency (Option B): Hypothyroidism

frequently causes mild macrocytosis due to decreased erythropoiesis. Orotic aciduria (Option C): Orotic aciduria is a rare cause of macrocytic anemia with increased MCV.

@Neet_pg_bot

Q4: All of the following anemias arise from reduced red cell production, except: (Q879974)

A. Iron deficiency anemia

B. Hereditary spherocytosis

C. Megaloblastic anemia

D. Aplastic anemia

Correct Answer: B. Hereditary spherocytosis

Explanation: Hereditary spherocytosis is a hemolytic anemia caused by increased red cell destruction, not reduced production. Incorrect Options: Iron deficiency anemia (Option A): Iron deficiency anemia arises from reduced red cell production due to insufficient iron for hemoglobin synthesis. Megaloblastic anemia (Option C): Megaloblastic anemia results from impaired DNA synthesis leading to defective red cell production. Aplastic anemia (Option D): Aplastic anemia is caused by bone marrow failure leading to decreased production of all blood cells.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 578.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: In individuals living with HIV infection, which hematologic abnormality is observed most commonly? (Q879969)

A. Thrombocytopenia

B. Neutropenia

C. Lymphocytosis

D. Anemia

Correct Answer: D. Anemia

Explanation: Anemia is the most common blood abnormality and can be caused by chronic disease, bone marrow suppression (from HIV or medications like zidovudine), opportunistic infections, and nutritional deficiencies. Incorrect Options: Thrombocytopenia (Option A): Common in HIV but less frequent than anemia. Caused by immune destruction and marrow suppression. Neutropenia (Option B): Seen, especially in advanced disease or related to medication side effects, but less common than anemia. Lymphocytosis (Option C): Not typical; more often, lymphopenia occurs due to CD4+ T-cell depletion.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 219.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: What is considered the most significant inflammatory mediator in the pathophysiology of anemia of chronic disease (AOCD)? (Q845881)

A. Interleukin-6

B. Transferrin

C. Interleukin-10

D. Interferon-γ

Correct Answer: A. Interleukin-6

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Interleukin-6 is the most important inflammatory mediator linked to the pathogenesis of anemia of chronic disease (AOCD). In chronic conditions, Interleukin-6 will increase and act on the liver. Releases Hepcidin (master regulator) Inhibits Fe absorption. Serum iron levels and transferrin saturation are decreased. Inhibits the release of Fe from ferritin. Therefore, ferritin levels increase. This leads to a decrease in TIBC. Interleukin-10 (Option C) is an anti-inflammatory cytokine, which supports erythropoiesis and maintains iron homeostasis. It reduces the impact of chronic inflammation on RBC production. Interferon-γ (Option D) is produced by activated Th1 cells. It promotes the immune-mediated destruction of stem cells and leads to bone marrow failure and pancytopenia in aplastic anemia.

@Neet_pg_bot

Q7: A 5-year-old child presents to the clinic with symptoms of irritability, abdominal pain, and vomiting. The physician suspects lead poisoning and orders a complete blood count along with a peripheral blood smear. Which of the following findings would most likely be seen on the peripheral blood smear in lead poisoning? (Q845895)

A. Schistocytes

B. Spherocytes

C. Basophilic stippling

D. Bite cells

Correct Answer: C. Basophilic stippling

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Basophilic stippling is a characteristic finding seen in lead poisoning. The retained rRNA appears as small blue granules on a stained peripheral blood smear, leading to the characteristic basophilic stippling seen on blood smears. The accumulation of ribosomal RNA in lead poisoning is a consequence of disrupted heme synthesis, leading to ineffective red blood cell maturation and the retention of rRNA in developing erythrocytes. Schistocytes (Option A): These fragmented red blood cells are typically seen in microangiopathic hemolytic anaemia caused by conditions such as thrombotic thrombocytopenic purpura (TTP) or disseminated intravascular coagulation (DIC), not in lead poisoning. Spherocytes (Option B): These are round cells with no central pallor, associated with hereditary spherocytosis Bite cells (Option D): Bite cells are seen in G6PD deficiency. In G6PD deficiency, oxidative stress leads to the denaturation of haemoglobin, resulting in the formation of Heinz bodies (aggregates of denatured haemoglobin). Macrophages in the spleen recognize and remove these Heinz bodies, creating a characteristic bite-shaped appearance. Morphological Defects in Blood Cell Lineages and Their Causes 1. RBC Morphological Defects (Size, Shape, Color, Inclusions) Morphological Defect Description Causes / Associated Diseases Microcytosis Small RBCs (↓ MCV) Iron deficiency anemia, Thalassemia, anemia of chronic disease, sideroblastic anemia Macrocytosis Large RBCs Megaloblastic anemia (B12/folate deficiency), liver disease, alcoholism Hypochromia ↓ Hb, large central pallor Iron deficiency anemia, Thalassemia Spherocytes Round RBCs, no central pallor Hereditary spherocytosis, Autoimmune hemolytic anemia Elliptocytes Elliptical RBCs Hereditary elliptocytosis, Iron deficiency anemia Target cells Bull’s eye appearance Thalassemia, liver disease, Sickle cell disease Schistocytes Fragmented RBCs Disseminated intravascular coagulation, Thrombotic thrombocytopenic purpura, Hemolytic uremic syndrome Sickle cells Crescent-shaped RBCs Sickle cell anemia Tear drop cells Tear-shaped RBCs Myelofibrosis, marrow infiltration Acanthocytes Spur cells Liver disease, abetalipoproteinemia Echinocytes Burr cells Uremia, CKD Rouleaux formation Stacked RBCs Multiple myeloma

Howell-Jolly bodies Nuclear remnants Splenectomy, megaloblastic anemia Basophilic stippling Ribosomal RNA Lead poisoning, thalassemia Heinz bodies Denatured Hb Glucose-6-phosphate dehydrogenase deficiency Cabot rings Mitotic spindle remnants Megaloblastic anemia 2. WBC Morphological Defects and Causes Neutrophil Abnormalities: Morphological Defect Description Causes Hypersegmented neutrophils >5 lobes Megaloblastic anemia Pelger-Huët anomaly Bilobed nucleus Congenital, Myelodysplastic syndrome Toxic granulation Coarse granules Severe bacterial infection Döhle bodies Blue cytoplasmic inclusions Infection, burns, inflammation Vacuolated neutrophils Cytoplasmic vacuoles Sepsis Auer rods Needle-like inclusions Acute myeloid leukemia Smudge cells Fragile lymphocytes Chronic lymphocytic leukemia Atypical lymphocytes Large reactive lymphocytes Infectious mononucleosis 3. Platelet Morphological Defects and Causes: Morphological Defect Description Causes Giant platelets Large platelets Bernard-Soulier syndrome, ITP Small platelets Small platelets Wiskott-Aldrich syndrome Platelet clumping Platelet aggregates EDTA artifact Hypogranular platelets ↓ granules Myelodysplastic syndrome Gray platelets Gray appearance Gray platelet syndrome Thrombocytopenia ↓ platelets ITP, aplastic anemia, leukemia Thrombocytosis ↑ platelets Myeloproliferative disorders

@Neet_pg_bot

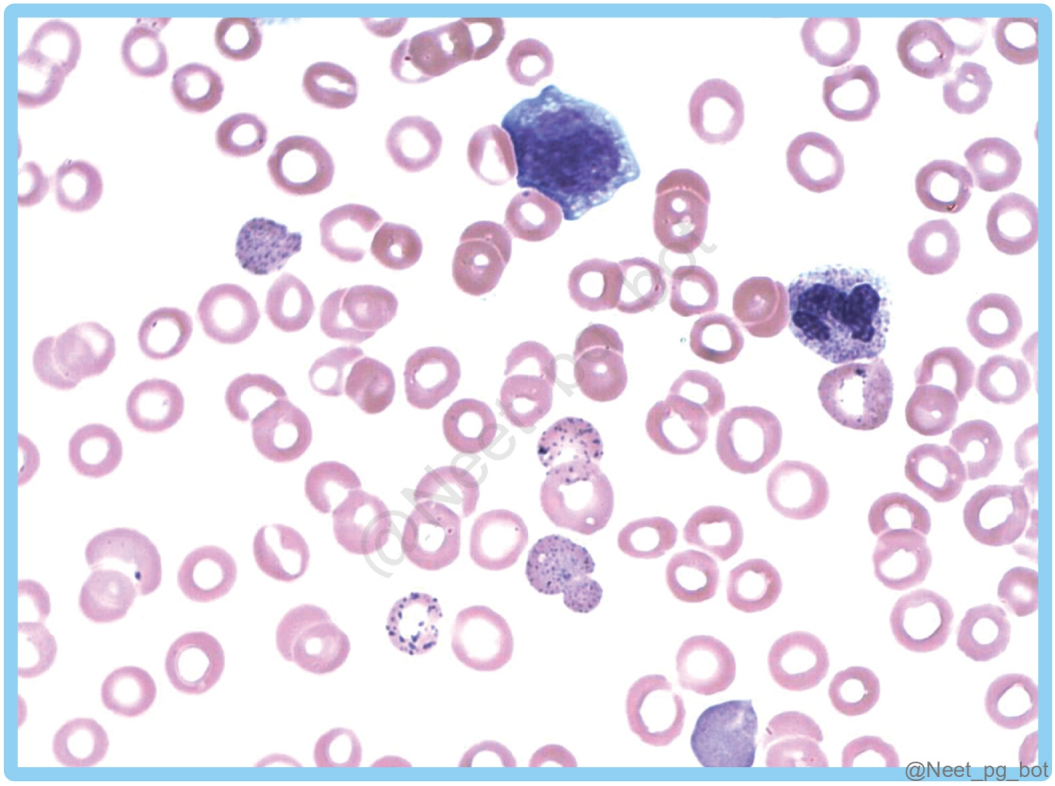
Q8: A peripheral blood smear revealed basophilic granules with Prussian blue stain. Which of the following bone marrow cells are associated with this condition? (Q845894)

A. Sideroblast

B. Siderocyte

C. Reticulocyte

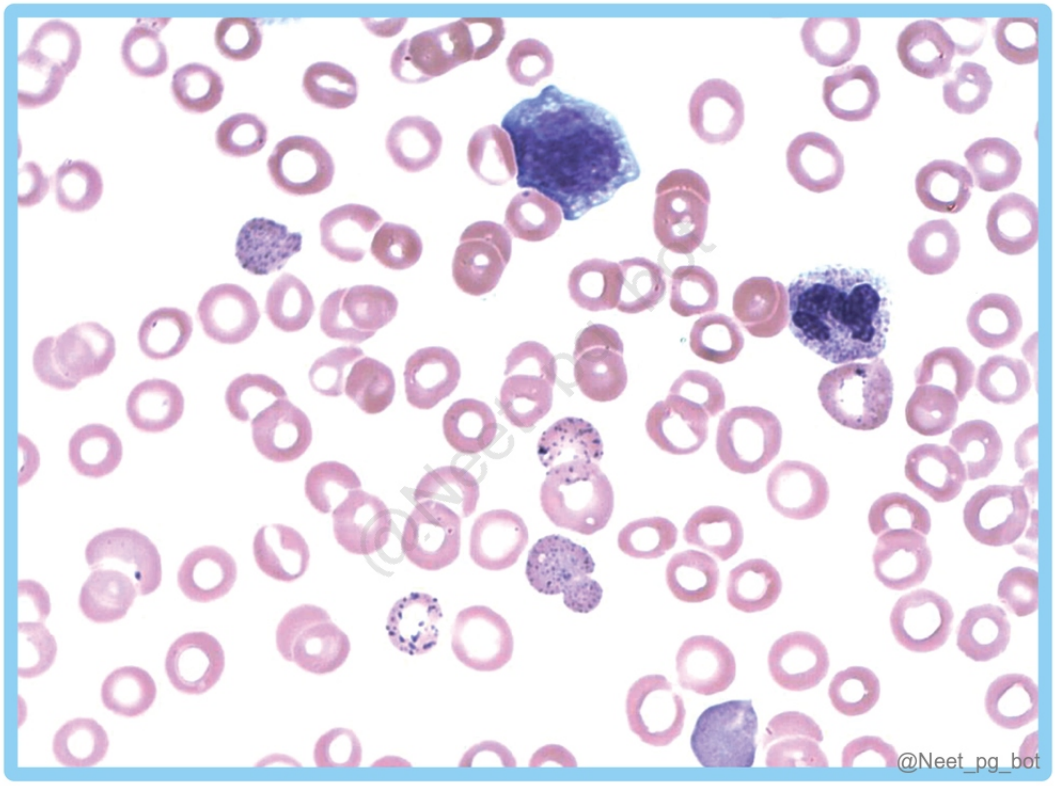
D. Bite cells



Correct Answer: A. Sideroblast

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The patient's peripheral smear reveals numerous basophilic iron granules, resembling Pappenheimer bodies in sideroblastic anemia, which has ringed sideroblasts on the bone marrow smear. Findings of sideroblastic anemia: Peripheral Smear: Pappenheimer bodies Bone Marrow: Ringed Sideroblasts Multiple basophilic iron aggregates Stain blue with Perl's/ Prussian blue Seen in sideroblastic anemia, lead poisoning, or hemochromatosis Blue granules form full or partial ring Blasts have a nucleus Iron is present in mitochondria in the perinuclear region. Stain blue on Perl's/Prussian blue. Seen with Sideroblastic anemia and Myelodysplastic syndrome. Associated with SF3B1 mutation Siderocyte (Option B) Red blood cells containing non hemoglobin ferric iron called siderotic granules on peripheral smear Seen in patients with absent spleen, sideroblastic anemia and hemolytic anemia Reticulocyte (Option C) Immature red blood cells produced in the bone marrow and released into the peripheral blood Brilliant cresyl blue stain Seen in hemolytic anemia, erythroblastosis fetalis and pregnancy. Bite Cells (Degmacytes) (Option D) Bite cells are erythrocytes with irregular membrane due to G6PD deficiency



@Neet_pg_bot

Q9: A 7-year-old girl presents to the clinic with complaints of fatigue, weakness, and pale skin. Her mother mentions that she has developed cravings for ice (pica). Laboratory tests reveal microcytic anaemia, and her serum ferritin levels are significantly low. Which of the following is the most likely infectious cause of her condition? (Q845887)

A. Giardia lamblia

B. Ancylostoma

C. Diphyllobothrium latum

D. Enterobius vermicularis

Correct Answer: B. Ancylostoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation (fatigue, pallor, and pica) and laboratory findings (microcytic anaemia, and low serum ferritin levels) in this patient point towards iron deficiency anaemia. Lab Parameters Iron Deficiency Anemia (IDA) Ferritin Low Transferrin saturation Low Serum Iron Low TIBC High Hookworm (Ancylostoma) infection is a well-known cause of iron deficiency anaemia, particularly in children. Hookworms attach to the intestinal wall to feed on the host's blood, leading to chronic blood loss. This results in microcytic anaemia due to iron deficiency, especially in children with limited dietary iron intake. Giardia lamblia (Option A): This protozoan parasite causes giardiasis, which primarily leads to malabsorption and chronic diarrhoea with fatty stools. Diphyllobothrium latum (Option C): This fish tapeworm causes megaloblastic anaemia(macrocytic) due to vitamin B12 deficiency rather than iron deficiency anaemia. Enterobius vermicularis (Option D): Commonly known as pinworm, this parasite primarily causes anal itching and discomfort, particularly in children. It does not lead to significant blood loss or iron deficiency anaemia.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 658

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following vitamin deficiencies is most commonly associated with sideroblastic anemia? (Q845886)

A. Vitamin B1 (Thiamine)

B. Vitamin B9 (Folic Acid)

C. Vitamin B6 (Pyridoxine)

D. Vitamin B12 (Cobalamin)

Correct Answer: C. Vitamin B6 (Pyridoxine)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Sideroblastic anaemia is characterized by defective heme synthesis, leading to the accumulation of iron in the form of ringed sideroblasts in the bone marrow. Causes of sideroblastic anaemia: Congenital causes Due to enzyme deficiencies like ALA synthase, ferrochelatase, etc. Acquired causes Vitamin B6 deficiency Drugs like isoniazid and chloramphenicol Lead and alcohol poisoning Vitamin B6 (Pyridoxine) is a cofactor for the enzyme Aminolevulinic Acid Synthase (ALAS), which catalyses the first step in the heme biosynthetic pathway. Deficiency of vitamin B6 leads to the development of sideroblastic anaemia. Vitamin B1 (Thiamine)(Option A) :

Thiamine is important for carbohydrate metabolism and nerve function. Its deficiency leads to conditions such as Wernicke-Korsakoff syndrome and beriberi but is not associated with sideroblastic anaemia. Folic acid and vitamin B12 are vital for DNA synthesis and red blood cell production. Their deficiencies lead to megaloblastic anaemia, but not sideroblastic anaemia and vitamin B12 deficiency also causes neurological issues(Subacute Combined Degeneration) (Options C and D).

@Neet_pg_bot

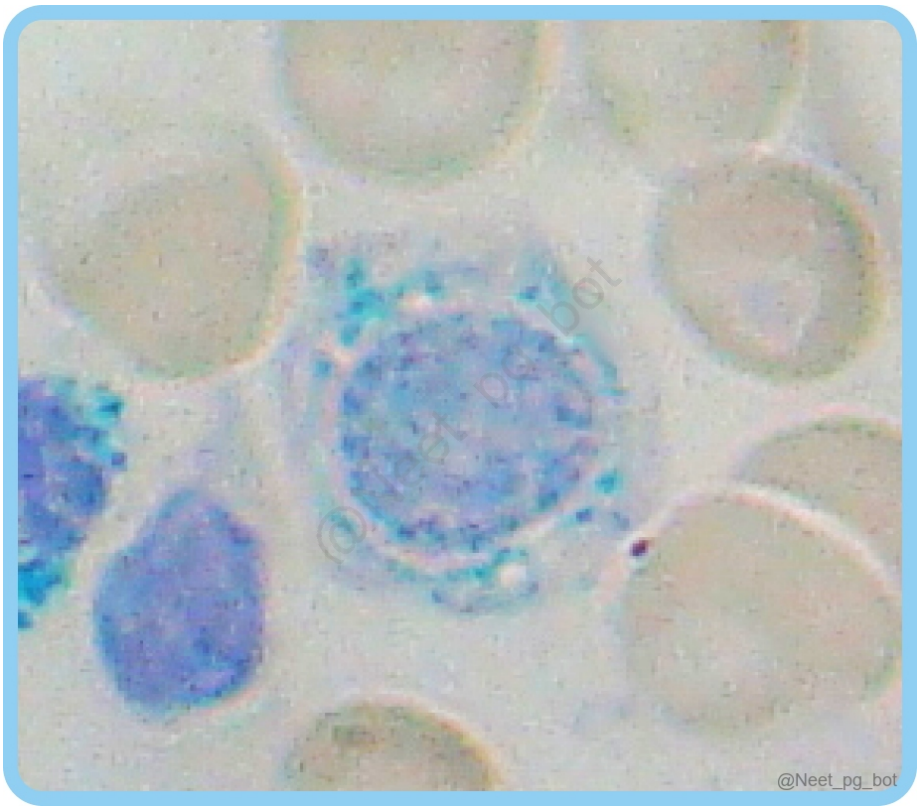
Q12: A 40-year-old female with a history of treatment for latent tuberculosis presents with fatigue. Physical examination reveals pallor and mild jaundice. Bone marrow smear revealed the following findings.which of the following is the most likely diagnosis? Options: (Q845884)

A. Iron deficiency anemia

B. Megaloblastic anemia

C. Sideroblastic anemia

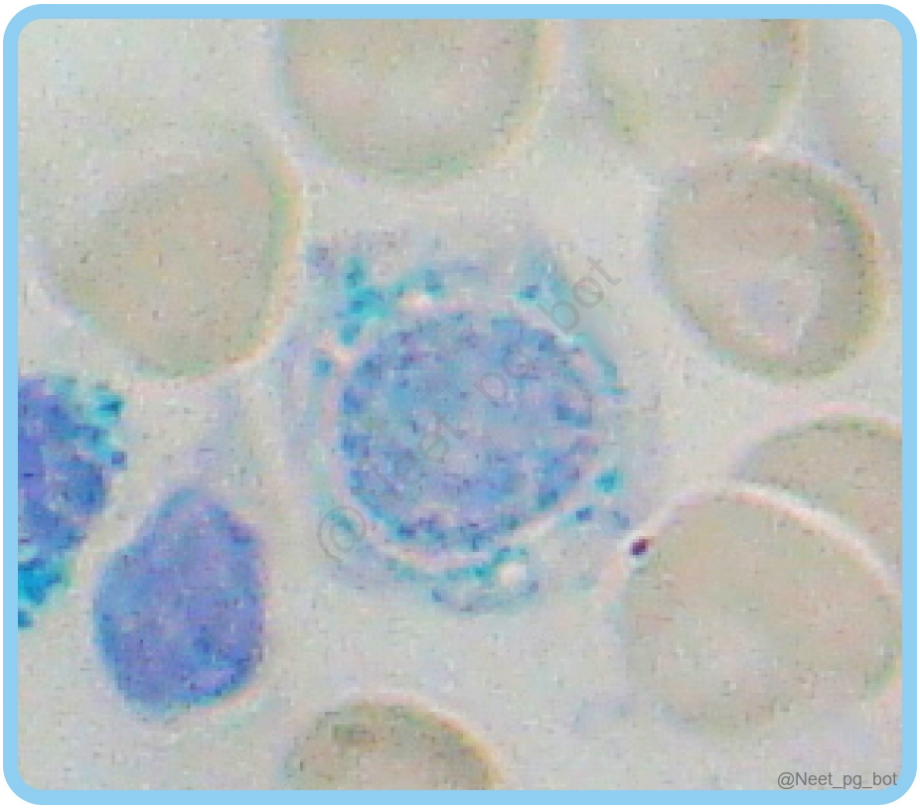
D. Hemolytic anemia



Correct Answer: C. Sideroblastic anemia

- *Listen (English)*
- *Listen (Hindi)*

Explanation: This patient’s history of treatment for latent tuberculosis with a bone marrow smear showing ringed sideroblasts suggests isoniazid induced sideroblastic anemia. Causes of sideroblastic anemia: Congenital causes Due to enzyme deficiencies like ALA synthase, ferrochelatase, etc. Acquired causes Vitamin B6 deficiency Drugs like isoniazid and chloramphenicol Lead and alcohol poisoning



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 620-621

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following new parameters has high specificity for differentiating anemia of chronic disease (ACD) from iron deficiency anemia (IDA)? (Q845883)

A. Serum transferrin receptor (sTfR)/log - ferritin index >1.5

B. Serum transferrin receptor (sTfR)/log - ferritin index <1.5

C. Reduced reticulocyte index

D. Blood film morphology

Correct Answer: B. Serum transferrin receptor (sTfR)/log - ferritin index <1.5

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The sTfR/log ferritin score was greater than 1.5 in all cases of IDA and ACD with concurrent IDA, while less than 1.5 in pure ACD patients. Parameter Finding Serum transferrin receptor (sTfR)-ferritin index sTfR reflects erythropoiesis, and ferritin describes iron stores. sTfR/log ferritin index > 1.5 in all cases of IDA and ACD with coexisting IDA. (Option A) sTfR/log ferritin index < 1.5 in pure ACD Reticulocyte index (Option C) Normal = 0.5-2.5% Reduced in IDA and AOCD Increased in hemolytic anemia. Blood film morphology (Option D) Predominantly: normocytic and normochromic anemia. Less commonly: microcytic and hypochromic anemia (also in IDA).

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 655-659

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which of the following investigations is the least helpful in determining the underlying cause of anemia? (Q845864)

A. MCV

B. MCH

C. Peripheral smear

D. Reticulocyte count

Correct Answer: B. MCH

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The least useful investigation in determining the underlying cause of anemia is MCH (Mean Corpuscular Hemoglobin). MCH measures the average amount of hemoglobin per red blood cell. MCH can be valuable when used together with MCV to refine the classification of anemia but it does not independently yield as much diagnostic information regarding the underlying causes of anemia as other tests MCV (Option A) categorizes anemia by measuring the red blood cell size: microcytic (<80 fL), normocytic (80-100 fL), and macrocytic (>100 fL), aiding in identifying underlying causes such as iron deficiency or vitamin B12 deficiency. Peripheral smear (Option C) is used to assess the morphology of red blood cells, white blood cells, and platelets, crucial in identifying abnormalities such as hypochromia , microcytosis , or macrocytosis ,. Reticulocyte count (Option D) measures the percentage of reticulocytes in the blood and can indicate the bone marrow's response to anemia. It helps differentiate between causes of anemia related to decreased production or increased destruction or loss of red blood cells.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 655

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 65-year-old female with a history of breast cancer presents with fatigue and pallor. Laboratory results indicate a hemoglobin level of 9.7 g/dL, low serum iron, elevated ferritin, and low total iron-binding capacity (TIBC). All of the following are true regarding this condition except? Anemia is caused by reduced erythroid progenitor proliferation and iron uptake. Causes include chronic infections,

autoimmune disorders and lymphoma. Peripheral smear does not show microcytic hypochromic anemia. All the patients benefit from erythropoietin administration. (Q845880)

A. 1, 3, 4

B. 3, 4

C. 4 only

D. 3 only

Correct Answer: B. 3, 4

Explanation: Anemia of chronic disease Caused by reduced erythroid progenitors and impaired iron utilization (statement 1) . Common cause of anemia due to chronic diseases (statement 2) , including Microbial infections: Osteomyelitis, bacterial endocarditis, lung abscess Immune disorders: Rheumatoid arthritis, inflammatory bowel disease Neoplasms: Lung, breast, and Hodgkin lymphoma Blood smear: Normocytic and normochromic (mostly), or hypochromic and microcytic (like IDA) (statement 3) . Management: Treat the underlying condition; some benefit with erythropoietin administration (statement 4) .

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 658-659

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: Which of the following statements correctly describes the principle of Prussian blue stain? (Q845879)

A. Ferrocyanide to ferricyanide

B. Ferrocyanide to ferric ferrocyanide

C. Ferroferric cyanide to ferrocyanide

D. Ferrocyanide to ferrocyanide

Correct Answer: B. Ferrocyanide to ferric ferrocyanide

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The Prussian blue stain is a histological stain used primarily to detect ferric iron (Fe^{3}■) in tissues, cells, and blood smears. It works based on the reaction of potassium ferrocyanide with ferric ions to form an insoluble blue compound called Prussian blue (Ferric ferro cyanide) which stains blue and is insoluble in water.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 655

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 24-year-old female with severe anemia started on parenteral iron. Which of the following would occur first in this patient as a response to therapy? (Q845878)

A. Increase in serum iron level

B. Erythroid hyperplasia in bone marrow

C. Increase in MCV

D. Increase in reticulocyte count

Correct Answer: A. Increase in serum iron level

Explanation: One of the earliest responses to the correction of iron deficiency anemia is increase in serum iron level Responses after initiation of treatment: 12 to 24 hours Replenishment of intracellular iron enzymes, decreased irritability; increased appetite, increase in serum iron. (Option A) 36 to 48 hours Erythroid hyperplasia in bone marrow (Option B ruled out) 48 to 72 hours Reticulocytosis, peaking at 5-7 days (Option D ruled out) 4 to 30 days Increase in hemoglobin level, increase in ferritin, increase in MCV (Option C ruled out) 1 to 3 months Repletion of stores

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 28-year-old female presented with easy fatigability and dyspnea on exertion. She was found to have a hemoglobin of 6 g/dL. What will be most likely finding in the peripheral blood smear of this patient? (Q845877)

A. Macrocytic red cells

B. Cabot ring

C. Hypersegmented neutrophils

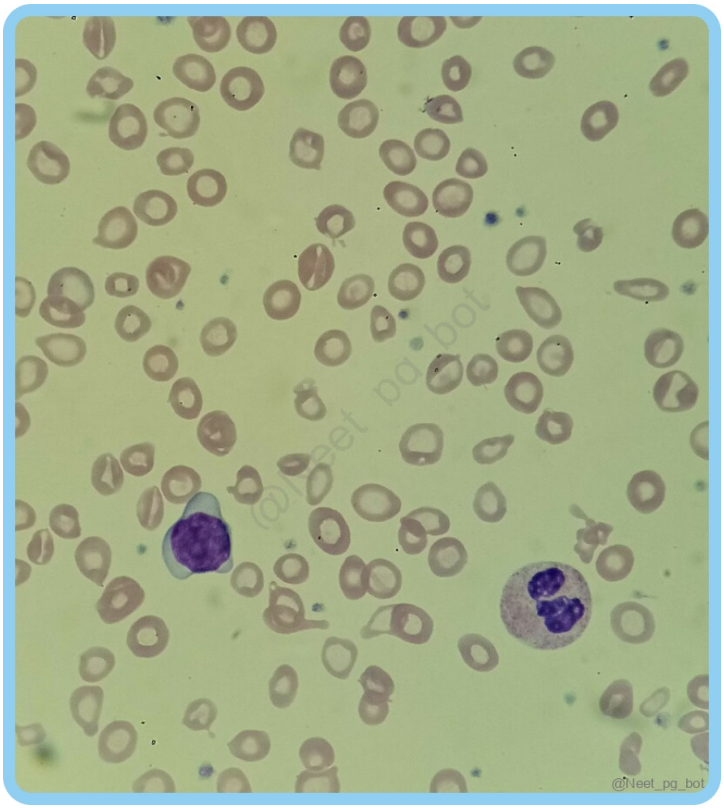
D. Microcytic and hypochromic red cells

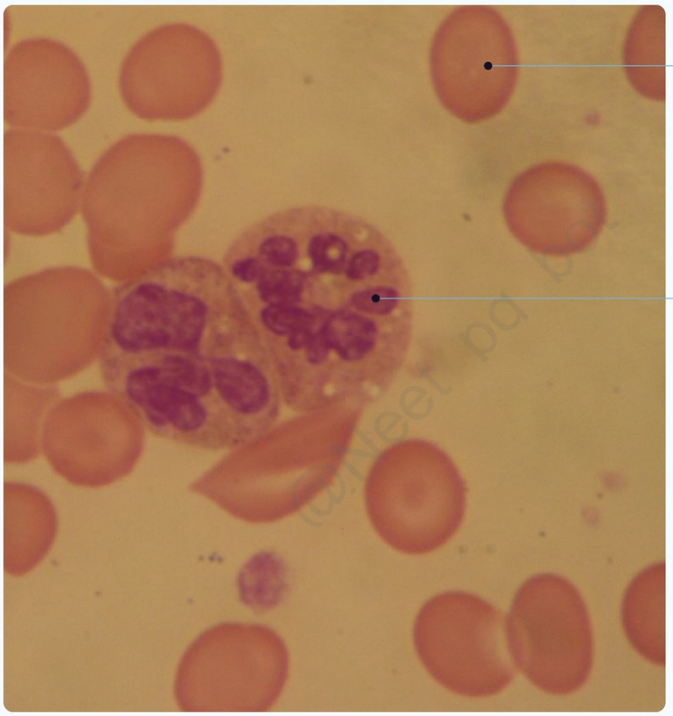
Correct Answer: D. Microcytic and hypochromic red cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Microcytosis (smaller than normal red cells) and hypochromia are classic findings in iron deficiency anemia, which is consistent with the patient's symptoms and low hemoglobin. In iron deficiency anemia (IDA), a peripheral blood smear can reveal characteristic changes. Hypochromic Red Blood Cells: The RBCs appear pale due to decreased hemoglobin content. Microcytic Red Blood Cells: RBCs are smaller than normal due to decreased hemoglobin synthesis. Anisocytosis: There is significant variation in the size of RBCs. Poikilocytosis: RBCs may show abnormal shapes, such as pencil cells, target cells (codocytes), and occasionally, elliptocytes. Macrocytic red cells (Option A): Macrocytosis typically indicates a deficiency in vitamin B12 or folate, not iron. Cabot rings (Option B): Appear as thin, thread-like structures that form a loop or figure-eight shape within RBCs. It is composed of remnants of the nuclear material remnants from erythroblasts or megakaryocytes. Associated with megaloblastic anemia. Hypersegmented neutrophils (Option C): These have more than 5 lobes in their nucleus. This condition is often associated with vitamin B12 deficiency or folate deficiency.





Oval shaped
macrocytes
Hypersegmented
neutrophil

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 32-year-old female diagnosed with iron deficiency anemia is prescribed oral iron supplements. Foods containing which of the following can she take to increase iron absorption? (Q845876)

A. Ascorbate

B. Oxalate

C. Carbonate

D. Phosphate

Correct Answer: A. Ascorbate

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Ascorbate (Vitamin C) enhances the absorption of non-heme iron (the type of iron found in plant-based foods and supplements) by reducing ferric iron (Fe^{3}■) to the more soluble ferrous form (Fe^{2}■), which is more readily absorbed in the duodenum. Factors affecting iron absorption: Enhancers Inhibitors Ascorbic acid Tannins Citric acid Carbonate Amino acid Oxalate Sugars in the diet Phosphate

@Neet_pg_bot

Q21: In a patient diagnosed with iron deficiency anemia, the values of all of the following increase except? (Q845875)

A. Total iron binding capacity

B. RBC protoporphyrin

C. Transferrin saturation

D. Transferrin receptor

Correct Answer: C. Transferrin saturation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Transferrin saturation decreases in iron deficiency anemia. It is the serum iron to TIBC ratio and reflects the percentage of transferrin saturated with iron. In iron deficiency, less iron is available for binding to transferrin, leading to a decreased saturation. Total iron binding capacity (TIBC) (Option A) is increased in iron deficiency anemia. It represents the maximum amount of iron that can be bound to transferrin. RBC protoporphyrin (Option B) is a precursor to heme, and in the absence of sufficient iron, protoporphyrin accumulates. Transferrin receptor (TfR) (Option D) expression on cells increases to enhance cellular uptake of iron when iron stores are low.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 656

↑ *Back to this question in Part A*

@Neet_pg_bot

Q22: A 10-year-old girl presented with fatigue, weakness and reduced exercise tolerance. Her mother reports that she has pica, frequently eating chalk and ice and the child also complains of brittle nails and occasional glossitis. Her laboratory results show reduced hemoglobin, MCV 75 fl, MCH 22 pg and RDW 28. What is the most likely diagnosis? (Q845874)

A. Iron deficiency anemia

B. Megaloblastic anemia

C. Sideroblastic anemia

D. Thalassemia major

Correct Answer: A. Iron deficiency anemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical presentation and investigation points towards the diagnosis of Iron deficiency anemia. Iron deficiency anemia typically presents with microcytic (low MCV) and hypochromic (low MCH) red blood cells. The elevated RDW suggests a wide variation in red blood cell sizes, which is characteristic of iron deficiency anemia. Iron deficiency anemia can result from dietary lack, impaired absorption, increased iron requirement (e.g., during pregnancy), or chronic blood loss (e.g., gastrointestinal bleeding). Clinical features include Koilonychia, alopecia, atrophic glossitis, and esophageal webs, pica and intestinal malabsorption, affecting overall nutritional status Megaloblastic anemia (Option B) usually presents with macrocytic anemia due to deficiencies in vitamin B12 or folate. Sideroblastic anemia (Option C) can also present with microcytosis, but it is usually associated with ringed sideroblasts in the bone marrow and RDW is usually normal or mildly elevated, not as high as 28. Thalassemia major (Option D) usually presents in infancy or early childhood with severe anemia, failure to thrive, and a need for regular blood transfusions. This patient's high RDW (28) suggests iron deficiency anemia, as thalassemia typically shows a normal RDW due to uniformly small red cells. There's no mention of classic features of thalassemia major, such as hepatosplenomegaly or bone deformities. Lastly, the MCV of 75 fL is low but not as profoundly low as usually seen in thalassemia major.

@Neet_pg_bot

Q23: A 45-year-old male patient was diagnosed with iron deficiency anemia. Which of the following is true about the intracellular regulation of iron in the above condition? IRP- Iron regulatory protein IRE- Iron response elements (Q845873)

A. Ferritin translation is increased by binding IRP to IRE.

B. Ferritin translation is decreased by binding IRP to IRE.

C. Transferrin receptor 1 translation is unaffected by binding IRP to IRE.

D. Transferrin receptor 1 translation is decreased by binding IRP to IRE.

Correct Answer: B. Ferritin translation is decreased by binding IRP to IRE.

Explanation: In iron deficiency anemia, ferritin translation is decreased by binding iron regulatory protein to iron response elements. Iron regulatory mechanism: IRP: Binds to IREs in specific mRNAs' untranslated regions (UTRs) to control the translation of proteins involved in iron metabolism. IRE: These are sequences found in the mRNAs of proteins involved in iron metabolism, such as ferritin and transferrin receptor 1 Ferritin: Ferritin stores iron inside cells. When iron levels are low, IRPs bind to IREs in the 5' UTR of ferritin mRNA, preventing its

translation to conserve iron. Transferrin receptor 1 (TfR1): TfR1 imports iron into cells. When iron levels are low, IRPs bind to IREs in the 3' UTR of TfR1 mRNA , stabilizing it and increasing its translation to enhance iron uptake.

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2932529/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: Which transport molecule facilitates the absorption of Fe2+ into enterocytes in the small intestine? (Q845872)

A. Ferroportin

B. Hephaestin

C. DMT-1

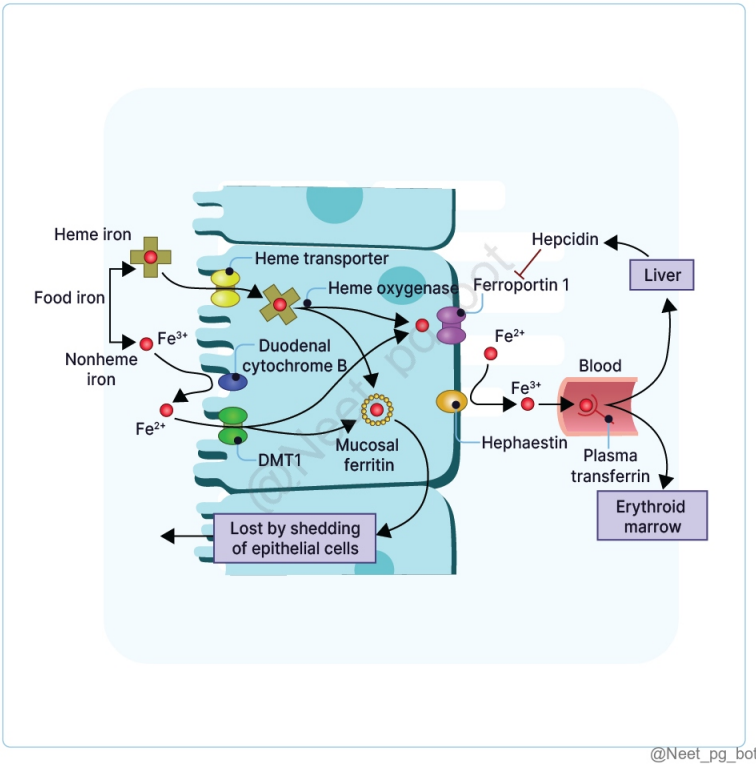
D. Hepcidin

Correct Answer: C. DMT-1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: DMT-1 is a transmembrane protein that facilitates the transport of divalent metal ions, primarily ferrous iron (Fe 2+), across the apical membrane of enterocytes in the duodenum. Heme iron enters the intestinal cells directly through a heme transporter. Non-heme iron (Fe^{3}■) is first reduced to Fe^{2}■ by duodenal cytochrome B, then Fe^{2}■ enters the cells via the DMT-1 transporter (Option C) . Inside the duodenal cell, Fe^{2}■ can either be stored as mucosal iron or transported into the bloodstream. Fe^{2}■ exits the cell through ferroportin (Option A) . In the blood, Fe^{2}■ is oxidized to Fe^{3}■ by hephaestin (Option B) and ceruloplasmin. Fe^{3}■ binds to transferrin for delivery to the bone marrow, where it is stored as ferritin; in cases of hemolysis, ferritin aggregates to form hemosiderin. The liver secretes hepcidin (Option D) , a protein that regulates iron absorption. When iron stores are adequate, hepcidin downregulates ferroportin expression, reducing iron absorption.



@Neet_pg_bot

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 656

↑ *Back to this question in Part A*

@Neet_pg_bot

Q25: A 28-year-old woman presents with fatigue and pallor. Lab tests show hemoglobin of 9 g/dL and MCV of 68 fL. Peripheral smear reveals microcytic and hypochromic red blood cells. Her symptoms and laboratory findings are consistent with iron deficiency anemia. Which of the following statements regarding iron deficiency anemia (IDA) is correct? (Q845871)

A. Serum ferritin levels are elevated.

B. Serum ferritin is the gold standard investigation

C. Decreased serum ferritin levels

D. Serum ferritin levels are not affected.

Correct Answer: C. Decreased serum ferritin levels

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Serum ferritin is a key marker used in diagnosing iron deficiency anemia. In iron deficiency, ferritin levels are decreased because ferritin stores decrease as iron stores deplete. (Option A and D) Serum ferritin levels below 30 ng/mL are generally considered indicative of depleted iron stores and are a reliable marker for iron deficiency. Serum ferritin is the gold standard investigation (Option B): While serum ferritin is commonly used as a marker for iron stores, it is not considered the gold standard test for diagnosing iron deficiency. A bone marrow aspirate to directly assess iron stores is the gold standard for diagnosing iron deficiency.

@Neet_pg_bot

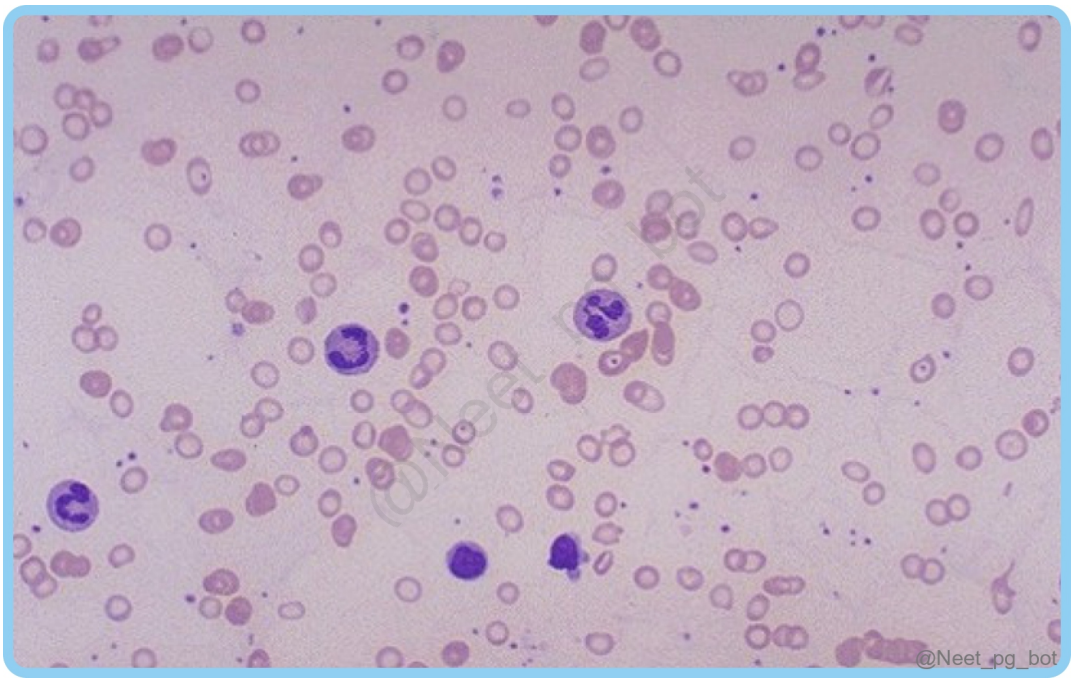
Q26: A 35-year-old woman has been experiencing fatigue, pallor, and shortness of breath for the past six months. Laboratory tests reveal a Hb of 6 gm/dl. Red cell distribution width is increased. Peripheral smear is shown below. Where is the likely site of absorption of the micronutrient deficient in this patient? (Q845870)

A. Jejunum

B. Ileum

C. Duodenum

D. Colon



Correct Answer: C. Duodenum

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The given clinical presentation of low hemoglobin, increased RDW, and microcytic hypochromic red cells on peripheral smear, points towards the diagnosis of Iron deficiency anemia . Iron is primarily absorbed through the duodenal mucosa , making duodenum the most likely site of absorption. Metabolism of iron: Iron from the diet (heme and non-heme) is converted to ferrous form in the stomach. Heme iron is primarily found in animal-based foods, while non heme iron is found in plant-based foods and iron-fortified foods. In the duodenum, ferrous iron is absorbed via DMT1 and transported into enterocytes. Inside, it binds to ferritin or enters the bloodstream via ferroportin. Iron binds to transferrin in the blood, facilitating its delivery to tissues for functions like hemoglobin synthesis. Hepcidin, a peptide hormone produced by the liver, plays a crucial role in regulating iron homeostasis. Jejunum (Option A) absorbs nutrients like amino acids, glucose, fatty acids, and folic acid. Ileum (Option B) completes nutrient absorption, including bile salts, vitamin B12 , and remaining nutrients, before the material enters the colon. Colon (Option D) focuses on absorbing water, electrolytes like sodium and chloride, and some vitamins from gut bacteria, such as vitamin K and biotin.

Q19 (p. 2697)					

Q1: A 72-year-old male complains of increasing tiredness and generalised weakness. On examination, a firm 1-cm nodule is palpated in the prostate gland. Laboratory studies show anemia with a normocytic, normochromic blood picture. Peripheral smear demonstrates occasional myelocytes, tear-drop erythrocytes, and about 2 nucleated red cells per 100 leukocytes. Which diagnosis best explains these findings? (Q880071)

A. Myelodysplastic syndrome

B. Myelophthisic anemia

C. Primary myelofibrosis

D. Myeloproliferative neoplasm

Correct Answer: B. Myelophthisic anemia

Explanation: Myelophthisic anemia results from bone marrow replacement by metastatic cancer, granulomas, or fibrosis. In this case, the firm prostate nodule suggests prostate carcinoma with marrow infiltration, while tear-drop cells, nucleated RBCs, and immature myeloid cells on smear indicate a leukoerythroblastic picture, which is classical for this condition. Incorrect Options: Myelodysplastic syndrome (Option A): Causes cytopenias with dysplastic marrow cells; smear shows abnormal morphology, not tear-drop cells or leukoerythroblastic picture. Primary myelofibrosis (Option C) also shows tear-drop cells and a leukoerythroblastic picture, but the marrow fibrosis is due to a myeloproliferative neoplasm, not metastatic tumor, and there is no prostate nodule in this condition. Prior exposure to radiation (Option D): Includes CML, PV, ET, PMF; causes abnormal blood counts but not typically due to marrow replacement by metastasis.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 601.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Myelophthisic anemia typically arises when normal bone marrow is replaced by abnormal tissue. Among the following, which is the leading cause? (Q880070)

A. Granulomatous disorders

B. Secondary deposits from malignant tumours

C. Myeloproliferative disorders

D. Prior exposure to radiation

Correct Answer: B. Secondary deposits from malignant tumours

Explanation: The most common cause of myelophthisic anemia is bone marrow infiltration by metastatic cancers (commonly breast, prostate, lung, kidney, thyroid), which replace normal hematopoietic tissue and lead to anemia or pancytopenia. Disrupted marrow function produces characteristic blood smear findings such as teardrop cells and immature precursors (leukoerythroblastosis). Incorrect Options: Granulomatous disorders (Option A) cause marrow infiltration by inflammatory granulomas but are less common than tumour metastases. Myeloproliferative disorders (Option C) can cause marrow fibrosis leading to anemia, but rarely cause the marrow replacement seen in myelophthisic anemia. Prior exposure to radiation (Option D): Radiation can damage bone marrow and cause aplasia, but does not typically cause the marrow replacement pattern seen in myelophthisic anemia.

References:

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 601.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following conditions are known to cause pure red cell aplasia? 1. Parvovirus B19 infection 2. Thymoma 3. Chronic neutrophilic leukaemia 4. Diamond–Blackfan anemia 5. Rifampicin use (Q880069)

A. 1, 2

B. 2, 3, 5

C. 1, 4

D. 1, 2, 4

Correct Answer: D. 1, 2, 4

Explanation: Parvovirus B19 infection , Thymoma , and Diamond-Blackfan anaemia are known to cause pure red cell aplasia (PRCA). Parvovirus B19 infection: Parvovirus B19 is the most common viral cause, destroying erythroid precursors and leading to transient or chronic PRCA, particularly in immunocompromised patients or those with chronic hemolytic anemia. Thymoma: Tumors of the thymus are strongly associated with PRCA, possibly due to autoimmune mechanisms where abnormal T cells attack red cell precursors. Chronic neutrophilic leukemia: It is not a known cause of PRCA. Diamond–Blackfan anemia: This is a congenital (inherited) pure red cell aplasia affecting children, characterized by failure of erythroid progenitors from birth. Rifampicin use: Drug-induced PRCA is rare but recognized with certain medications; rifampicin is not commonly implicated.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 601.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Aplastic anemia has the potential to evolve into certain hematologic malignancies or disorders over time. Which of the following are known possible transformations? 1. Acute myeloid leukaemia 2. Acute lymphoblastic leukaemia 3. Chronic myeloid leukaemia 4. Chronic lymphocytic leukaemia 5. Myelodysplastic syndrome (Q880036)

A. 2, 3, 4

B. 1, 2

C. 1, 5

D. 1, 3, 5

Correct Answer: C. 1, 5

Explanation: Aplastic anemia can evolve into acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) due to clonal evolution of hematopoietic stem cells or as a consequence of immunosuppressive therapy. Acute myeloid leukemia (AML): Aplastic anemia can evolve into AML, particularly after immunosuppressive therapy, as clonal evolution of hematopoietic stem cells leads to malignant transformation. Myelodysplastic syndrome (MDS): MDS is a clonal bone marrow disorder characterized by ineffective hematopoiesis and risk of progression to AML. It can develop in patients previously diagnosed with aplastic anemia, representing a clonal evolution. Acute lymphoblastic leukaemia (ALL) , chronic myeloid leukaemia (CML) , and chronic lymphocytic leukaemia (CLL) : These lymphoid or chronic myeloproliferative leukaemias are not typically reported secondary transformations of aplastic anemia.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Pages 599-600.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: Which of the following represents the most common known cause of aplastic anemia? (Q880030)

A. Drugs

B. Autoimmune disorders

C. Infections

D. Radiation exposure

Correct Answer: A. Drugs

Explanation: Some drugs, such as antibiotics (like chloramphenicol), anti-inflammatory drugs, and chemotherapy agents, can damage the bone marrow and lead to aplastic anemia. This is the most commonly identified cause when a specific cause is found, but overall, many cases are idiopathic (unknown cause). Incorrect Options: Autoimmune disorders (Option B): The autoimmune destruction of hematopoietic stem cells is a common underlying cause of aplastic anaemia, particularly in idiopathic cases, and often responds to immunosuppressive therapy. Infections (Option C): Viral infections such as hepatitis, EBV, HIV, and parvovirus B19 may cause aplastic anemia. Radiation exposure (Option D): High doses of ionising radiation can cause bone marrow aplasia, usually seen in cancer therapy or radiation accidents.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 599.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 55-year-old female with a history of rheumatoid arthritis on long-term therapy presents with dizziness on standing. Clinical examination reveals pallor and koilonychia. Considering the type of anemia associated with chronic inflammatory states, which of the following statements is correct? (Q880025)

A. Both serum iron and tissue iron are within normal limits

B. The anemia may present as normocytic and normochromic

C. Hepcidin production is suppressed

D. Total iron-binding capacity (TIBC) is increased

Correct Answer: B. The anemia may present as normocytic and normochromic

Explanation: Anemia of chronic disease (ACD) typically presents as a mild to moderate normocytic, normochromic anemia, especially early in the disease. It may become microcytic over time. Incorrect Options: Both serum iron and tissue iron are within normal limits (Option A): In anemia of chronic disease (ACD), serum iron is low due to hepcidin-induced iron sequestration, but total body iron stores (tissue iron) are normal or increased. Hepcidin production is suppressed (Option C): Hepcidin production is increased in ACD, causing decreased iron absorption and release from macrophages. Total iron-binding capacity (TIBC) is increased (Option D): TIBC decreases in ACD since transferrin (the main iron-binding protein) synthesis is suppressed by inflammatory cytokines.

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 599.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: With respect to antibodies associated with pernicious anemia, which of the following descriptions is incorrect? (Q880019)

A. Type I antibody can be detected in both serum and gastric secretions

B. Type I antibody interferes with the attachment of vitamin B12 to intrinsic factor

C. Type II antibody blocks the interaction of the intrinsic factor–B12 complex with ileal receptors

D. Type III antibody targets haptocorrin

Correct Answer: D. Type III antibody targets haptocorrin

Explanation: Haptocorrin binds vitamin B12 in the stomach to protect it from acid degradation, but is not the target of autoimmune antibodies in pernicious anemia. Incorrect Options: Binding of cobalamin to haptocorrin in the stomach (Option A): Type I antibody (“blocking antibody”) can be detected in serum and gastric secretions and prevents the binding of vitamin B12 to intrinsic factor. Transport of cobalamin via transcobalamin II (Option B): Type I antibody inhibits vitamin B12 from binding to intrinsic factor, preventing intrinsic factor-vitamin B12 complex formation. Interaction of vitamin B12 with intrinsic factor (Option C): Type II antibody (“binding antibody”) binds to the intrinsic factor-vitamin B12 complex and blocks its uptake in the terminal ileum.

References:

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 594.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 28-year-old woman who underwent ileal resection for Crohn's disease presents with features of megaloblastic anemia. Which step in vitamin B12 absorption and transport is most likely impaired in her case? (Q880008)

A. Cubilin receptor–mediated uptake

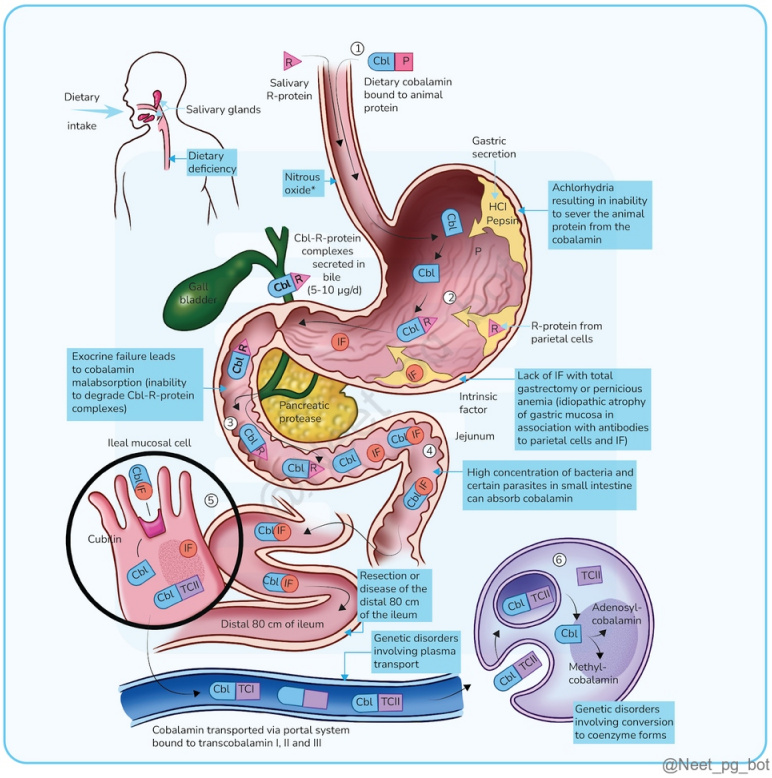
B. Binding of cobalamin to haptocorrin

C. Transport of cobalamin via transcobalamin II

D. Interaction of vitamin B12 with intrinsic factor

Correct Answer: A. Cubilin receptor–mediated uptake

Explanation: Vitamin B12 absorption occurs mainly in the terminal ileum, where the intrinsic factor–vitamin B12 complex binds to the cubilin receptor on the ileal enterocyte surface for absorption. Extensive ileal resection, as in Crohn's disease surgery, impairs this step, leading to B12 deficiency and megaloblastic anemia. Incorrect Options: Binding of cobalamin to haptocorrin in the stomach (Option B): Binding of vitamin B12 to haptocorrin occurs in the stomach; this step is unaffected by ileal resection. Transport of cobalamin via transcobalamin II (Option C): Transcobalamin II transports vitamin B12 in the plasma after absorption; this process is not impaired by ileal resection. Interaction of vitamin B12 with intrinsic factor (Option D): Vitamin B12 binds intrinsic factor in the duodenum; this early step remains intact in ileal resection.



@Neet_pg_bot

Robbins and Cotran, Pathologic Basis of Disease, 11th Edition, Page 593.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A patient presents with inflammation of the mouth and tongue. He is a non-vegetarian. As part of the evaluation, a Schilling test was done and found unremarkable. Which of the following investigations could lead to the aetiology behind this presentation? (Q845910)

A. Serum folate levels

B. Peripheral blood smear

C. Anti-IF antibody levels

D. Serum Vitamin B12 levels

Correct Answer: A. Serum folate levels

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: It is a scenario of possible megaloblastic anaemia due to folate deficiency. Hence, serum/red cell folate can lead to the aetiology behind this presentation. Schilling test is done by orally administering the patient with radioactive vitamin B12 and checking its presence in the urine. If present, as with this case, it is understood that there is no problem with the absorption. In addition to an unremarkable Schilling test, the fact that vitamin B12 deficiency is uncommon among non-vegetarians suggests a diagnosis of folate-deficient megaloblastic anaemia. Stage of test 24-hour urinary excretion of radiolabelled B12 Inference Stage 1: Oral radiolabelled B12 + IM dose of unlabelled B12 (to saturate liver stores) >10% (Normal) Malnutrition <10% Stage 2 of the test is done Stage 2: Oral radiolabelled B12 + Intrinsic factor >10% Pernicious anaemia <10% Stage 3 of the test is done Stage 3: Oral radiolabelled B12 + Antibiotics (5-day course) >10% Small intestinal bacterial overgrowth <10% Stage 4 of the test is done Stage 4: Oral radiolabelled B12 + Recombinant pancreatic enzymes >10% Pancreatic insufficiency (Cystic fibrosis, chronic pancreatitis) <10% Consider other ileal diseases Peripheral blood smear (Option B) may exhibit megalocytes with hyper-segmented neutrophils suggestive of megaloblastic anaemia, but the aetiology cannot be identified based on this. Anti-IF (intrinsic factor) antibodies (Option C) are found in patients with pernicious anaemia, and since the Schilling test is unremarkable, it can be ruled out.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 654, 655

Harrison’s Principles of Internal Medicine, 21st Edition, Page 771

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A group of scientists is studying the mechanisms involved in the pathogenesis of megaloblastic Anaemia secondary to vitamin deficiencies. The final study results demonstrate a "folate trap" as one of the likely pathophysiologic mechanisms of megaloblastic Anaemia. Which of the following is closely associated with the "folate trap"? (Q875986)

A. Normal serum tetrahydrofolate

B. Reduced serum methyltetrahydrofolate

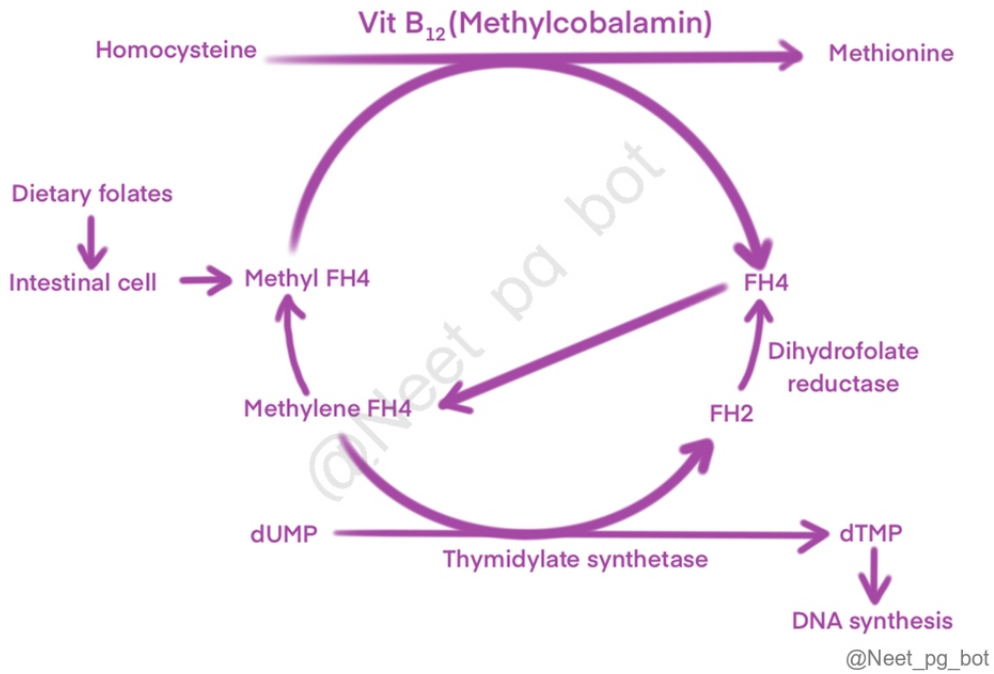
C. Normal serum B12

D. Reduced serum vitamin B12

Correct Answer: D. Reduced serum vitamin B12

Explanation: Option D: Reduced Serum Vitamin B12 Megaloblastic Anaemia is caused by a deficiency of vitamin B12 or folic acid. Vitamin B12 or methylcobalamin is required for the conversion of homocysteine to methionine

by methionine synthase. In this reaction, methylcobalamin recovers a methyl group from N 5 -methyltetrahydrofolate (N 5 -methyl FH 4), which is the principal form of folic acid in plasma. N 5 - methyl FH 4 is converted to tetrahydrofolic acid (FH 4) during this process. Tetrahydrofolic acid is crucial for DNA synthesis because its derivative N 5,10 -methylene FH 4 is required to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). The " methyl tetrahydrofolate trap " hypothesis has been proposed to explain the cause of impaired DNA synthesis in vitamin deficiencies. Folic acid deficiency can occur due to vitamin B12 deficiency due to an impairment of methionine synthase resulting in the trapping of folate as methyltetrahydrofolate whereby methyl THFA accumulates in serum leading to folate trap phenomenon and increased urinary excretion of folate. Conversion of methyl FH4 [tetrahydrofolate] to FH4 requires Vita min B12. Hence in Vitamin B12 deficiency, this conversion is impaired & most of the folate remains trapped as methyl FH4 ("folate trap"). Methylene FH4 required for the synthesis of dTMP is thus not generated (functional folate deficiency), ultimately leading to defective synthesis of DNA. Option A: Normal Serum Tetrahydrofolate In "the folate trap," most of the folic acid is trapped in the form of methyltetrahydrofolat e, as its conversion to tetrahydrofolate requires vitamin B12 during the conversion of homocysteine to methionine. The serum levels of tetrahydrofolate would therefore be reduced in vitamin B12 deficiency. Option B: Reduced Serum Methyltetrahydrofolate Vitamin B12 is required to convert methyltetrahydrofolate to tetrahydrofolate during the reaction involving the conversion of homocysteine to methionine. Serum methyltetrahydrofolate levels would be increased in vitamin B12 deficiency because of the trapping of the folic acid as methyltetrahydrofolate. Option C: Normal Serum Vitamin B12 Megaloblastic Anaemia is characterised by a "folate trap" secondary to vitamin B12 deficiency. The serum levels of vitamin B12 would therefore be reduced than normal.



References:

Robbins & Cotran Pathologic Basis of Disease 10th edition, page 653

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following statements is correct regarding the normal metabolism of vitamin B12? A. Haptocorrin from salivary glands binds to B12 in the stomach. B. It is absorbed in the duodenum with the help of intrinsic factor and transcobalamin II. C. Gastric enzymes play an important role in splitting of haptocorrin-B12 complex. D. It is stored primarily in the liver and has a large reserve capacity. E. It acts as a cofactor for converting homocysteine to methionine and methylmalonyl-CoA to succinyl-CoA. (Q845897)

A. A, B, C, and D

B. A, D, and E

C. A and C

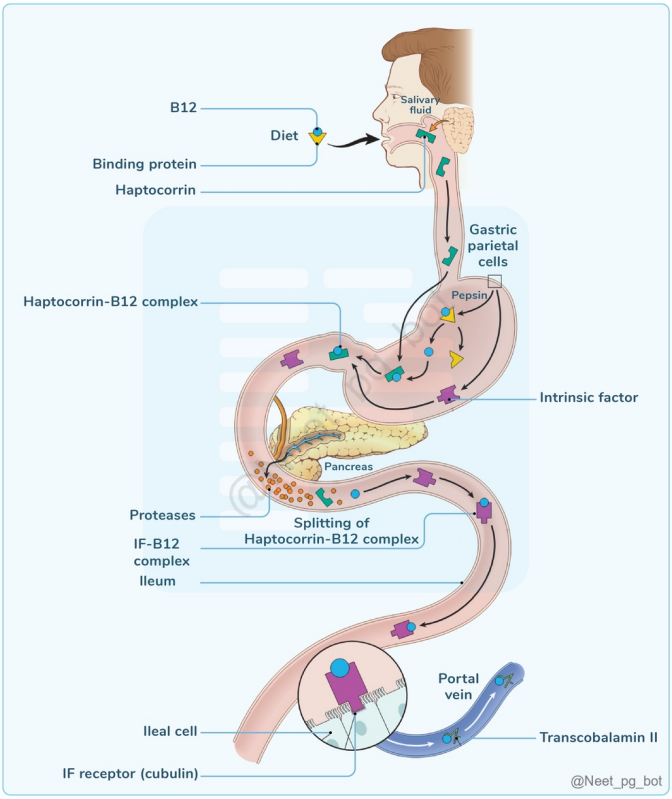
D. C and D

Correct Answer: B. A, D, and E

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Vitamin B12 Absorption and Transport: Vitamin B12 is absorbed in the terminal ileum (Option B). Haptocorrin , secreted by the salivary gland , binds to B12 in the stomach and enters the duodenum (Option A) . Haptocorrin is separated from B12 by pancreatic enzymes and binds to IF (Option C) . Absorbed B12 is transported by transcobalamin II (Option B) . Stored primarily in the liver and has a large reserve capacity to last several years (Option D) . Vitamin B12 is a cofactor for: (Option E) Conversion of homocysteine to methionine. Methyl malonyl-CoA to succinyl-CoA.



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 651-653

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following is true when increased urinary formiminoglutamic acid is detected in a patient to whom histidine is given? (Q845907)

A. Presence of antibodies against intrinsic factor

B. Deficiency of folic acid is present

C. Neurological symptoms are common

D. Presence of worm infestation

Correct Answer: B. Deficiency of folic acid is present

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Elevated urinary levels of formiminoglutamic acid (FIGlu) in a patient to whom histidine is given suggests the presence of folic acid deficiency . This is called the FIGlu test. Folic acid is normally required in its tetrahydrofolate form to regulate DNA synthesis and the production of methionine, glutamate, etc. Formiminoglutamic acid derived from histidine will be converted to glutamate in the presence of folic acid. If there is a folic acid deficiency, this conversion will not occur, leading to elevated urinary formiminoglutamic acid. Presence of antibodies against intrinsic factor (Option A): Antibodies to intrinsic factor will be seen in pernicious anaemia in which there will be vitamin B12 deficiency. Neurological symptoms are common (Option C): Neurological symptoms will be seen in Vitamin B12 deficiency , not folate deficiency.

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 653

Harper's Illustrated Biochemistry, 32nd Edition, Page 545

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following helps differentiate megaloblastic anaemia caused by vitamin B12 deficiency, not folate? (Q845905)

A. Reduced plasma homocysteine levels

B. Neurological symptoms improve after folate administration

C. Raised urinary methylmalonic acid levels

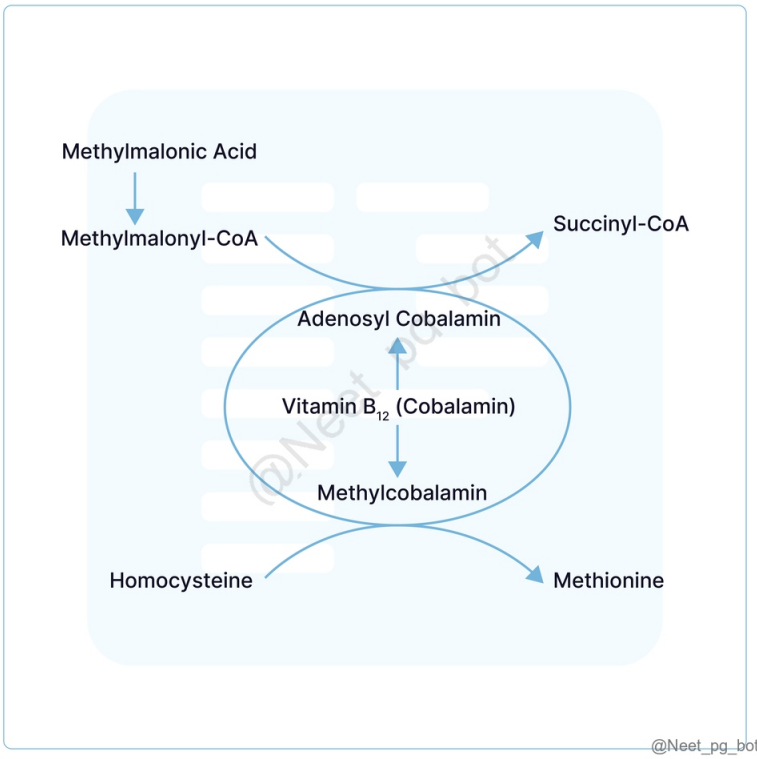
D. Anaemia doesn't improve after folate administration

Correct Answer: C. Raised urinary methylmalonic acid levels

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Plasma and urinary methylmalonic acid levels will be elevated in case of vitamin B12 deficiency but not with folate deficiency. This is because the enzyme methylmalonyl coenzyme A mutase's isomerisation of methylmalonyl coenzyme A to succinyl coenzyme A requires adenosylcobalamin (a form of vitamin B12) as a cofactor. A deficiency of vitamin B12 thus leads to increased plasma and urine levels of methylmalonic acid. Vitamin B12 is key in converting homocysteine to methionine; hence, its deficiency will lead to elevated homocysteine levels (Option A) rather than reduction. Neurological symptoms will remain the same, if not worsen, after folate administration in case of Vitamin B12 deficient megaloblastic anaemia (Option B) . Improvement in symptoms and reduction in megaloblastic count occur after folate administration, even if the anaemia is due to Vitamin B12 deficiency (Option D) .



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 653, 654

↑ *Back to this question in Part A*

@Neet_pg_bot

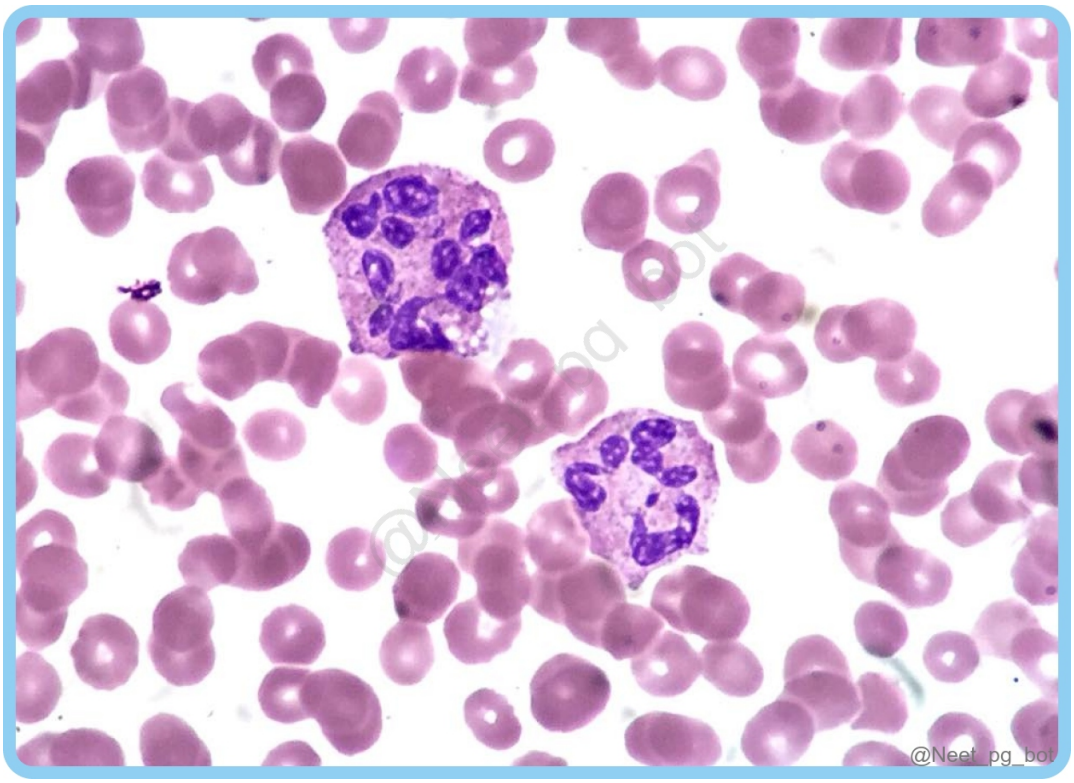
Q14: A patient presents with tiredness and myalgia for the past 3 months. She has hypertension, psoriasis and hyperuricemia, for which she is on multiple medications. A peripheral blood smear is done which is given in the image below. Which of her following medications would have caused these symptoms? (Q845903)

A. Hydrochlorothiazide

B. Adalimumab

C. Methotrexate

D. Colchicine



Correct Answer: C. Methotrexate

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The peripheral blood smear shows enlarged oval-shaped red blood cells (macro-ovalocytes) with hyperchromia and hypersegmented neutrophils. This suggests megaloblastic anaemia , which in this scenario would be due to folate deficiency caused by methotrexate. Common causes of folate deficiency are given below : Decreased intake Inadequate diet. Alcoholism. Infancy. Impaired absorption Malabsorption states. Intrinsic intestinal disease. Anticonvulsants, oral contraceptives. Increased loss Haemodialysis. Increased requirement Pregnancy. Infancy. Disseminated cancer. Markedly increased hematopoiesis. Impaired utilisation Folic acid antagonists (Methotrexate).

Q18: A 60-year-old female presents with chronic fatigue, shortness of breath, tingling and numbness in her hands and feet, bloating, and epigastric pain after meals. She has a history of occasional heartburn and nausea. On examination, she is pale, has a smooth, enlarged tongue with the following findings on the hand. Lab investigations show haemoglobin to be 9.6 g% and MCV 112. What is the most likely diagnosis? (Q845899)

A. Iron deficiency anaemia

B. Folate deficiency

C. Pernicious anaemia

D. Thalassemia

Correct Answer: C. Pernicious anaemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Pernicious anaemia is the likely diagnosis due to macrocytic anaemia (high MCV), chronic fatigue, neurological symptoms (tingling and numbness), and gastrointestinal issues (bloating and epigastric pain). The physical signs of pallor and a smooth, enlarged tongue, along with the image of knuckle hyperpigmentation further indicate vitamin B12 deficiency, characteristic of pernicious anaemia. Pernicious Anemia: Pernicious anaemia is a specific form of megaloblastic anaemia caused by autoimmune gastritis that impairs the production of the intrinsic factor required for vitamin B12 uptake from the gut. Three types of antibodies: Type 1: Inhibit B12 binding to intrinsic factor . Type 2: Inhibit B12-IF binding to iliac cubilin receptors. Type 3: Target parietal cells. Clinical features : Fatigue and pallor. Hyperpigmentation : Mainly on knuckles and interphalangeal areas. Atrophic glossitis (beefy red smooth tongue). Atrophic gastritis (due to antibodies against parietal cells). Increased gastric adenocarcinoma risk. Neurological manifestations: Subacute combined degeneration of the spinal tract. Both sensory and motor loss (combined degeneration) Headache, fatigue , impaired balance , paresthesia, muscle weakness and neuropathy . Blood smear: Iron deficiency anaemia typically presents with microcytic anaemia (Option A) . Folate deficiency can present with macrocytic anaemia but is less likely to cause neurological symptoms and knuckle hyperpigmentation (Option B) . Thalassemia presents with microcytic anaemia and is not associated with hyperpigmentation or neurological symptoms (Option C) .

@Neet_pg_bot

Q19: All of the following are the causes of anaemia due to vitamin B12 deficiency, except? (Q845898)

A. Pernicious anemia

B. Chronic alcoholism

C. Diphyllobothrium latum infection

D. Gastric resection

Correct Answer: B. Chronic alcoholism

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Chronic alcoholism causes megaloblastic anaemia due to folate deficiency. Causes of Vitamin B12 deficiency: Reduced Dietary Intake Increased demand Impaired Absorption Vegetarian diet Pregnancy Lactation Growing child Pernicious anemia (Option A) Infections- Diphyllobothrium latum (Option C) Gastrectomy (Option:D) Ileal disorders Malabsorption Ileal resection Diverticula of bowel

Q1: Caspase-1 is primarily involved in which type of programmed cell death? (Q865391)

A. Apoptosis

B. Pyroptosis

C. Necroptosis

D. Necrosis

Correct Answer: B. Pyroptosis

Explanation: Caspase-1 plays a central role in Pyroptosis , a form of programmed cell death associated with inflammation. It is a form of apoptosis in which there is release of the fever-inducing cytokine IL-1. Microbial products entering infected cells are recognized by cytoplasmic receptors, activating the multiprotein complex

inflammasome. This complex activates caspase 1 which converts the inactive IL-1 to active IL-1, causing fever, inflammation and leucocyte recruitment. (Option B) Pyroptosis is the mechanism by which some microbes cause the death of infected cells and trigger local inflammation. Apoptosis (Option A) is a controlled, non-inflammatory cell death involving caspases-8, -9, -3, and -7, but not caspase-1, and serves to remove damaged cells without triggering an immune response. Necroptosis (Option C) is a programmed inflammatory cell death triggered when apoptosis is blocked, involving RIPK1, RIPK3, and MLKL—but not caspase-1, distinguishing it from pyroptosis. Necrosis (Option D) is an uncontrolled, non-programmed cell death due to injury (e.g., trauma or ischemia), causing inflammation without involving caspases, including caspase-1.

@Neet_pg_bot

Q2: A 24-year-old male was brought to the emergency department after suffering severe injuries in a motorcycle accident. His blood pressure was 80/60 mm Hg, and he was tachycardic with cold, clammy skin. An ultrasound examination revealed a ruptured spleen. Arterial blood gas analysis was suggestive of metabolic acidosis. Which of the following conditions most likely caused the patient to suffer? (Q857122)

A. Cardiogenic shock

B. Septic shock

C. Hypovolemic shock

D. Neurogenic shock

Correct Answer: C. Hypovolemic shock

Explanation: Hypovolemic shock occurs due to significant blood or fluid loss, leading to reduced blood volume and inadequate tissue perfusion. This patient's low blood pressure, tachycardia, cold, clammy skin, and metabolic acidosis suggest shock caused by blood loss from the ruptured spleen. Shock is a state of circulatory failure that impairs tissue perfusion and leads to cellular hypoxia. Initially, cellular injury is reversible, but prolonged shock can cause irreversible tissue damage and may be fatal. It can result from various conditions, such as severe haemorrhage, extensive trauma, burns, myocardial infarction, pulmonary embolism, and microbial sepsis. The causes of shock can be categorised into three main types: Cardiogenic shock: (Option A) Caused by low cardiac output due to myocardial pump failure. This may result from intrinsic myocardial damage (e.g., infarction), ventricular arrhythmias, extrinsic compression (e.g., cardiac tamponade), or outflow obstruction (e.g., pulmonary embolism). Hypovolemic shock: Occurs due to low blood volume, often from massive haemorrhage or fluid loss (e.g., severe burns). This leads to reduced cardiac output and impaired tissue perfusion. Septic shock: (Option B) Sepsis : Life-threatening organ dysfunction due to a dysregulated host response to infection. Septic Shock : A

subset of sepsis with profound circulatory, cellular, and metabolic abnormalities that increase mortality risk. Systemic Inflammatory Response Syndrome (SIRS) : A sepsis-like condition triggered by non-microbial insults, such as burns, trauma, or pancreatitis. Both SIRS and septic shock are marked by a massive release of inflammatory mediators, causing arterial vasodilation, vascular leakage, and venous blood pooling, leading to tissue hypoperfusion, cellular hypoxia, and organ dysfunction. Neurogenic Shock (Option D) : Occurs following spinal cord injury, leading to acute vasodilation and hypotension. Anaphylactic Shock : Caused by an IgE-mediated hypersensitivity reaction, resulting in acute vasodilation, hypotension, and tissue hypoperfusion.

@Neet_pg_bot

Q3: Which of the following is true regarding sirtuins? Increases insulin sensitivity and glucose metabolism Promotes genes that increase longevity They are of 7 types They are one of the types of histone deacetylases (Q855087)

A. 1, 2, 3

B. 1, 2, 3, 4

C. 2, 3

D. 2, 4

Correct Answer: B. 1, 2, 3, 4

Explanation: Sirtuins are NAD-dependent protein deacetylases. (Statement 4) Seven types (Statement 3) of sirtuins exist in mammals, each with unique functions. They help the body adapt to environmental stresses like food deprivation and DNA damage . Longevity : Sirtuins promote genes that increase longevity (Statement 2) , reduce metabolism, inhibit apoptosis, and protect against oxidative damage. Sirtuins enhance insulin sensitivity and glucose metabolism (Statement 1) Caloric restriction : Increases sirtuin activity, reducing IGF-1 signalling, leading to slower cell growth, reduced metabolism, and cellular damage. Sirtuin-6 : Plays a key role in metabolic adaptations and DNA repair by activating repair enzymes. Anti-ageing : Sirtuins are linked to anti-ageing effects. Red wine : A compound in red wine is believed to activate sirtuins, potentially contributing to increased lifespan.

@Neet_pg_bot

Q4: Cell-in-cell appearance is seen in which of the following? (Q855076)

A. Necrosis

B. Apoptosis

C. Necroptosis

D. Entosis

Correct Answer: D. Entosis

Explanation: Entosis refers to the process where one cell is engulfed by another, leading to a "cell-in-cell" appearance. Entosis : It refers to a homotypic process where one epithelial cell invades the cytoplasm of another epithelial cell. The host cell forms a vacuole around the internalized cell, which deforms its organelles, including the nucleus. The inner cell may survive within the host cell for up to 12 hours or longer, eventually being digested by the outer cell through an autophagosomal mechanism, or it may escape. {{caption_text}} Necrosis (Option A) is an uncontrolled form of cell death characterized by cell swelling, rupture, and inflammation. Apoptosis (Option B) is a controlled, programmed cell death where cells shrink and fragment into apoptotic bodies. Necroptosis (Option C) is a form of regulated cell death that mimics necrosis but is genetically controlled. Unlike apoptosis, it is associated with inflammation and occurs via receptor-interacting protein kinases (RIPK1 and RIPK3), leading to membrane rupture and the release of intracellular contents.

@Neet_pg_bot

Q5: Senile atrophy occurs due to which of the following? (Q856024)

A. Denervation

B. Decreased nutrition

C. Decreased workload

D. Reduced blood supply

Correct Answer: D. Reduced blood supply

Explanation: Chronic ischemia from progressive arterial occlusion leads to tissue atrophy. In older adults, reduced cerebral blood flow due to atherosclerosis causes senile atrophy of the brain. Loss of innervation (denervation atrophy) (Option A) : Skeletal muscle metabolism and function rely on nerve supply. Damage to the nerves results in atrophy of the muscle fibres they innervate. Inadequate nutrition (Option B) : Severe protein-calorie malnutrition, such as marasmus , causes the breakdown of skeletal muscle proteins for energy after fat stores are depleted, leading to muscle wasting (cachexia) . This is common in chronic inflammatory diseases and cancer. In cachectic states, excessive TNF production contributes to appetite suppression and lipid depletion, further exacerbating muscle atrophy. Decreased workload (disuse atrophy) (Option C) : Immobilization of bones, such as through a plaster cast or prolonged bed rest, leads to rapid muscle atrophy. Initially, the decrease in cell size is reversible upon resumption of activity. However, with prolonged disuse, muscle fibres shrink in size and number (due to apoptosis), and muscle atrophy may be accompanied by increased bone resorption, resulting in disuse osteoporosis.

@Neet_pg_bot

Q6: Which among the following is less related to irreversible cell injury? (Q820573)

A. Blebs formation

B. Karyolysis

C. Amorphous densities

D. Pyknotic nucleus

Correct Answer: A. Blebs formation

Explanation: Correct Option A - Blebs formation: Blebs formation is actually a characteristic feature of reversible cell injury, not irreversible injury. Blebs formation is less related to irreversibility when compared to other features given in the options. Blebs are small, bubble-like protrusions on the cell membrane that result from cytoskeletal and membrane alterations. They can be observed in conditions like ischemia and toxic injury. Reversibility implies that the cell can recover its normal structure and function when the damaging stimulus is removed. Incorrect Options: Option B - Karyolysis: Karyolysis refers to the dissolution of the cell nucleus due to DNA degradation. This is indeed a feature of irreversible cell injury. In irreversible injury, the cell's nuclear structure and DNA integrity are compromised beyond repair, leading to processes like karyolysis. Option C - Amorphous Densities: The presence of amorphous densities is often associated with irreversible cell injury. These densities can be observed under electron microscopy and represent aggregates of denatured or altered proteins, lipids, and other cellular components. They are a sign of severe damage and cell death. Option D - Pyknotic Nucleus: Pyknosis is the irreversible condensation of chromatin within the nucleus, resulting in a small, darkly stained and shrunken nucleus. This is indeed a feature of irreversible cell injury. Pyknotic nuclei indicate severe cellular damage that cannot be reversed, leading to cell death.

@Neet_pg_bot

Q7: Which of the following is an anti-apoptotic gene? (Q857450)

A. BAK

B. MCL1

C. PUMA

D. BAD

Correct Answer: B. MCL1

Explanation: MCL1 is an anti-apoptotic gene and part of the BCL-2 family. Apoptosis is a key process for maintaining cell balance and eliminating damaged cells, regulated by the interplay between pro-apoptotic and anti-apoptotic genes. MCL1 inhibits apoptosis by preventing the activation of pro-apoptotic proteins, thereby promoting cell survival. Apoptotic genes: Anti Apoptotic genes :- BCL-2 , BCL-XL , MCL-1 Pro Apoptotic genes:- BAX and BAK (Option A ruled out) Apoptosis initiators:- BAD, BIM, BID, Noxa and Puma (Option C & D ruled out)

@Neet_pg_bot

Q8: Which of the following diseases is caused by abnormal folding of proteins? (Q857433)

A. Creutzfelt Jakob disease

B. Cirrhosis

C. Nephritic syndrome

D. Sickle cell anemia

Correct Answer: A. Creutzfelt Jakob disease

Explanation: Creutzfeldt-Jakob disease (CJD) is a type of prion disease caused by the abnormal folding of proteins, specifically prion proteins (PrP), which leads to neurodegeneration. It is irreversible and fatal . The disease progresses quickly, and death usually occurs within a year. It is characterised by Rapidly progressive dementia Myoclonus Ataxia Visual disturbances Diagnosis: It is confirmed via MRI (increased signal in basal ganglia) and EEG findings Cirrhosis (Option B) is liver scarring typically caused by chronic liver diseases (e.g., hepatitis, alcoholism), not protein misfolding. Nephritic syndrome (Option C) is a kidney disorder involving inflammation, typically due to immune complex deposition, not protein misfolding. Sickle cell anaemia (Option D) is caused by a genetic mutation in the haemoglobin gene (HbS) that leads to abnormal haemoglobin, but not a misfolding of proteins in the same sense as prion diseases.

@Neet_pg_bot

Q10: Identify the correct statements regarding amyloidosis. Amyloidosis is called so because it looks like the deposition of starch. Beta-pleated sheets are seen. AL is a type of secondary amyloidosis. It is an extracellular protein. (Q857424)

A. 1, 2 and 3

B. 1, 4

C. 2, 3 and 4

D. 1, 2 and 4

Correct Answer: D. 1, 2 and 4

Explanation: Amyloidosis is a group of disorders characterized by the extracellular deposition of amyloid fibrils that are produced by the aggregation of misfolded proteins. (Statement 4) The presence of abundant charged sugar groups in these adsorbed proteins gives the deposits staining characteristics that were thought to resemble starch (amylose). Therefore, the deposits were called amyloid (Statement 1). 95% of amyloid consists of fibril proteins, with the remaining 5% being glycosaminoglycans (dermatan sulfate and heparan sulfate) and plasma proteins, notably serum amyloid P . AL amyloidosis is a primary form of amyloidosis, whereas secondary form can be caused by various etiologies and is associated with characteristic amyloid deposition (Statement 3). Physical nature of amyloid: Light microscopy with H & E stains: Amyloid is an amorphous , eosinophilic , hyaline , and extracellular substance. Electron microscopy: All types of amyloid, regardless of clinical setting or chemical composition, consist of continuous, nonbranching fibrils with a diameter of approximately 7.5 to 10 nm. X-ray crystallography and infrared spectroscopy: Characteristic cross-β-pleated sheet conformation, which is responsible for the distinctive Congo-red staining and apple-green birefringence of the amyloid. (Statement 2)

@Neet_pg_bot

Q11: Apoptotic bodies comprise of? (Q860513)

A. Include cytoplasm + intranuclear material + organelle

B. Cytoplasm + organelle

C. Organelle + intranuclear material

D. Only organelle

Correct Answer: A. Include cytoplasm + intranuclear material + organelle

Explanation: Apoptotic bodies are comprised of cytoplasm, intranuclear material and cellular organelles. Apoptosis (caspase-dependent programmed cell death): It is a type of cell death that is induced by a tightly regulated suicide program in which cells destined to die activate intrinsic enzymes that degrade the cells' genomic DNA and nuclear and cytoplasmic proteins. It is an active process. It eliminates cells that are injured beyond repair without eliciting a host reaction, thus limiting collateral tissue damage. Apoptosis results from the activation of enzymes called caspases, which leads to DNA fragmentation. The process of apoptosis may be divided into: Initiation phase: Caspases 8,9,10 become catalytically active and unleash a cascade of other caspase Execution phase: During which the terminal caspases 3,6,7 trigger cellular fragmentation. Morphological features:- Cell shrinkage Chromatin condensation Formation of cytoplasmic blebs and apoptotic bodies (cytoplasm and tightly packed organelles, with or without nuclear fragments) (Option A) Phagocytosis of apoptotic bodies, usually by

macrophages. Histopathology: The apoptotic cell appears as a round or oval mass of intensely eosinophilic cytoplasm with fragments of dense nuclear chromatin. {{caption_text}} The cell is reduced in size and contains brightly eosinophilic cytoplasm and a condensed nucleus. Types: Apoptosis occurs in two broad contexts: Physiological apoptosis. Pathological apoptosis. Physiological Apoptosis Pathological Apoptosis The removal of supernumerary cells (in excess of the required number) during development. Involution of hormone-dependent tissues on hormone withdrawal, such as endometrial cell breakdown during the menstrual cycle. Elimination of potentially harmful self-reactive lymphocytes to prevent immune reactions against one's own tissues. Death of host cells that have served their useful purpose, such as neutrophils in an acute inflammatory response and lymphocytes at the end of an immune response. DNA damage. Accumulation of misfolded proteins Apoptosis can be induced during certain infections- as in adenovirus and HIV infections and viral hepatitis. It may also contribute to pathologic atrophy in parenchymal organs after duct obstruction, such as occurs in the pancreas, parotid gland, and kidney.

@Neet_pg_bot

Q12: Which of the following types of cell death involves activation of caspase enzymes? (Q866340)

A. Necrosis and Apoptosis

B. Apoptosis and Pyroptosis

C. Apoptosis and necroptosis

D. Apoptosis only

Correct Answer: B. Apoptosis and Pyroptosis

Explanation: Apoptosis and Pyroptosis involves activation of caspase enzymes. Apoptosis A tightly regulated suicide program where cells activate enzymes to degrade their DNA and proteins. It's an active process eliminating irreparably damaged cells without causing inflammation or tissue damage. Driven by activation of caspases that cause DNA fragmentation Phases: (Option B) Initiation phase: Activation of caspases 8, 9, 10 triggers a cascade. Execution phase: Terminal caspases 3, 6, 7 lead to cellular breakdown. Morphological features: Cell shrinkage Chromatin condensation Cytoplasmic blebs and formation of apoptotic bodies Phagocytosis of apoptotic bodies by macrophages Histopathology: Apoptotic cells appear as round/oval with intensely eosinophilic cytoplasm and dense nuclear chromatin fragments. Pyroptosis It is a form of programmed cell death involving release of IL-1, a fever-inducing cytokine. Microbial products in cells activate the inflammasome complex. Inflammasome activates caspase-1, which converts inactive IL-1 to active IL-1. (Option B) Active IL-1 causes fever, inflammation, and leukocyte recruitment. Pyroptosis helps eliminate infected cells and triggers local inflammation. Necrosis (Option A) is a form of accidental cell death that does not involve caspases. Necroptosis (Option C) is a programmed form of necrosis that occurs independently of caspases.

@Neet_pg_bot

Q13: Supravital stains are used in the identification of all except? (Q857588)

A. Reticulocytes

B. Copper in tissue

C. Heinz bodies

D. Ribosomal RNA

Correct Answer: B. Copper in tissue

Explanation: Supravital stains are typically used to identify cellular components such as reticulocytes (immature red blood cells), Heinz bodies (denatured haemoglobin), and ribosomal RNA (which is seen in reticulocytes as a network). However, copper in tissue is not identified using supravital stains; it requires special staining techniques like rhodanine stains. {{caption_text}}

@Neet_pg_bot

Q14: A diabetic male presented with seizures. Radiological examination shows a lesion. Histopathological examination shows liquefactive necrosis. What is the most important mechanism responsible for this? (Q866754)

A. Enzymatic degradation

B. Mechanical

C. Ischemic

D. Pressure

Correct Answer: A. Enzymatic degradation

Explanation: Diabetic patient with seizures → raises suspicion for a brain lesion (possibly abscess, infarct, or infection-related pathology). Histopathology: liquefactive necrosis → classic type of necrosis seen in brain tissue. Liquefactive necrosis in brain is mainly due to hydrolytic enzyme action breaking down tissue. In the CNS, ischemia or infection activates microglia and infiltrating neutrophils. These cells release lysosomal hydrolytic enzymes. Brain tissue is rich in lipids and has little structural stroma, so enzymatic digestion quickly converts tissue into a liquid mass. Mechanism: enzymatic degradation > structural breakdown → liquefactive necrosis. Mechanical (Option B): Trauma can cause hemorrhage or contusion, but necrosis type is not primarily from mechanical injury alone, here histology points to enzymatic breakdown. Ischemic (Option C): Ischemia in most organs causes coagulative necrosis, except in the brain, where it still leads to liquefactive necrosis, but the mechanism is enzymatic digestion, not ischemia per se. Pressure (Option D): Increased intracranial pressure can cause herniation or atrophy, not liquefactive necrosis by itself.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which of the following is pro-apoptotic? (Q866665)

A. Bcl-2

B. Bcl-xL

C. Mcl-1

D. Bax

Correct Answer: D. Bax

Explanation: The correct answer is Bax , because it is a pro-apoptotic member of the Bcl-2 protein family. The Bcl-2 family regulates the intrinsic (mitochondrial) apoptosis pathway. Members are divided into: Anti-apoptotic : Bcl-2, Bcl-xL, Mcl-1 → preserve mitochondrial membrane integrity, prevent cytochrome c release. Pro-apoptotic : Bax, Bak, Bok → promote mitochondrial outer membrane permeabilisation (MOMP), allowing cytochrome c release and caspase activation. Mnemonic: "Bax and Bak Break" (break the mitochondrial membrane) → pro-apoptotic. "Bcl and Bcl-xL Build" (preserve the membrane) → anti-apoptotic.

@Neet_pg_bot

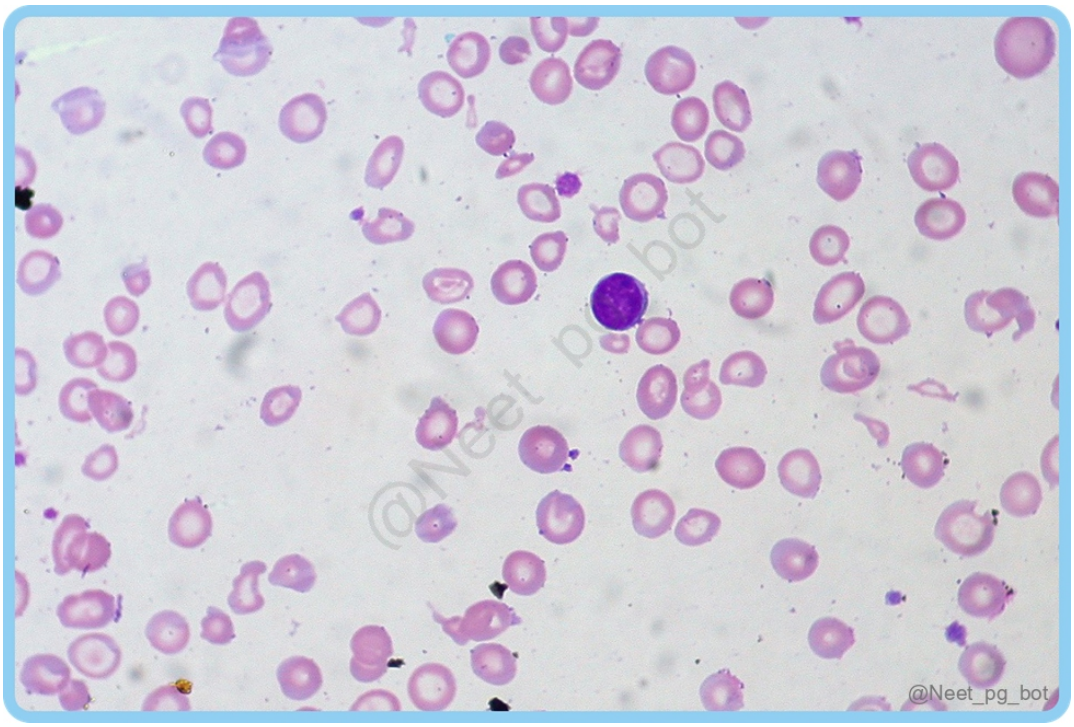
Q16: A female patient presented with fatigue and a history of piles. Routine complete blood count analysis showed a hemoglobin of 8.5 g/dL, an MCV of 65 fL, and an RBC count of 3.2 million and RDW is increased. A peripheral smear is given below. Which of the following is the next best investigation for this patient? (Q855974)

A. HbA2 levels

B. Serum ferritin levels

C. Serum folate levels

D. Serum homocysteine levels



Correct Answer: B. Serum ferritin levels

Explanation: : Folate deficiency causes macrocytic anemia , not microcytic anemia. The MCV here is low , making folate levels less relevant. Serum homocysteine levels (Option D) : This would be more relevant for vitamin B12 or folate deficiency , which typically causes macrocytic anemia , not microcytic anemia.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 620, 621, 655, 658, 659

↑ *Back to this question in Part A*

@Neet_pg_bot

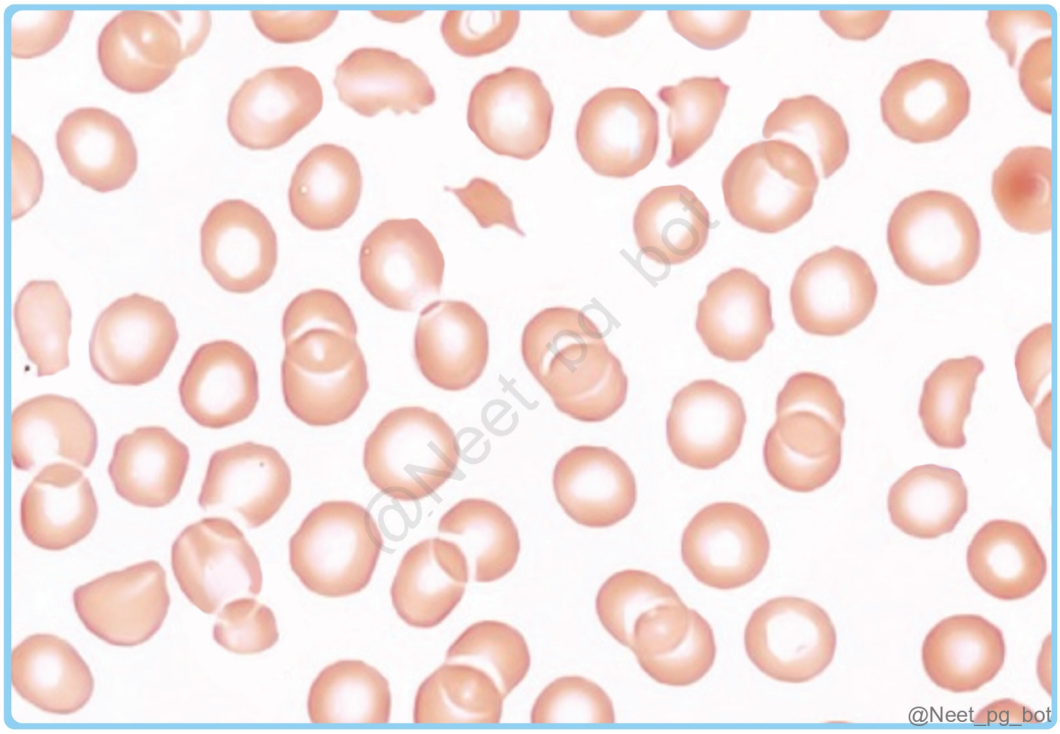
Q17: An elderly patient presents with anemia and hemoglobinuria. Investigations reveal increased bilirubin and lactate dehydrogenase. The peripheral smear image is given below. Which of the following is associated with this? (Q855931)

A. Splenomegaly

B. Mechanical second heart valve

C. Increased HbA2

D. Goitre



Correct Answer: B. Mechanical second heart valve

Explanation: refers to an enlarged thyroid gland , and it is typically associated with thyroid disorders. The patient's symptoms and lab results point toward a haematological problem, specifically hemolysis , which would not be linked to a thyroid disorder like goitre.

Robbins and Cotran, Pathologic Basis of Disease, 10th edition, Pages 566, 637,

MedscapeLink

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A child presents with recurrent chest infections and abdominal pain. There is a history of delayed growth and bone problems causing facial changes. On examination, he had icterus and mild splenomegaly. Peripheral smear shows following finding. What is the likely diagnosis? (Q855920)

A. Beta thalassemia

B. HbC disease

C. Sickle cell disease

D. Acute coronary disease

Correct Answer: A. Beta thalassemia

Explanation: The clinical presentation described, with recurrent chest infections, abdominal pain, delayed growth, bone problems, icterus, and mild splenomegaly, points towards a hemoglobinopathy, and the peripheral smear showing target cells is also consistent with Beta-thalassemia. Thalassemia is a genetic disorder affecting haemoglobin production and causing microcytic, hypochromic anemia. Hemoglobin consists of two alpha (α) and two beta (β) chains, and mutations in the genes responsible for these chains lead to alpha or beta thalassemia, inherited in an autosomal recessive pattern. Beta thalassemia is caused by mutations in the HBB gene on chromosome 11, affecting β chain production. The severity depends on whether one or both β genes are mutated: Beta Thalassemia Trait (β-thalassemia minor) (1 mutated gene) Beta Thalassemia Intermedia (2 mutated genes with partial function) Beta Thalassemia Major (β0-thalassemia) (2 mutated genes, with complete absence of β chain production) Beta Thalassemias Major (Transfusion-dependent) Intermedia (Non-transfusion-dependent) Minor (Trait or Carrier) Genotype Homozygous: β■/β■ β■/β■ β■/β■ Variable: β■/β■ or β■/β■ or β■/β or β■/β Heterozygous: β■/β or β■/β Laboratory Findings Severe microcytic anemia with target cells (Hb 3–4 g/dL) Moderate microcytic anemia Mild microcytic anemia Hemoglobin Electrophoresis HbA■ (5% or more); HbF (up to 95%); No HbA HbA■ (4% or more); HbF (up to 50%) HbA■ (4% or more); HbF (up to 5%) Incorrect options: HbC disease (Option B) results in mild hemolysis splenomegaly and usually presents with milder symptoms compared to beta-thalassemia . Electrophoresis in HbC disease would reveal elevated levels of HbC, not HbA, and affected individuals generally experience normal growth and development. Sickle cell disease (Option C) is caused by a mutation in the beta-globin gene , leading to the production of HbS (sickle haemoglobin). The electrophoresis in this condition would show a predominant HbS peak. Acute coronary disease (Option D) is a cardiovascular condition that primarily affects adults. This condition would present with chest pain, shortness of breath, and EKG changes rather than jaundice, splenomegaly, and bone deformities. The patient described here is a child, making ACS an unlikely diagnosis.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 644 - 647

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 9-month-old boy presents with progressive pallor and abdominal distention. On examination, hepatosplenomegaly and malar eminence are observed. Laboratory investigations reveal a low hemoglobin level, and the Mentzer index is less than 13. Considering these findings, what is the most likely diagnosis for this patient? (Q859851)

A. Megaloblastic anemia

B. Iron deficiency anaemia

C. Thalassemia

D. Pernicious anemia

Correct Answer: C. Thalassemia

Explanation: Beta-thalassemia major typically presents in infants between 6 and 24 months with symptoms like progressive pallor due to severe anemia, abdominal distention from hepatosplenomegaly, and characteristic facial bone changes (malar eminence) caused by marrow expansion. The low Mentzer index (<13) supports the diagnosis of a microcytic hypochromic anemia like thalassemia rather than iron deficiency. Early diagnosis is crucial for management, including regular blood transfusions to improve survival and growth. Thalassemia Major (β-Thalassemia Major) Features Description Definition A severe form of β-thalassemia caused by homozygous or compound heterozygous mutations in the β-globin gene (HBB) on chromosome 11, leading to absent or markedly reduced β-globin chain production. Genetics Autosomal recessive disorder, caused by mutations in the β-globin gene leading to defective hemoglobin synthesis. Pathophysiology Reduced or absent β-globin chains lead to excess α-globin chains, which form unstable precipitates, causing ineffective erythropoiesis, hemolysis, and severe anaemia. Clinical Features Symptoms appear around 6 months of age (as fetal haemoglobin declines); severe anaemia, growth retardation, hepatosplenomegaly, skeletal deformities (crew-cut appearance on skull X-ray, frontal bossing), jaundice, and delayed puberty. Hematological Findings Peripheral smear : Microcytic hypochromic anaemia, target cells, anisopoikilocytosis, nucleated RBCs. Bone marrow : Erythroid hyperplasia with expansion of marrow cavities. Hemoglobin Electrophoresis Absent or very low HbA, markedly increased HbF (>90%), variable HbA2. Complications Iron overload (due to repeated transfusions leading to secondary hemochromatosis) Cardiac failure (due to iron deposition) E ndocrinopathies (diabetes, hypothyroidism, hypogonadism) Osteopenia/osteoporosis I ncreased infection risk (especially from Yersinia and viral infections). Diagnosis Blood tests (CBC, peripheral smear), Hb electrophoresis/HPLC , Serum ferritin (for iron overload), Genetic testing (HBB gene mutations), Prenatal diagnosis (chorionic villus sampling or amniocentesis). Treatment Regular blood transfusions , iron chelation therapy (deferoxamine, deferasirox, deferiprone), splenectomy (in refractory cases), and hematopoietic stem cell transplantation (HSCT) (only curative option). Prevention Carrier screening, genetic counselling, prenatal diagnosis, preimplantation genetic diagnosis (PGD) in high-risk couples. The Mentzer index (MCV/RBC count) helps distinguish IDA from beta-thalassemia minor , with a value <13 suggesting beta-thalassemia minor . An elevated RDW favours IDA in microcytic, hypochromic anaemia. Confirmatory test: Hemoglobin electrophoresis showing HbA■ >3.5% confirms beta-thalassemia minor. Megaloblastic anaemia (Option A) The main causes are folate and vitamin B12 deficiency. Peripheral blood shows hypersegmented neutrophils and macroovalocytes as early changes. Bone marrow is hypercellular, with numerous megaloblasts and giant metamyelocytes. {{caption_text}} Iron deficiency anemia (Option B) is the most common nutritional deficiency in the world. Diagnostic criteria include anaemia, hypochromic and microcytic red cell indices, low serum ferritin and iron levels, low transferrin saturation, and increased total iron-binding capacity. {{caption_text}} Pernicious anaemia (Option D): The most common cause of vitamin B12 deficiency, resulting from autoimmune destruction of gastric mucosa, leading to intrinsic factor deficiency.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 23-year-old male patient presented with a history of fatigue and tiredness. On investigation, he was found to have Hb = 9 g/dl and MCV = 101 FL. A peripheral smear examination showed macrocytic RBC and hypersegmented neutrophils. Which of the following is the most likely etiology? (Q858518)

A. Lead poisoning

B. Iron deficiency anaemia

C. Hemolytic anemia

D. Chronic alcoholism

Correct Answer: D. Chronic alcoholism

Explanation: The patient presents with macrocytic anemia (MCV = 101 fL) and peripheral smear findings of macrocytic RBCs and hypersegmented neutrophils, which strongly indicate megaloblastic anemia. This condition is most commonly caused by deficiencies in vitamin B12 or folate , often due to poor dietary intake, malabsorption, or chronic alcohol use. Chronic alcohol consumption is a well-known cause of macrocytic anemia, either due to direct toxic effects on hematopoiesis or through the development of folate deficiency , a key cause of megaloblastic anemia. {{caption_text}} Lead poisoning (Option A) typically causes microcytic anemia due to interference with heme synthesis. Iron deficiency anemia (Option B) is characterised by microcytic, hypochromic anaemia resulting from reduced haemoglobin production. Hemolytic anemia (Option C) may cause mild macrocytosis due to increased reticulocyte production; hypersegmented neutrophils are not seen. The hallmark findings of hemolysis (e.g., jaundice, reticulocytosis) are absent in this case.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 651

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A 52-year-old male patient comes with complaints of abdominal pain, nausea, and vomiting. A peripheral blood smear reveals macrocytes and hypersegmented neutrophils, and an endoscopy reveals atrophic gastritis. Which of the following conditions is likely to be seen in this patient? (Q854855)

A. Vitamin B12 deficiency

B. Folate deficiency

C. Pyridoxine deficiency

D. Niacin deficiency

Correct Answer: A. Vitamin B12 deficiency

Explanation: Vitamin B12 deficiency is commonly associated with macrocytic anemia, which is characterized by the presence of macrocytes and hypersegmented neutrophils on the peripheral blood smears. {{caption_text}} It can be caused by atrophic gastritis , which leads to impaired absorption of B12 due to reduced intrinsic factor production. Atrophic gastritis is frequently seen in pernicious anemia , a common cause of vitamin B12 deficiency. Causes of Vitamin B12 deficiency: Reduced Dietary Intake Increased demand Impaired Absorption Vegetarian diet Pregnancy Lactation Growing child Pernicious anemia (Option A) Infections- Diphyllobothrium latum (Option C) Gastrectomy (Option:D) Ileal disorders Malabsorption Ileal resection Diverticula of bowel Folate deficiency (Option B) can cause macrocytic anemia and hypersegmented neutrophils. However, it is less commonly associated with atrophic gastritis, and the absence of other features like neural tube defects (in pregnancy) makes it less likely in this case. Pyridoxine deficiency (Option C) (Vitamin B6) deficiency causes microcytic anemia and not macrocytic anemia and is unlikely to explain the findings of macrocytes and hypersegmented neutrophils. Niacin deficiency (Option D) (Vitamin B3) deficiency causes pellagra , which is characterised by the "three D's": dermatitis, diarrhea, and dementia. It does not cause macrocytic anemia or hypersegmented neutrophils.

Q22: What does the vacutainer tube depicted in the provided image contain? (Q856491)

A. Na-EDTA

B. Trisodium citrate

C. NAF-heparin

D. Clot activator

Correct Answer: D. Clot activator

Explanation: Clot activator is found in red-top vacutainer tubes and is used to promote blood clotting, which is needed for serum separation in various tests. Vacutainer Color Additive Purple/Lavender Na-EDTA (Option A) Blue Trisodium Citrate (Option B) Green Heparin (NAF-heparin) (Option C) Red No additive or Clot activator Yellow Acid citrate dextrose Gray Sodium fluoride, Potassium oxalate

@Neet_pg_bot

Q23: The JAK2 mutation is most commonly associated with: (Q856485)

A. Polycythemia vera

B. Essential thrombocytosis

C. Chronic myelogenous leukemia (CML)

D. Primary myelofibrosis (PMF)

Correct Answer: A. Polycythemia vera

Explanation: In polycythemia vera (>95% cases) , the JAK2 mutation leads to the persistent activation of the JAK-STAT signalling pathway, resulting in the uncontrolled proliferation and survival of red blood cell precursors. This overproduction increases red blood cell count in the bloodstream, leading to blood thickening and potential complications like thrombosis. Essential thrombocytosis (Option B) is characterized by the overproduction of platelets in the bone marrow, increasing the risk of abnormal blood clotting. Although JAK2 mutations can occur in essential thrombocytosis, they are less frequent compared to polycythemia vera. Chronic myelogenous leukaemia (CML) (Option C) is primarily associated with the Philadelphia chromosome, which results from a reciprocal translocation between chromosomes 9 and 22. This translocation leads to the creation of the BCR-ABL fusion gene, which causes uncontrolled proliferation of myeloid cells. Primary myelofibrosis (PMF) (Option D) involves the excessive production of abnormal blood cells, often leading to fibrosis (scarring) of the bone marrow. JAK2 mutations can also occur in primary myelofibrosis, though they are less common than in polycythemia vera.

@Neet_pg_bot

Q24: A 16-year-old boy presents with jaundice and splenomegaly. His father had a similar illness during adolescence. The MCHC was high. What is the most likely diagnosis? (Q866370)

A. IDA

B. Hereditary spherocytosis

C. Thalassemia major

D. AIHA

Correct Answer: B. Hereditary spherocytosis

Explanation: Hereditary Spherocytosis (HS) An inherited disorder caused by intrinsic defects in the red blood cell membrane skeleton, leading to spheroid, less deformable red cells vulnerable to splenic sequestration and destruction. 75% of cases are autosomal dominant . Remaining cases often involve severe forms due to compound heterozygosity (inheritance of two different defects). Etiopathogenesis HS is marked by a loss of membrane surface area relative to the intracellular volume, leading to spherical red blood cells with reduced or absent central pallor . Spherocytes have decreased deformability , resulting in their retention and destruction in the spleen , causing hemolysis. spectrin , ankyrin, AE1(band 3) , protein 4.2 that weakens the vertical connections between the cytoskeletal framework and lipid bilayer. The ANK1 gene on chromosome 8p produces Ankyrin . Two proposed mechanisms for membrane loss: In cells with spectrin/ankyrin deficiency . Reduced AE1/protein . Clinical features 60-70% of patients present with moderate disease, typically in infancy or childhood. Common findings in children include: Anaemia may be asymptomatic, Jaundice is usually intermittent and acholuric (unconjugated hyperbilirubinemia). >75% show palpable splenomegaly . Family history. Complications Gallbladder Disease : Chronic hemolysis can lead to bilirubinate gallstones . Crisis Events : Hemolytic Crisis : Commonly associated with viral illnesses in childhood; typically mild and self-resolving. Aplastic Crisis : Rare but may cause severe anaemia and require hospitalisation, often linked to parvovirus infection. Typically lasts 10–14 days and may reveal undiagnosed HS in asymptomatic patients. Megaloblastic Crisis : Occurs in patients with increased folate needs, preventable by supplementation. Other rare complications may include leg ulcers , chronic dermatitis, and skeletal abnormalities. HS has been associated with increased risks of hematologic malignancies and thrombotic events post-splenectomy. Incorrect Options: Iron deficiency anaemia (Option A): Usually microcytic, hypochromic anaemia with low MCHC, no jaundice, no splenomegaly, and no strong family history. Thalassemia minor (Option C): Presents in infancy with severe anaemia, failure to thrive, hepatosplenomegaly, and bone deformities; MCHC is not elevated, and family history often shows transfusion-dependent anaemia. AIHA (Option D): Can also have spherocytes and jaundice, but is typically acquired, not familial, and the Coombs test is positive . It is often acute/subacute onset, not a chronic familial condition.

Q25: A phlebotomist is asked to collect blood samples for a patient undergoing multiple tests. Which of the following is the correct order of blood collection to avoid contamination of the samples based on the additives in the collection tubes? (Q854685)

A. Light blue → Lavender → Red → Grey

B. Grey → Red → Light blue → Lavender

C. Light blue → Red → Lavender → Grey

D. Red → Lavender → Grey → Light blue

Correct Answer: C. Light blue → Red → Lavender → Grey

Explanation: The correct order here is Light blue → Red → Lavender → Grey In blood collection, it's crucial to follow the correct order to prevent contamination between tubes with different additives. The correct order of drawing the blood in vacutainers is Blood culture → Light blue → Red or Yellow → Green → Lavender → Grey Vacutainer colour Additive Uses Blood culture Broth media (aerobic/anaerobic) For detecting bacterial and fungal infections Light blue {{caption_text}} Trisodium citrate For coagulation tests Red or Yellow {{caption_text}} {{caption_text}} No additive (Red) / Gel separator (Yellow) For serum collection (serology, chemistry) Green Heparin For plasma collection (chemistry tests) Lavender {{caption_text}} EDTA For haematology tests (e.g., CBC, blood smears) Pink EDTA For blood bank tests (e.g., crossmatch, blood type Grey {{caption_text}} Potassium Oxalate + Sodium Fluoride For glucose, lactate, and alcohol tests

@Neet_pg_bot

Q26: Which of the following causes microcytic anemia? Iron deficiency Thalassemia Lead poisoning Vitamin B12 deficiency (Q879228)

A. 1, 2, 3

B. 1, 2

C. 1, 3

D. 1, 2, 3, 4

Correct Answer: A. 1, 2, 3

Explanation: Microcytic anemia is characterised by decreased mean corpuscular volume (MCV < 80 fL) due to defective haemoglobin synthesis . This can result from a deficiency of iron , defective globin chain production , or impaired heme synthesis . Microcytic Anaemia Normocytic Anaemia Macrocytic Anaemia S ideroblastic anemia. I ron deficiency anemia (Option 1) T halassemia (Option 2) A nemia of chronic disease L ead poisoning (Option 3) (Mnemonic- SITAL) Acute Blood Loss Hemolytic Anaemia (hereditary spherocytosis) Anemia of Chronic Disease Bone Marrow Disorders (e.g., Aplastic Anaemia) Renal Disease Endocrine Disorders (e.g., Hypothyroidism) Early stages of iron deficiency anemia Vitamin B12 Deficiency Folate Deficiency Alcohol Abuse Liver Disease Hypothyroidism Myelodysplastic Syndrome Vitamin B12 deficiency (Option 4) causes macrocytic (megaloblastic) anemia due to impaired DNA synthesis, not microcytic anemia.

@Neet_pg_bot

Q27: A patient presents with microcytic hypochromic anemia (MCV: 70–79 fL) and a Mentzer index of 11 with increased RBC count. Peripheral blood smear reveals target cells. Which of the following investigations is the most appropriate for establishing the diagnosis? (Q879222)

A. Bone marrow examination

B. Hb electrophoresis

C. Serum ferritin

D. Serum iron and TIBC

Correct Answer: B. Hb electrophoresis

Explanation: This patient’s features - microcytic hypochromic anemia, low Mentzer index (<13), increased RBC count, and target cells - strongly suggest thalassemia trait rather than iron deficiency anemia. The investigation of choice for confirmation is hemoglobin electrophoresis , which quantifies Hb fractions (HbA, HbA■, HbF). Incorrect Options: Bone marrow examination (Option A): Unnecessary for thalassemia trait, as peripheral smear and hemoglobin studies are sufficient. Serum ferritin (Option C): Normal in thalassemia trait; low ferritin indicates

iron deficiency, not thalassemia. Serum iron and TIBC (Option D): Typically normal in thalassemia trait and mainly used to assess iron deficiency anemia.

Q29: Which of the following oil red O stain is used? (Q855393)

A. Formalin fixation

B. Frozen section

C. Alcohol fixation

D. Glutaraldehyde fixation

Correct Answer: B. Frozen section

Explanation: Oil Red O stain is commonly used in frozen sections to detect the presence of lipids, particularly neutral lipids such as triglycerides. It is a lipophilic dye that selectively stains lipids within cells or tissues. It binds to the neutral lipid droplets and produces a bright red colour when examined under a microscope. {{caption_text}} This stain is particularly useful in identifying lipid accumulation in various tissues and organs, including adipose tissue, liver, muscle, and atherosclerotic plaques. Frozen sections are typically used for rapid intraoperative diagnosis or for research purposes. Formalin fixation (Option A) refers to the preservation of tissue samples using formaldehyde solutions, leading to the cross-linking of proteins and modification of lipid structures, which may interfere with the staining properties of Oil Red O. Alcohol fixation (Option C) involves the preservation of tissues using alcohol-based solutions, such as ethanol or methanol. It can also alter the structure of lipids, affecting the staining properties of Oil Red O. Glutaraldehyde fixation (Option D) is typically used for electron microscopy studies. It may lead to changes in lipid composition and affect the staining properties of Oil Red O.

@Neet_pg_bot

Q30: Which of the following needles is commonly used for bone marrow biopsy? (Q855114)

A. Klima needle

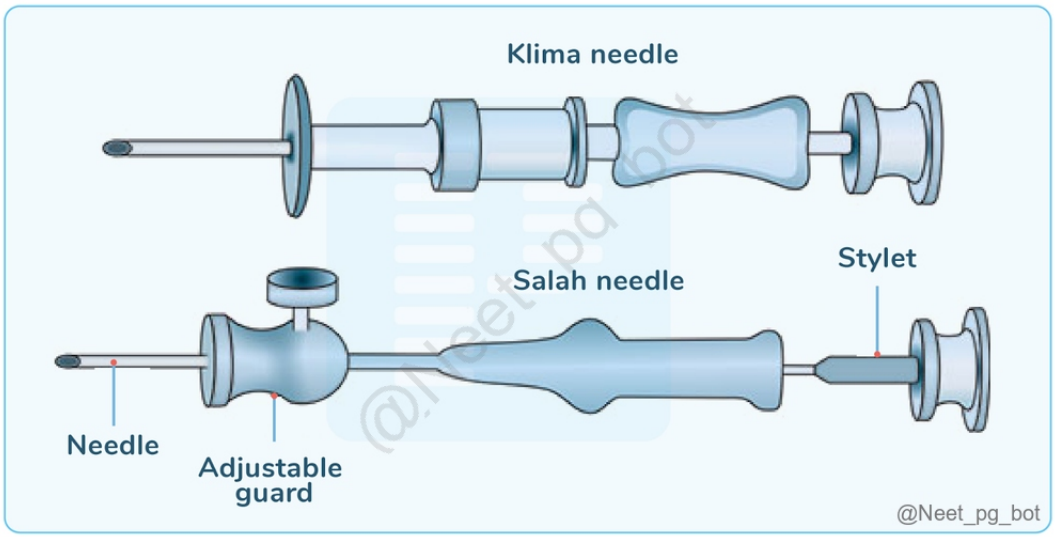
B. Salah needle

C. Jamshidi needle

D. Islam needle

Correct Answer: C. Jamshidi needle

Explanation: The Jamshidi needle is the most widely used needle for bone marrow aspiration and biopsy. It has a hollow, beveled tip designed to obtain a core of bone marrow with minimal trauma. Common sites for biopsy using this needle are the posterior superior iliac spine and sternum (for aspiration only). It allows both aspiration of liquid marrow and core biopsy for histology in the same procedure. The needle is preferred for its ease of use, safety, and high-quality sample retrieval. {{caption_text}} Incorrect Options: Option A) Klima needle: Rarely used; mainly historical, not standard for marrow biopsy. Option B) Salah needle: Not a standard or recognized needle for bone marrow procedures. ■ Option D) Islam needle: Not used for bone marrow biopsy; no clinical standard. {{caption_text}}



@Neet_pg_bot

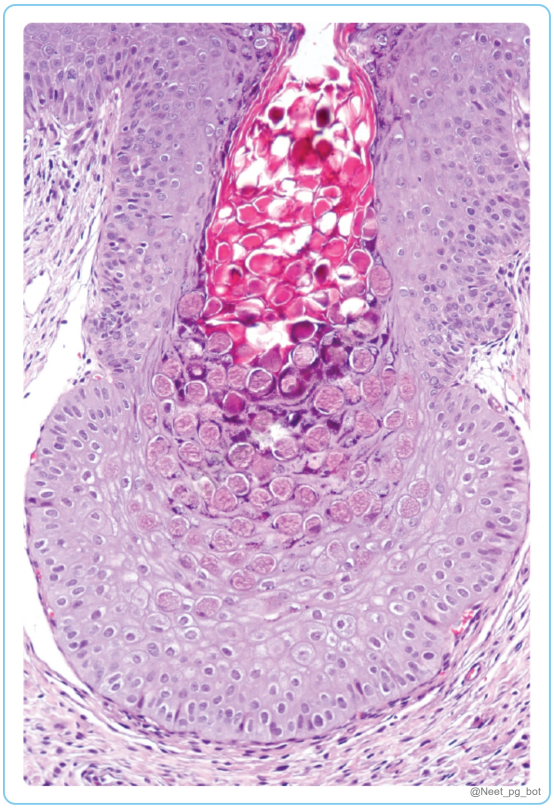
Q31: A child presents with multiple skin lesions over the inner thigh and genital areas. Initially, the lesions started as macules and later developed into nodules. Some of the nodules have a central umbilication. The histology of the lesion is shown below. What would be found on a biopsy? (Q855108)

A. Multinucleate giant cells (Tzanck cells)

B. Donovan bodies

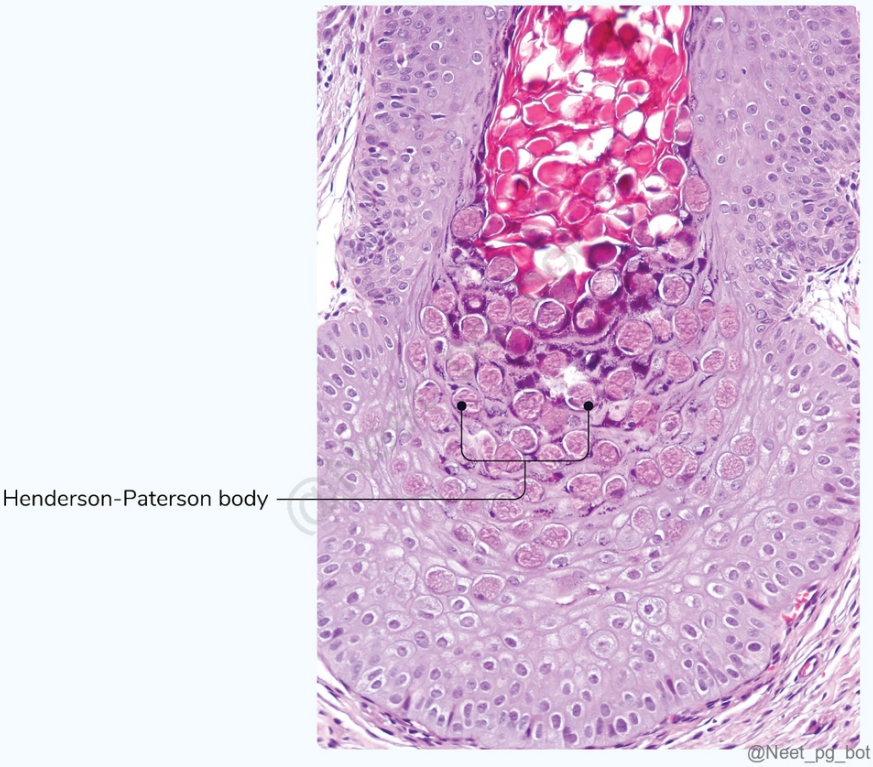
C. Henderson-Patterson bodies

D. Koilocytes



Correct Answer: C. Henderson-Patterson bodies

Explanation: The given clinical scenario and image are diagnostic of Molluscum contagiosum lesions, which show intracytoplasmic inclusion bodies called Henderson-Patterson bodies /molluscum bodies. Molluscum Contagiosum: Caused by: Poxvirus (MCV-1 to MCV-4) MCV-1 is the most common. MCV-2 is often sexually transmitted. Common in: Children (2-12 years): Spread through direct contact or shared items (e.g., towels) Adults: Typically sexually transmitted, affecting genitals, lower abdomen, buttocks, and inner thighs Incubation period: Approximately 6 weeks Clinical Features: Pearly, dome-shaped papules (1-5 mm in diameter) with a dimpled centre. The central waxy core contains cytoplasmic viral inclusions. Common sites in children: Trunk, arms, and legs Common sites in adults: Genitals, lower abdomen, buttocks, and inner thighs Microscopic examination: Lesion characteristics: Cup-like, verrucous epidermal hyperplasia. Diagnostic structure : Molluscum body : Large (up to 35 µm), ellipsoid, homogeneous cytoplasmic inclusion. Found in the stratum granulosum and stratum corneum . Eosinophilic in the stratum granulosum. Pale blue hue in the stratum corneum. {{caption_text}} Multinucleate giant cells (Tzanck cells) (Option A) are typically seen in herpesvirus infections (like herpes simplex or varicella-zoster), not in molluscum contagiosum. They are large cells with multiple nuclei, and their presence is a hallmark of herpesvirus infections. {{caption_text}} Donovan bodies (Option B) are characteristic of granuloma inguinale , caused by Klebsiella granulomatis . The bodies are intracellular and appear in macrophages. They are unrelated to molluscum contagiosum. {{caption_text}} Koilocytes (Option D) are cells with a characteristic perinuclear halo and are associated with human papillomavirus (HPV) infections, such as warts. {{caption_text}}



@Neet_pg_bot

Q33: A woman presents with nodular lesions, 4-6 mm in size, on the inner thighs and peri-anal region. The lesions appear pale, and histopathological examination reveals multiple intracytoplasmic inclusion bodies consistent with Henderson-Patterson bodies. What is the most likely diagnosis? (Q855907)

A. Trichodysplasia spinulosa

B. Condyloma acuminata

C. Molluscum contagiosum

D. Donovanosis

Correct Answer: C. Molluscum contagiosum

Explanation: The patient's presentation of pale, nodular lesions on the inner thighs and peri-anal region, along with the presence of Henderson-Patterson bodies, is characteristic of Molluscum contagiosum . Henderson-Patterson bodies are eosinophilic inclusion bodies that are diagnostic for Molluscum contagiosum virus (MCV) infection.

The virus primarily infects the skin, causing characteristic lesions that are typically described as pearl-like, dome-shaped, and umbilicated. The lesions are generally painless and self-limiting, though they can persist for months or even years. {{caption_text}} Molluscum Contagiosum: Caused by: Poxvirus (MCV-1 to MCV-4) MCV-1 is the most common. MCV-2 is often sexually transmitted. Common in: Children (2-12 years): Spread through direct contact or shared items (e.g., towels). Adults: Typically sexually transmitted, affecting genitals, lower abdomen, buttocks, and inner thighs. Incubation period: Approximately 6 weeks. Clinical Features: Pearly, dome-shaped papules with a dimpled centre. Papules are 1-5 mm in diameter. The central waxy core contains cytoplasmic viral inclusions. Common sites in children: Trunk, arms, and legs. Common sites in adults: Genitals, lower abdomen, buttocks, and inner thighs. Microscopic examination: Lesion Characteristics: Cup-like, verrucous epidermal hyperplasia. Diagnostic Structure : Molluscum body , a large (up to 35 µm), ellipsoid, homogeneous cytoplasmic inclusion. Found in the stratum granulosum and stratum corneum . Eosinophilic in the stratum granulosum. Pale blue hue in the stratum corneum. Trichodysplasia Spinulosa (Option A) is a viral infection that predominantly affects immunocompromised individuals, especially organ transplant recipients. It typically manifests as follicular papules and spiny nodules on the face, neck, and upper extremities. Histologically, it shows hyperkeratosis, follicular plugging, and hair shaft abnormalities. Condyloma acuminata (Option B) , or genital warts, is caused by the human papillomavirus (HPV) and is a sexually transmitted infection. These warts usually appear as flesh-coloured, cauliflower-like growths in the genital and perianal regions. Histologically, they are characterized by hyperkeratosis, acanthosis, and koilocytosis, where squamous cells exhibit a clear halo around the nucleus. {{caption_text}} Donovanosis (Option D), also called granuloma inguinale, is a bacterial infection caused by Klebsiella granulomatis . It presents as painless nodules or ulcers in the genital and perianal regions. Histologically, it shows granulomatous inflammation with Donovan bodies, which are large, rod-shaped, intracytoplasmic bacteria

Q34: Which of the following methods is iron in tissues stained? (Q855899)

A. Masson’s trichrome

B. Prussian blue

C. PAS

D. Fite-Faraco

Correct Answer: B. Prussian blue

Explanation: Iron in tissues is stained using Prussian blue. This staining technique relies on the reaction between Fe3+ ions and ferrocyanide ions to form an insoluble blue pigment. When tissue sections are treated with a solution of potassium ferrocyanide and hydrochloric acid, any iron present in the tissue reacts with the ferrocyanide, producing the blue pigment. This stain is specific for iron and is frequently employed to detect iron deposition in conditions like hemochromatosis and hemosiderosis. Prussian blue stain Iron {{caption_text}} Masson Trichrome Differentiate Collagen & muscle fibers {{caption_text}} Fite-Faraco stain Leprosy {{caption_text}} PAS stain Glycogen {{caption_text}}

@Neet_pg_bot

Q35: The following image shows an instrument used to estimate haemoglobin levels. What does it measure? (Q855893)

A. Alkaline hematin

B. Acid hematin

C. Oxyhemoglobin

D. Deoxyhemoglobin

@Neet_pg_bot

Correct Answer: B. Acid hematin

Explanation: The image depicts a device known as the Sahli hemoglobinometer, which is used to estimate haemoglobin levels in blood. The hemoglobinometer works by adding a dilute acid to a small sample of blood, causing the formation of acid hematin , a derivative of haemoglobin formed when haemoglobin reacts with an acid. This acid hematin is then compared to a standard colour chart to determine the haemoglobin concentration.

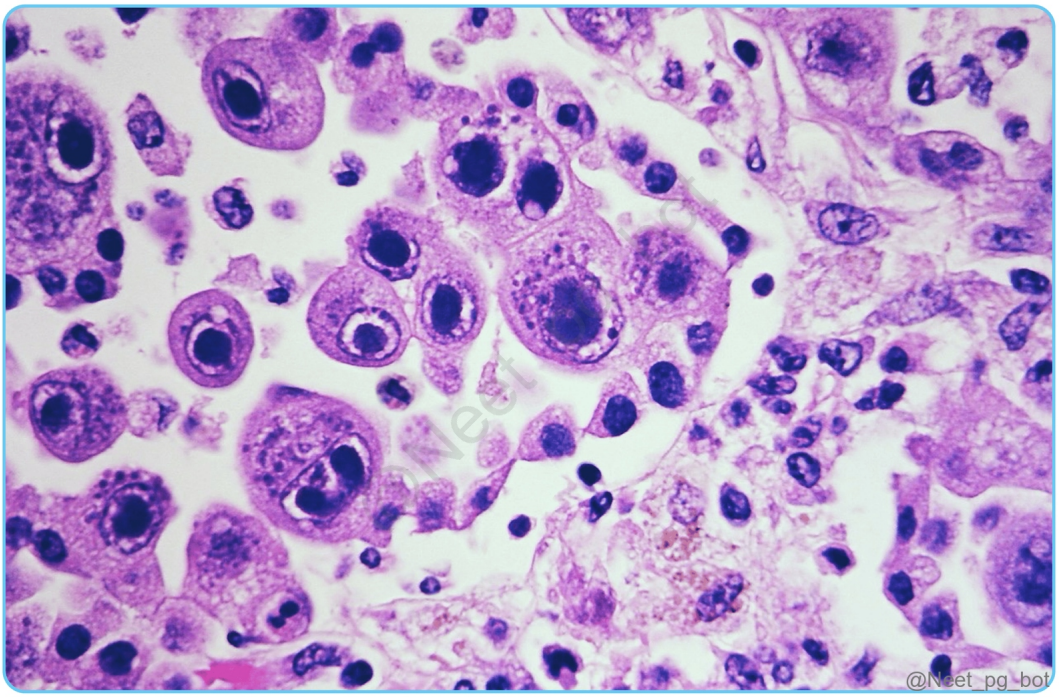
Q36: The given inclusion bodies are characteristic of which of the following organisms? (Q858119)

A. Human papillomavirus

B. Cytomegalovirus

C. Epstein-Barr virus

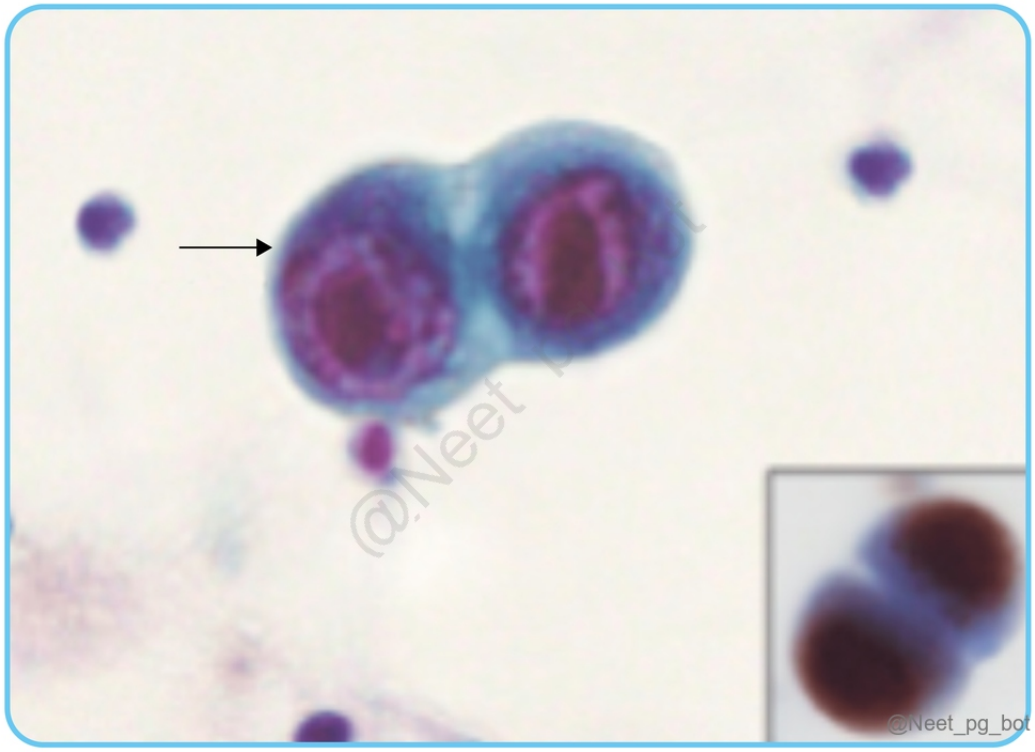
D. Herpes simplex virus

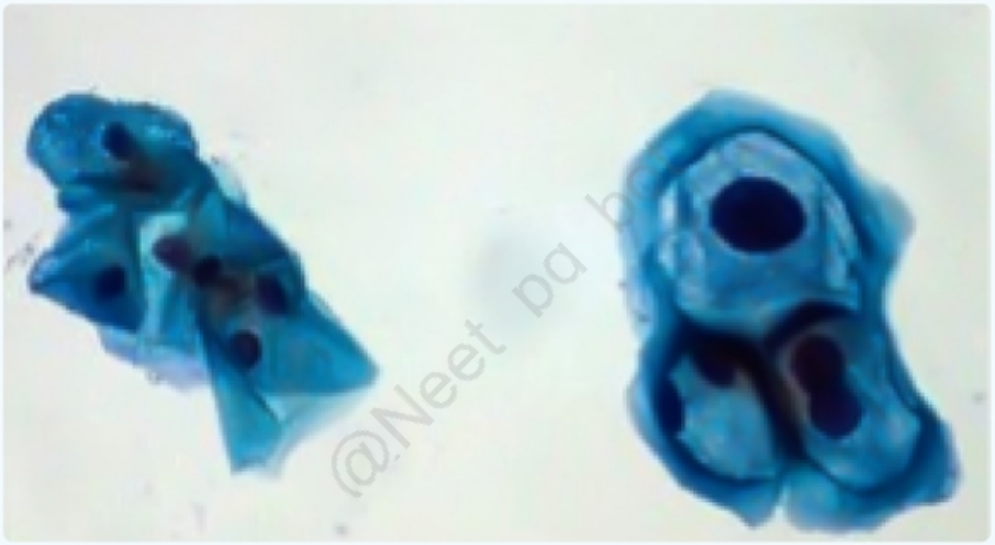


Correct Answer: B. Cytomegalovirus

Explanation: The presence of inclusion bodies, which gives the characteristic “Owl-eye appearance,” suggests Cytomegalovirus. CMV infection Modes of transmission Oral route, respiratory & body secretions (most common) Vertical transmission Sexual transmission Organ transplantation Blood transfusion Investigations Peripheral smear Owl’s eye appearance of inclusion bodies {{caption_text}} Virus isolation It is done by Human fibroblast cell line culture Shell vial culture Antigen detected PP65 Antibody detection It is done by ELISA, and the antibodies detected are CMV IgM antibodies. CMV IgG antibodies. Against PP150 and PP65. Against the PP52. PCR Used in detecting CMV DNA. Quantitative nucleic acid testing (QNAT) by PCR is the most sensitive and specific testing. Treatment Ganciclovir (drug of choice) Foscarnet (in Ganciclovir resistance) CMV immunoglobulins and Ganciclovir are given to bone marrow transplant patients. Incorrect Options: Human papillomavirus (Option A) is a sexually transmitted virus, including low-risk strains 6 & 11, causing benign

genital warts, and high-risk strains 16 & 18 , linked to cervical carcinoma, vulvar intraepithelial neoplasia (VIN) and vulvar carcinoma. It is characterised by the presence of enlarged, hyperchromatic nuclei with perinuclear halos (koilocytes) in the superficial layers of the epithelium. {{caption_text}} Epstein-Barr virus (Option C) is primarily associated with infectious mononucleosis and certain lymphoproliferative disorders. It is characterised by ‘ Downey cells’, i.e. atypical lymphocytes (large, vacuolated) and Ballerina skirt appearance. {{caption_text}} Herpes simplex virus (Option D) causes vesicular lesions and is characterised by intranuclear inclusion bodies in infected cells. It is characterised by multinucleated giant cells with faceted nuclei and homogeneously stained 'ground-glass' chromatin (Tzanck cells) in the Tzanck smear and the formation of Lipschutz bodies (Cowdry type A). {{caption_text}}





Koilocytes showing perinuclear halo on pap smear

@Neet_pg_bot

Q37: A 20-year-old female with easy fatiguability and pallor presented to the OPD. The image of her hand is shown below. What is the most likely diagnosis? (Q856480)

A. Aplastic anemia

B. Vitamin B12 deficiency

C. Iron deficiency anaemia

D. Hypoalbuminemia

Correct Answer: C. Iron deficiency anaemia

Explanation: The image shows koilonychia, a concave nail deformity with raised edges, commonly seen in iron deficiency anaemia. The patient's fatigue and pallor further support this diagnosis. Iron deficiency anaemia: Iron deficiency anaemia can result from dietary lack, impaired absorption, increased iron requirement (e.g., during pregnancy), or chronic blood loss (e.g., gastrointestinal bleeding). Clinical features include Koilonychia , alopecia, atrophic glossitis, oesophagal webs, pica and intestinal malabsorption, affecting overall nutritional status. Characteristic changes seen in peripheral smear: Hypochromic: The RBCs appear pale due to decreased haemoglobin content. Microcytic: RBCs are smaller than normal due to decreased haemoglobin synthesis. {{caption_text}} Anisocytosis: There is significant variation in the size of RBCs. Poikilocytosis: RBCs may show abnormal shapes, such as pencil cells, target cells (codocytes), and occasionally, elliptocytes. Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) indicates depleted iron stores. Serum Iron (Fe) Low levels are seen in iron deficiency anaemia. Total Iron Binding Capacity (TIBC) Increased TIBC reflects the increased capacity of transferrin to bind iron in response to low iron stores. Red Cell Distribution Width (RDW) Increased RDW is often seen in iron deficiency anaemia Bone Marrow Aspiration and Iron Staining Confirmatory test Aplastic anaemia (Option A) is a condition where the bone marrow fails to produce enough blood cells, resulting in a reduction of red blood cells, white blood cells, and platelets. Vitamin B12 deficiency (Option B) leads to megaloblastic anaemia and is often accompanied by neurological symptoms such as numbness and tingling. Hypoalbuminemia (Option D) is characterized by low blood albumin levels. It is associated with Muehrcke's lines , which appear as paired, narrow white bands on the fingernails. {{caption_text}}

@Neet_pg_bot

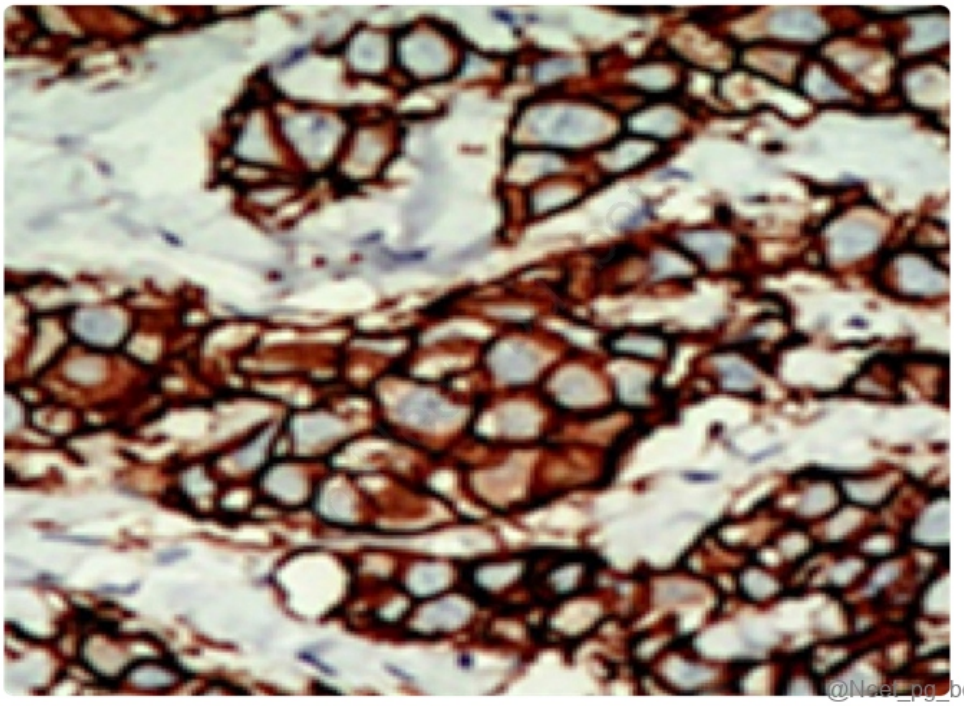
Q38: The image below represents the presence of HER2 neu cells in a patient with breast carcinoma. What agent is used to produce this characteristic discolouration? (Q854670)

A. FITC

B. Phycoerythrin

C. Cyanate dye

D. Diaminobenzidine



Correct Answer: D. Diaminobenzidine

Explanation: 3,3′-Diaminobenzidine (DAB) is a commonly used chromogen in immunohistochemistry (IHC) to detect HER2 overexpression in certain breast cancers. It serves as a substrate for a peroxidase enzyme coupled to a primary or secondary antibody. It is oxidised and converted to an insoluble polymer, precipitating as a dark brown pigment, which allows visualisation of the target molecule. FITC (Fluorescein Isothiocyanate) (Option A) is a fluorescent dye that is used in fluorescence microscopy to detect specific antigens but does not produce a brown colour. It would instead produce a green fluorescence. Phycoerythrin (Option B) is another fluorescent dye often used in flow cytometry and fluorescence microscopy but does not produce a brown colouration. It fluoresces red-orange and is used for labelling antibodies. Cyanate dye (Option C) is commonly used in fluorescence-based applications such as fluorescent labelling of biomolecules in biological and biochemical research. These dyes are known for their high sensitivity and photostability.

@Neet_pg_bot

Q39: CD markers can be detected by which of the following tests? (Q866390)

A. Cytogenetics

B. Next-generation sequencing

C. Flow cytometry

D. Karyotype

Correct Answer: C. Flow cytometry

Explanation: CD markers (Cluster of Differentiation) are surface proteins used to identify and classify immune cells, and they are typically detected using Flow Cytometry , which employs fluorescent-labeled antibodies. Principle : Detects physical and chemical characteristics of individual cells in a fluid stream using laser-based technology. Detects : CD markers (surface antigens) using fluorescent-labeled antibodies. Cell size, granularity, and fluorescence. Used in : Immunophenotyping (e.g., leukemia/lymphoma classification) Stem cell enumeration Monitoring HIV (CD4 count) Output : Dot plots or histograms showing expression of specific markers. Incorrect Options: Cytogenetics (Option A): Detects chromosomal abnormalities, not surface markers. Next-generation sequencing (NGS) (Option B): Detects gene mutations, not surface proteins. Karyotype (Option D): Analyzes chromosome structure and number, not proteins.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q40: In Pap smear cytology, which of the following is the most appropriate fixative used to preserve cellular details immediately after smearing? (Q866744)

A. 50% formaldehyde

B. 95% ethanol

C. 70% ethanol

D. 10% buffered formalin

Correct Answer: B. 95% ethanol

Explanation: 95% ethanol is the fixative used in a conventional pap smear. Fixatives are chemicals that preserve biological tissues by stabilizing cellular structures and preventing decay or degradation. The goal is to maintain the tissue in a life-like state as much as possible for microscopic examination. Fixation helps maintain the tissue's integrity by preventing autolysis (self-digestion) and putrefaction (bacterial decay). Crosslinking Fixatives: These fixatives work by forming covalent bonds between the proteins and other cellular structures, effectively "locking" them in place. This preserves the tissue's structural integrity. Formaldehyde: Most commonly used in the form of 10% neutral-buffered formalin. (Option D) Glutaraldehyde : Often used for electron microscopy due to its ability to preserve fine cellular structures. Osmium tetroxide : Used primarily for electron microscopy, particularly for preserving lipids and membranes. Precipitating Fixatives: These work by precipitating proteins and other cellular components, which makes them less soluble and helps preserve their structure. Methanol Ethanol Additive Fixatives: They chemically bind to tissue components, such as proteins or nucleic acids, and stabilise them. They are typically more gentle and produce better preservation of ultrastructure. Formaldehyde (Option A) Glutaraldehyde Non-Additive Fixatives: Alcohol Acetone Pap smear Site The transformation zone of the cervix, where the squamous epithelium (ectocervix) and columnar epithelium (endocervix) meet. This is the most common site for cervical cancer to develop. Instruments Ayre spatula collects cells from the ectocervix Cervical broom (also called a cytobrush) from the transition zone Endocervical brush from the endocervix Procedure Conventional Pap smear : Cells are collected with a spatula or brush, smeared onto a slide, and immediately fixed with a spray fixative or by immersing in 95% ethanol with/without ether Liquid-based cytology : Cells are collected and then rinsed into a liquid fixative vial. This is considered more sensitive than the conventional Pap smear as it provides a more uniform distribution of cells.

@Neet_pg_bot

Q41: Which of the following measures is associated with an increased life span? (Q855961)

A. Regular moderate exercise for 30 min

B. Decrease stress

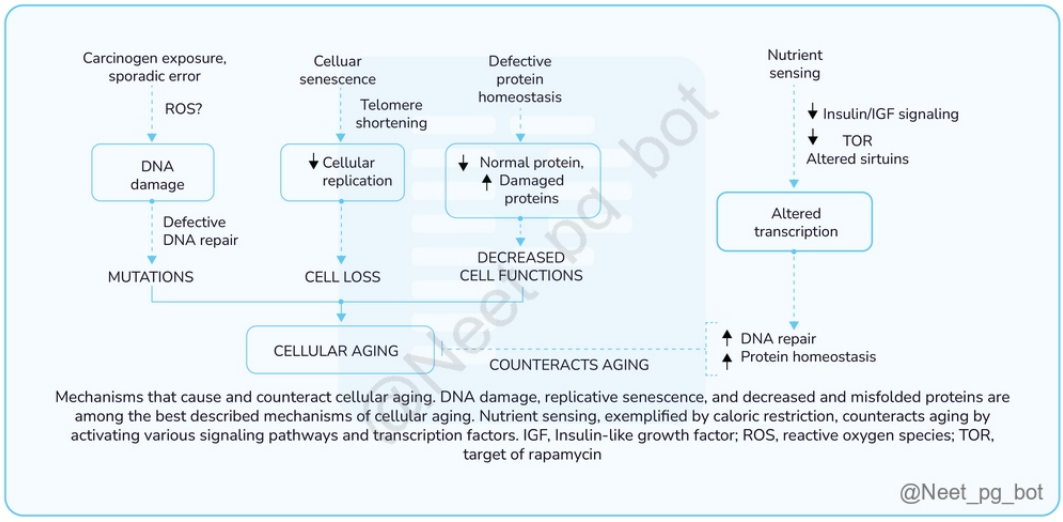
C. Decreasing calorie intake by 30%

D. Pharmacological intervention with proton pump inhibitors

Correct Answer: C. Decreasing calorie intake by 30%

Explanation: aloric restriction has increased lifespan across various species, including nonhuman primates and humans. This is linked to two key neurohormonal circuits regulating metabolism: Insulin and IGF-1 Signaling IGF-1, produced in response to growth hormone, mimics insulin signalling, promoting an anabolic state, cell growth, and replication. Sirtuins These are NAD-dependent deacetylases that help adapt to stressors like food deprivation and DNA damage. They promote longevity by regulating genes that reduce metabolic activity, apoptosis, and oxidative damage. Sirtuins also improve insulin sensitivity and glucose metabolism. Caloric

restriction reduces IGF-1 signalling, which may reduce cellular damage while simultaneously increasing sirtuins, particularly sirtuin-6 , to promote DNA repair and metabolic adaptation. Hence, caloric restriction, particularly a reduction in calories by about 20-30%, can reduce IGF-1 signalling and increase sirtuin activity, which together is thought to extend lifespan. Regular moderate exercise for 30 min (Option A) is associated with numerous health benefits, like improved cardiovascular health, better metabolic function, and reduced risk of chronic diseases. While it may increase health span , it is not as directly proven to increase lifespan compared to caloric restriction. Decrease stress (Option B): Chronic stress is associated with a range of negative health effects, all of which can reduce lifespan. Stress management techniques can help improve health and increase longevity, but this relationship is more indirect and variable. Pharmacological intervention with proton pump inhibitors (Option D) : PPIs are used to reduce stomach acid and treat conditions like GERD and peptic ulcers. While they are effective for symptom relief, they are not associated with increased lifespan.



Mechanisms that cause and counteract cellular aging. DNA damage, replicative senescence, and decreased and misfolded proteins are among the best described mechanisms of cellular aging. Nutrient sensing, exemplified by caloric restriction, counteracts aging by activating various signaling pathways and transcription factors. IGF, Insulin-like growth factor; ROS, reactive oxygen species; TOR, target of rapamycin

@Neet_pg_bot

Q42: Choose the correct statement regarding the telomerase theory of ageing: (Q855914)

A. Telomere stability is associated with ageing

B. Abnormal telomerase activation is associated with ageing

C. Decreased telomere length is associated with ageing

D. Increased telomere length is associated with ageing

Correct Answer: C. Decreased telomere length is associated with ageing

Explanation: : Telomere stability refers to maintaining the length of telomeres, which are protective caps at the ends of chromosomes. As we age, telomeres shorten rather than remain stable, which is a key factor in cellular ageing, not stability. Abnormal telomerase activation is associated with ageing (Option B): Abnormal telomerase activation is more commonly associated with cancer (where cells avoid normal ageing and continue to divide) rather than the ageing process itself. In ageing, telomerase activity tends to decline, not increase.

@Neet_pg_bot

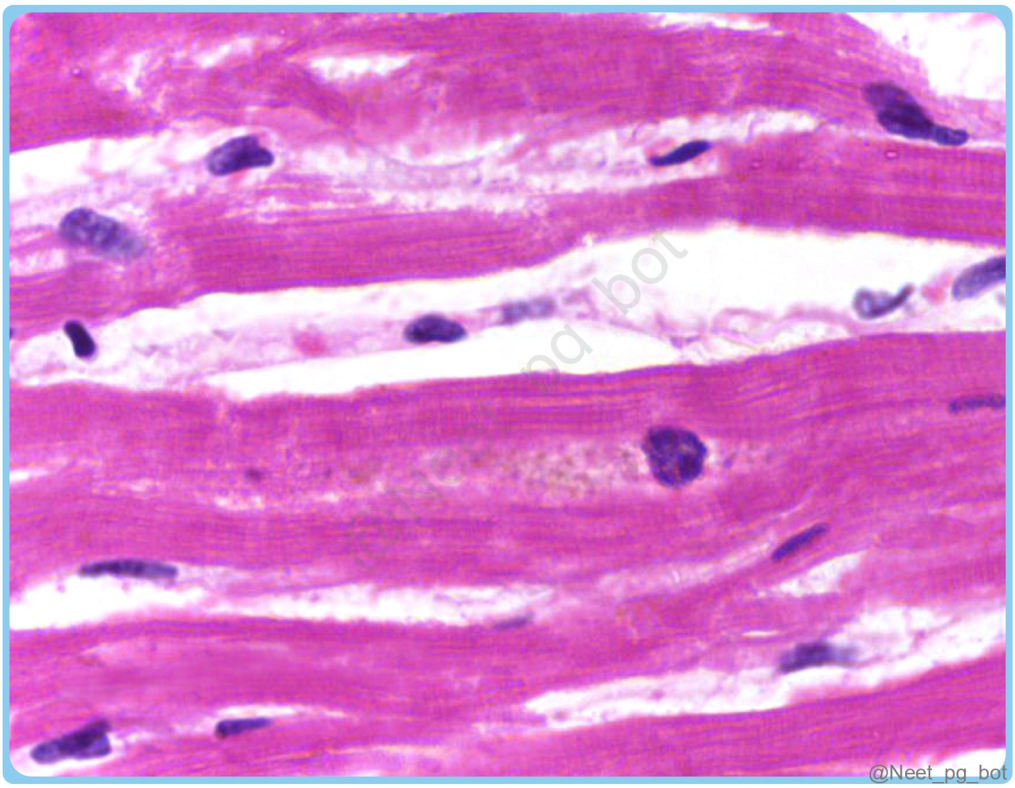
Q43: The body of an 82-year-old man has been seen for a post-mortem to determine the cause of death. You are examining a histopathological slide containing a section of his cardiac tissue where you notice some pigmentation. Which is the substance that is seen in the image given below? (Q859859)

A. Melanin

B. Lipofuscin

C. Hemosiderin

D. Iron



Correct Answer: B. Lipofuscin

Explanation: The histopathological image shows lipofuscin in the section of cardiac tissue. Lipofuscin is a yellow to red-brown pigment found in cardiac muscle cells, particularly around the nucleus in the hearts of elderly, debilitated people. {{caption_text}} Melanin (Option A) is a black or brown pigment found in skin, hair, and certain brain areas, not typically seen in cardiac tissue. Hemosiderin (Option C) is an iron-storage complex resulting from the breakdown of haemoglobin, typically associated with conditions like haemorrhage or hemochromatosis. Iron (Option D) : Elemental iron deposition in tissues is pathological and associated with diseases like hemochromatosis or chronic blood transfusions. Staining with Prussian blue would help confirm iron presence.

@Neet_pg_bot

Q44: Among the following, which molecule is required for the presentation of the antigens by the APCs to TH2 cells? (Q859298)

A. NK cells

B. G-protein coupled receptor

C. MHC

D. Lectin receptor

Correct Answer: C. MHC

Explanation: Antigen-presenting cells (APCs) such as dendritic cells, macrophages, and B cells play a crucial role in the adaptive immune response by presenting antigens to T-helper (TH2) cells . This process requires Major Histocompatibility Complex (MHC) Class II molecules , which are essential for the activation of CD4+ T cells, including TH2 cells. MHC Molecule Role : APCs process antigens and present them on their surface bound to MHC Class II molecules. MHC Class II molecules interact with the T-cell receptor (TCR) on CD4+ T cells. This interaction is critical for the differentiation and activation of TH2 cells, which secrete cytokines to mediate humoral immunity. Incorrect Options: NK cells (Option A) are part of the innate immune system and do not present antigens or directly interact with TH2 cells. G-protein coupled receptors (Option B) are involved in cell signalling but are not involved in antigen presentation to T cells. Lectin receptors (Option D) are involved in innate immune recognition, particularly of carbohydrate molecules, but they do not mediate antigen presentation to TH2 cells.

@Neet_pg_bot

Q45: Which of the following caspases binds to Cyt c and the APAF-1 complex? (Q856488)

A. Caspase 1

B. Caspase 8

C. Caspase 9

D. Caspase 4

Correct Answer: C. Caspase 9

Explanation: In the intrinsic apoptotic pathway , the release of cytochrome c (Cyt c) from the mitochondria triggers the formation of the apoptosome, a complex consisting of Cyt c, apoptotic protease-activating factor 1 (APAF-1), and procaspase 9. This complex is essential for initiating the caspase cascade that leads to cell death.

Apoptosis (Caspase-dependent programmed cell death): Apoptosis is a type of cell death that is induced by a tightly regulated suicide program in which cells destined to die activate intrinsic enzymes that degrade the cells' genomic DNA and nuclear and cytoplasmic proteins. It is an active process. It eliminates cells that are injured beyond repair without eliciting a host reaction, thus limiting collateral tissue damage. Apoptosis results from activating enzymes called caspases, leading to DNA fragmentation. The process of apoptosis may be divided into an initiation phase , during which caspases 8,9,10 become catalytically active and unleash a cascade of other caspases, and an execution phase , during which the terminal caspases 3,6,7 trigger cellular fragmentation. Morphological features:- Cell shrinkage Chromatin condensation Formation of cytoplasmic blebs and apoptotic bodies Phagocytosis of apoptotic bodies, usually by macrophages. Histopathology: In H&E-stained tissue, the apoptotic cell appears as a round or oval mass of intensely eosinophilic cytoplasm with fragments of dense nuclear chromatin. {{caption_text}} The above image shows apoptosis of an epidermal cell in an immune reaction. The cell is reduced in size and contains brightly eosinophilic cytoplasm and a condensed nucleus Types: Apoptosis occurs in two broad contexts: Physiological apoptosis. Pathological apoptosis. Apoptosis in physiological conditions Apoptosis in pathological conditions 1. The removal of supernumerary cells (in excess of the required number) during development. 2. Involution of hormone-dependent tissues on hormone withdrawal, such as endometrial cell breakdown during the menstrual cycle. 3. Elimination of potentially harmful self-reactive lymphocytes to prevent immune reactions against one's own tissues. 4. Death of host cells that have served their useful purpose, such as neutrophils in an acute inflammatory response and lymphocytes at the end of an immune response. 1. DNA damage. 2. Accumulation of misfolded proteins 3. Apoptosis can be induced during infections such as adenovirus , HIV , and viral hepatitis . 4. It may also contribute to pathologic atrophy in parenchymal organs after duct obstruction, such as occurs in the pancreas, parotid gland, and kidney

@Neet_pg_bot

Q46: All of the following are crosslinking fixatives except? (Q856893)

A. Glutaraldehyde

B. Formaldehyde

C. Methanol

D. Osmium tetroxide

Correct Answer: C. Methanol

Explanation: Methanol is not a crosslinking fixative. It is a dehydrant coagulant fixative. Fixatives are chemicals that preserve biological tissues by stabilizing cellular structures and preventing decay or degradation. The goal is to maintain the tissue in a life-like state as much as possible for microscopic examination. Fixation helps maintain the tissue's integrity by preventing autolysis (self-digestion) and putrefaction (bacterial decay). Crosslinking Fixatives: These fixatives work by forming covalent bonds between the proteins and other cellular structures, effectively "locking" them in place. This preserves the tissue's structural integrity. Formaldehyde (Option B) : Most commonly used in the form of 10% neutral-buffered formalin. Glutaraldehyde (Option A) : Often used for electron microscopy due to its ability to preserve fine cellular structures. Osmium tetroxide (Option D) : Used primarily for electron microscopy, particularly for preserving lipids and membranes. Precipitating Fixatives: These work by precipitating proteins and other cellular components, which makes them less soluble and helps preserve their structure. Methanol Ethanol Additive Fixatives: They chemically bind to tissue components, such as proteins or nucleic acids, and stabilize them. They are typically more gentle and produce better preservation of ultrastructure. Formaldehyde Glutaraldehyde Non-Additive Fixatives: Alcohol Acetone

@Neet_pg_bot

Q47: A chronic alcoholic patient presented with increasing abdominal girth. On examination, shifting dullness was present, and the liver span was less than 7cm. Histopathological examination revealed the presence of intracytoplasmic eosinophilic inclusions in hepatocytes. What is the content of these inclusions? (Q856152)

A. Intermediate filaments

B. Actin

C. Microtubules

D. Fibronectin

Correct Answer: A. Intermediate filaments

Explanation: The presence of intracytoplasmic eosinophilic inclusions in hepatocytes is a key finding in alcoholic liver disease. Mallory-Denk bodies or Mallory hyaline bodies are eosinophilic , intracytoplasmic inclusions composed of intermediate filaments, particularly cytokeratin 8 and 18, commonly seen in hepatocytes in conditions such as alcoholic liver disease. Conditions where Mallory Hyaline bodies are seen are (Mnemonic: N ew Indian WATCH) N on-alcoholic fatty liver disease (NAFLD) Indian childhood cirrhosis W ilson's disease A lpha-1 antitrypsin deficiency ; A lcoholic Liver Disease T umor of the liver (Hepatocellular carcinoma) Chronic C holestatic conditions H epatic or Primary Biliary cirrhosis (not seen in Secondary biliary cirrhosis) {{caption_text}} Actin (Option B) is a structural protein found in microfilaments but does not typically form eosinophilic inclusions in alcoholic liver disease. Microtubules (Option C) are involved in intracellular transport and cell division but do not form eosinophilic inclusions in hepatocytes. Fibronectin (Option D) is an extracellular matrix protein , and although it plays a role in tissue repair and scarring , it is not associated with the formation of intracytoplasmic inclusions in liver cells, especially in alcoholic liver disease.

@Neet_pg_bot

Q48: A 70-year-old patient presented with cough, fatigue, and weight loss. He was diagnosed with squamous cell carcinoma on bronchoscopy. The resected specimen had a hilar lymph node that was 1 cm in size and showed a black pigment. What is the black pigment likely to be? (Q856097)

A. Anthracotic pigment

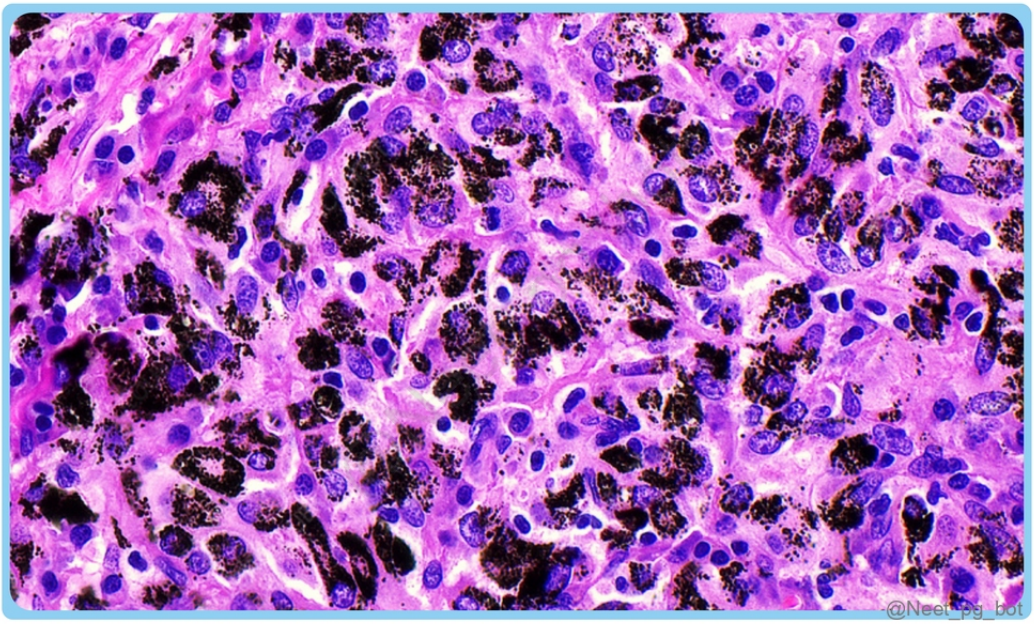
B. Melanin

C. Lipochrome

D. Hemosiderin

Correct Answer: A. Anthracotic pigment

Explanation: Anthracotic pigment is a black, carbon-based pigment commonly seen in lymph nodes and lungs, as well as in individuals with chronic smoking or environmental pollution exposure. These particles are engulfed by macrophages in the lungs and then transported to nearby lymph nodes, often leading to anthracosis . HPE shows carbon-laden macrophages. In patients with lung cancer , particularly squamous cell carcinoma , the presence of hilar lymphadenopathy and black pigment is a common finding due to the direct proximity of the lungs and lymphatic drainage of carbon particles. {{caption_text}} Melanin (Option B) is responsible for skin and hair pigmentation and protects against UV radiation. While it can sometimes be found in melanomas (a type of skin cancer), it is not typically found in the lungs or lymph nodes. {{caption_text}} Lipochrome (Option C) is a group of yellow to brown pigments that arise from the breakdown of lipids (fats). On microscopy, it appears as a yellow-brown, finely granular cytoplasmic pigment, often deposited in the perinuclear location. These pigments can be found in various tissues but are not typically associated with lung diseases or lymph node involvement . {{caption_text}} Hemosiderin (Option D) is an iron-containing pigment derived from the breakdown of hemoglobin . While hemosiderin can appear brown, it does not appear as a black pigment in the context of smoking-related lung disease or cancer . {{caption_text}}



@Neet_pg_bot

Q49: A 20-year-old female who is a known case of sickle cell anaemia was rushed to the emergency department with a complaint of extreme pain in the legs and fingers for the past 4 hours. Further examination revealed pain and tenderness in the right upper quadrant, and investigations showed sickle cells on peripheral blood smear and high bilirubin(indirect). What is the diagnosis? (Q860284)

A. IDA

B. Thalassemia

C. Anaemia of chronic disease

D. Sickle cell crisis

Correct Answer: D. Sickle cell crisis

Explanation: The patient, a known case of sickle cell anaemia, presenting with severe leg and finger pain for the past 4 hours, right upper quadrant tenderness, sickle cells on the peripheral blood smear, and elevated indirect bilirubin is likely undergoing a vaso-occlusive crisis (type of sickle cell crisis) , a common complication of Sickle Cell Disease (SCD) . Complications Acute Painful Episodes (Vaso-Occlusive Crisis) Characterised by unprovoked, severe, symmetrical pain often requiring strong opioids The most common acute event in sickle cell disease. Lasting from days to weeks. Sudden death during acute pain episodes can occur, possibly due to arrhythmias or pulmonary embolism. Acute Chest Syndrome: Symptoms include chest pain, cough, fever, hypoxia, and pulmonary infiltrates on x-ray. It can be mild in children (e.g., due to viral infections) or severe with multiple lobes affected. Thrombocytopenia, leukocytosis, and rapid anaemia suggest severe complications like acute respiratory distress syndrome (ARDS) and multiorgan failure. Osteonecrosis: Involves the hips bilaterally . Chronic pain can progress to severe disability; MRI detects early stages, while X-rays are less sensitive. Leg ulcer: Ulcers range from small and superficial to deep, covering most of the lower leg. Painful and difficult to treat if recurrent, long-standing and large ulcer. Other Complications: Priapism Stroke and silent infarction Gallstones/Surgery Hepatic disease Nephropathy Lung/pulmonary hypertension Retinopathy Aplastic crisis: Caused by parvovirus B19 infection Multiorgan failure IDA (Iron Deficiency Anemia) (Option A) presents with microcytic hypochromic anaemia, not sickle cells on the smear. It also lacks acute pain crises and indirect hyperbilirubinemia. Thalassemia (Option B) causes chronic anaemia with target cells, not acute vaso-occlusive pain. It is also associated with ineffective erythropoiesis rather than hemolysis-induced hyperbilirubinemia. Anaemia of chronic disease (ACD) (Option C) is linked to chronic inflammation and cytokine-mediated iron sequestration, typically presenting with normocytic or microcytic anaemia without acute pain crises or hemolysis.

@Neet_pg_bot

Q50: Investigations of a patient being evaluated for leukaemia revealed a WBC count of 450,000/μL, with eosinophilia and basophilia. What is the likely diagnosis in this case? (Q855989)

A. Acute Lymphoblastic Leukemia (ALL)

B. Chronic Myelogenous Leukemia (CML)

C. Chronic Lymphocytic Leukemia (CLL)

D. Acute Myelogenous Leukemia (AML)

Correct Answer: B. Chronic Myelogenous Leukemia (CML)

Explanation: A very high WBC count (450,000/microliter) with eosinophilia and basophilia is suggestive of Chronic Myelogenous Leukemia (CML) . Chronic Myeloid Leukemia (CML) Category Description Genetics Philadelphia chromosome t(9;22) Origin Myeloid lineage Etiopathogenesis BCR-ABL fusion gene from t(9;22) increases tyrosine kinase activity, leading to uncontrolled myeloid proliferation. Radiation exposure is a risk factor. Clinical Features Affects adults. Presents with splenomegaly, fatigue, weight loss, night sweats, and abdominal discomfort. It can progress to blast crisis, resembling acute leukaemia. Diagnosis Bone marrow aspirate to confirm. FISH detects the BCR-ABL fusion gene. Bone Marrow aspirate findings. Presence of scattered macrophages with abundant wrinkled, green-blue cytoplasm, called sea-blue histiocytes or pseudo-Gaucher cells. The marrow is markedly hypercellular due to massively increased numbers of maturing granulocytic precursors (elevated eosinophils and basophils) Increased megakaryocytes, commonly with small, dysplastic forms called dwarf megakaryocytes. Normal or slightly decreased erythroid progenitors (increased myeloid: erythroid ratio). Increased deposition of reticulin fibres. Management Tyrosine kinase inhibitors (TKIs) like Imatinib. {{caption_text}} Acute Lymphoblastic Leukemia (ALL) (Option A): Lymphoblasts in bone marrow >=20% Cytoplasmic vacuolations They contain fat (Oil Red O Positive) Hand mirror-shaped cells {{caption_text}} Acute Myeloid Leukemia (AML) (Option D) : Blasts ≥ 20% Myeloblasts with AuerRods {{caption_text}} Chronic Lymphocytic Leukemia (CLL) (Option C) : Smudge cells (or parachute/basket cell): Due to the fragility of lymphocytes during slide preparation Convent girl appearance : Lot of homogenous, small, mature-like, round lymphocytes with scant cytoplasm {{caption_text}} Chronic Myeloid Leukemia (CML): Leukocytosis Cell Types: Neutrophils(multilobed nucleus), metamyelocytes (indented nucleus), myelocytes (D-shaped nucleus), and eosinophils (orange cells) College girl/garden party appearance : Due to the variety of cell appearances Shift to the Left: Presence of immature cell types, mainly immature neutrophils, in the blood.

@Neet_pg_bot

Q51: Which of the following is true regarding glucose-6-phosphate dehydrogenase (G6PD) deficiency? (Q856478)

A. Spectrin defect

B. Bite cells are present

C. Cells do not lyse in a hypotonic solution

D. Cells lyse in hypertonic solution

Correct Answer: B. Bite cells are present

Explanation: In glucose-6-phosphate dehydrogenase deficiency , oxidative stress leads to the formation of bite cells (also called degmacytes) due to the removal of damaged portions of the cell membrane. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited enzyme affecting red blood cells. Caused by a lack of the G6PD enzyme, which protects red blood cells from oxidative damage. Oxidative stress makes red blood cells vulnerable, leading to hemolysis. A characteristic feature is the presence of bite cells (degmacytes). Heinz bodies, formed from denatured haemoglobin, are not visible with Romanowsky stains. When Romanowsky stains are used, the denatured haemoglobin may not be detected, resulting in the appearance of bite cells. Abnormality Condition Reason Bite cells {{caption_text}} G6PD deficiency Oxidative stress leads to cross-linking of sulfhydryl groups in haemoglobin → Denaturation of haemoglobin → Heinz bodies. RBCs with Heinz bodies pass through the spleen → Splenic macrophages try to pluck these Heinz bodies → Membrane loss → Bite cells . Target cells {{caption_text}} Thalassemia ↓ Haemoglobin content in RBCs → ↓ RBC volume → Surface area relatively unchanged → ↑ Surface area to volume ratio→ Altered lipid composition → ↑ Formation of membrane protrusions→ ↑ Membrane instability → ↓ Hemoglobin accumulation in certain membrane areas → Central area with haemoglobin, clear zone, outer ring. Uneven distribution of haemoglobin and lipids → Characteristic "bull's-eye" appearance of Target cells Sickle-shaped RBC {{caption_text}} Sickle Cell Anemia Abnormal Hemoglobin (HbS) → HbS molecules polymerize under low oxygen → RBCs become rigid and assume a sickle shape. Spherocytes {{caption_text}} Hereditary Spherocytosis Genetic defect in RBC membrane protein(spectrin) ■ Loss of membrane surface area ■ RBCs become spherical. Spectrin defect (Option A) is a structural protein that maintains the shape and flexibility of red blood cells. Deficiency of spectrin is seen in hereditary spherocytosis , not G6PD deficiency. Cells do not lyse in hypotonic solution (Option C): In G6PD deficiency, red blood cells are more likely to lyse in hypotonic solutions due to their increased vulnerability to oxidative stress. Cells lyse in hypertonic solution (Option D): Red blood cells do not typically lyse in hypertonic solutions; instead, they undergo crenation. The lysis occurs more readily in hypotonic solutions, especially in G6PD deficiency.

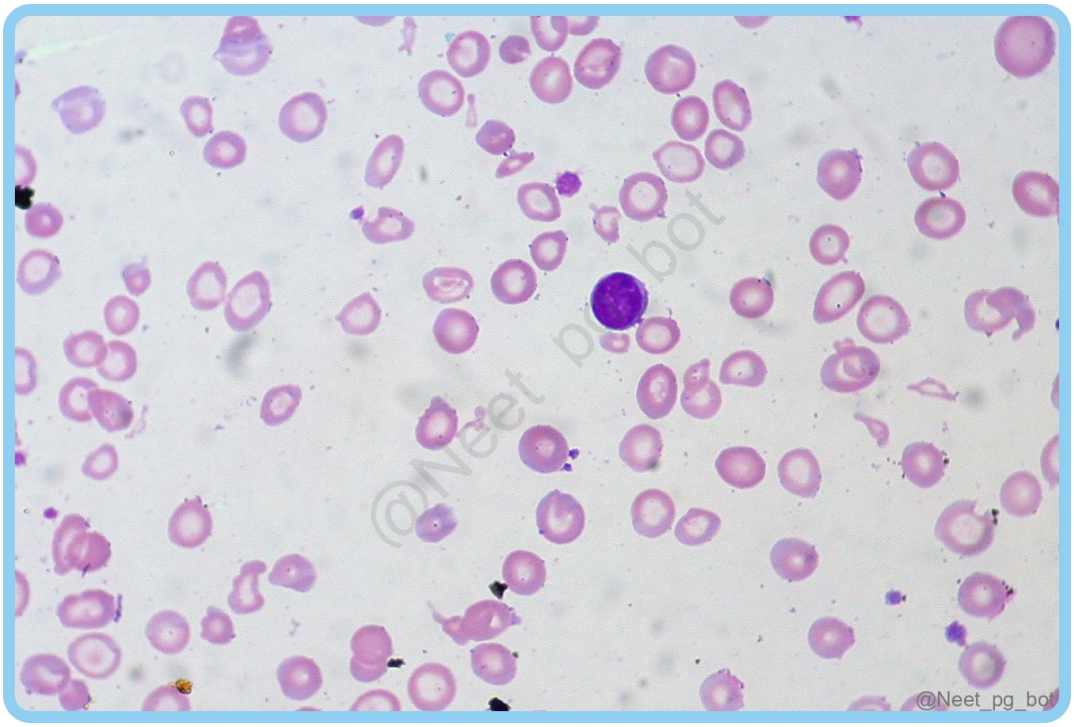
Q52: A 35-year-old woman presents with fatigue. Investigations reveal the following: Hemoglobin (Hb): 5 gm%, low mean corpuscular haemoglobin (MCH), and low mean corpuscular volume (MCV). The peripheral smear shows microcytic hypochromic red blood cells. What is the most likely diagnosis? {{caption_text}} (Q855889)

A. Megaloblastic anaemia

B. Iron deficiency anaemia

C. Thalassemia major

D. Essential thrombocytosis



Correct Answer: B. Iron deficiency anaemia

Explanation: The laboratory findings and peripheral smear indicate iron deficiency anaemia, characterized by microcytic, hypochromic RBCs, anisocytosis, and poikilocytosis. Iron deficiency anaemia can result from dietary lack, impaired absorption, increased iron requirement (pregnancy), or chronic blood loss (gastrointestinal bleeding). Clinical features include Koilonychia, alopecia, atrophic glossitis, oesophagal webs, pica and intestinal malabsorption, affecting overall nutritional status. Iron studies commonly used in the diagnosis of iron deficiency anaemia (IDA): Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) indicates depleted iron stores. Serum Iron (Fe) Low levels are seen in iron deficiency anaemia. Total Iron Binding Capacity

(TIBC) Increased TIBC reflects the increased capacity of transferrin to bind iron in response to low iron stores. Red Cell Distribution Width (RDW) Increased RDW is often seen in iron deficiency anaemia Bone Marrow Aspiration and Iron Staining Confirmatory test Learning Objective: Microcytic Anaemia Normocytic Anaemia Macrocytic Anaemia S ideroblastic anemia. I ron deficiency anaemia. T halassemia. A naemia of chronic disease. L ead poisoning. (Mnemonic- SITAL) Acute Blood Loss Hemolytic Anaemia(hereditary spherocytosis) Anaemia of Chronic Disease Bone Marrow Disorders (e.g., Aplastic Anaemia) Renal Disease Endocrine Disorders (e.g., Hypothyroidism) Early stages of iron deficiency anaemia Vitamin B12 Deficiency Folate Deficiency Alcohol Abuse Liver Disease Hypothyroidism Myelodysplastic Syndrome

Q53: Match the following cell types with their associated malignancy: Cell Type Associated Malignancy 1. Popcorn cell a. Acute promyelocytic leukemia 2. Faggot cell b. Lymphocyte-predominant Hodgkin's lymphoma 3. Cerebriform nuclei c. Burkitt lymphoma 4. Starry sky appearance d. Sezary syndrome (Q855885)

A. 1-b, 2-a, 3-d, 4-c

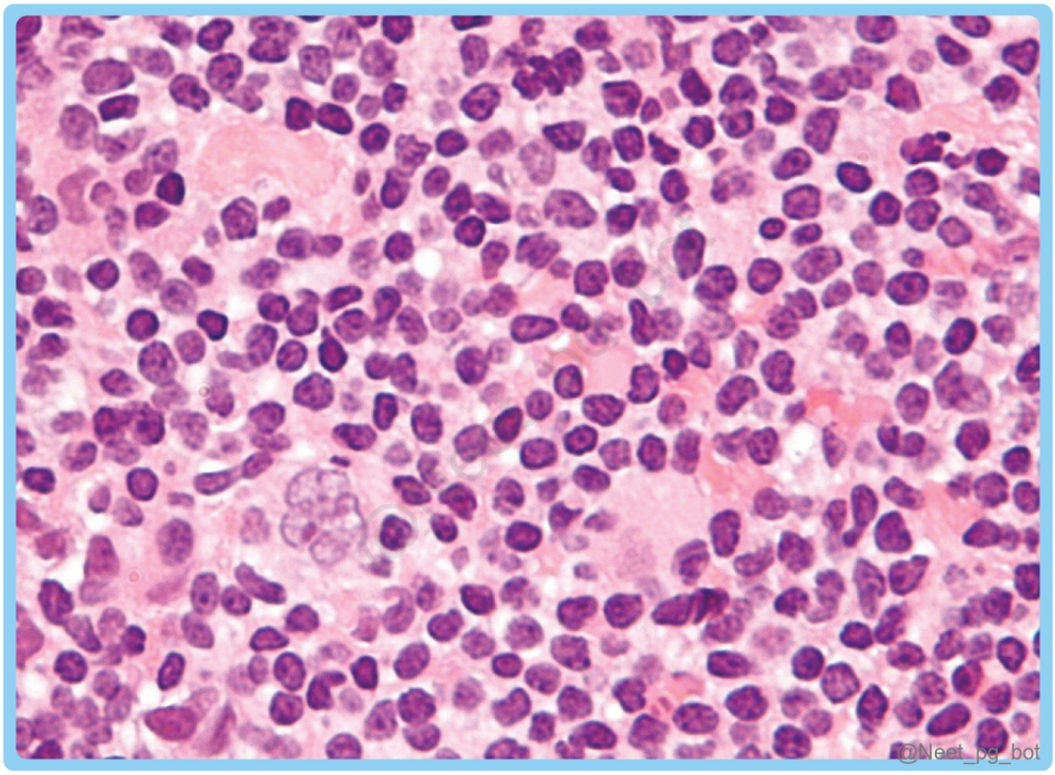
B. 1-a, 2-d, 3-c, 4-b

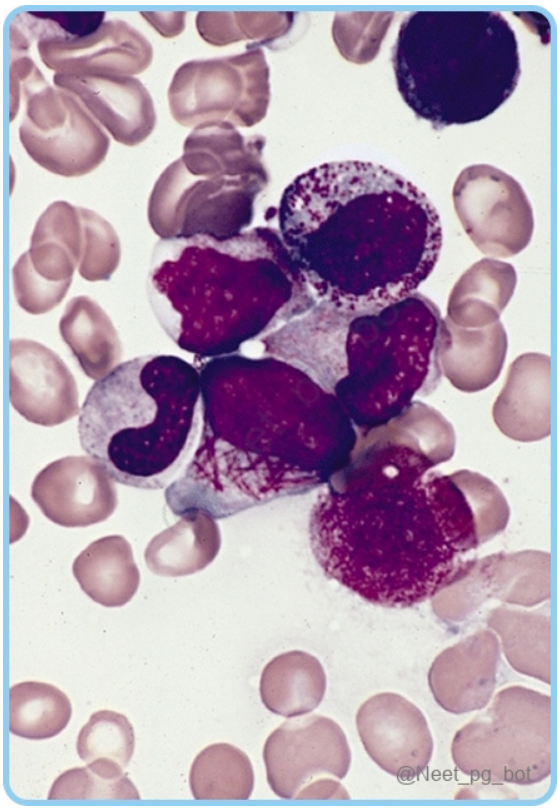
C. 1-b, 2-c, 3-a, 4-c

D. 1-a, 2-b, 3-d, 4-c

Correct Answer: A. 1-b, 2-a, 3-d, 4-c

Explanation: Cell Type Associated Malignancy Popcorn cell Lymphocyte-predominant Hodgkin’s lymphoma Faggot cell Acute promyelocytic leukemia Cerebriform nuclei Sezary syndrome Starry sky appearance Burkitt lymphoma Popcorn cells are characteristic of lymphocyte-predominant Hodgkin's lymphoma . These cells have a distinctive appearance with irregular nuclei and are found in the background of reactive lymphocytes. Popcorn cells {{caption_text}} Cells with multiple infolded nuclear membranes, small nucleoli, fine chromatin, and abundant pale cytoplasm. Seen in Nodular lymphocyte-Predominant Hodgkin lymphoma. Faggot cells are seen in acute promyelocytic leukaemia (APL) . These are abnormal promyelocytes that appear as bundles of rods (also called Auer rods) within the cells. AML-M3 Acute promyelocytic leukemia t(15:17) - PML-RAR■ fusion Blocks promyelocyte → myelocyte transformation Bone marrow: Auer rods form criss-cross called faggot cell {{caption_text}} Can cause DIC PAS+ Cerebriform nuclei are a feature of Sezary syndrome , a type of cutaneous T-cell lymphoma. The nuclei have a convoluted, brain-like appearance, which is a key histological finding. {{caption_text}} Starry sky appearance is associated with Burkitt lymphoma . It refers to darkly stained tumour cells with numerous bright spots representing macrophages engulfing apoptotic tumour cells. {{caption_text}}





@Neet_pg_bot

Q54: Which of the following is a feature of hemolytic anaemia? (Q858116)

A. Increased haptoglobin

B. Neutropenia

C. Reticulocytopenia

D. Decreased haptoglobin

Correct Answer: D. Decreased haptoglobin

Explanation: Decreased haptoglobin is a hallmark of hemolytic anaemia and helps distinguish it from other types of anaemia. In hemolytic anaemia, the destruction of RBCs increases the amount of free haemoglobin in the blood, which binds to haptoglobin. Other conditions where haptoglobin is reduced are (intravascular hemolysis): Paroxysmal Nocturnal Hemoglobinuria (PNH) Microangiopathic Hemolytic Anemia (MAHA)- HUS, TTP, DIC

Paroxysmal cold hemoglobinuria/Cold hemolysin type AIHA G6PD deficiency Neutropenia (Option B) refers to a low number of neutrophils, a type of white blood cell, which is not directly associated with hemolytic anaemia . Hemolytic anaemia primarily involves RBC destruction, not neutrophil abnormalities. Reticulocytopenia (Option C) : In hemolytic anaemia , the body responds to RBC destruction by producing more reticulocytes (immature red blood cells) as part of the compensatory mechanism. Thus, you would typically see reticulocytosis , not reticulocytopenia .

@Neet_pg_bot

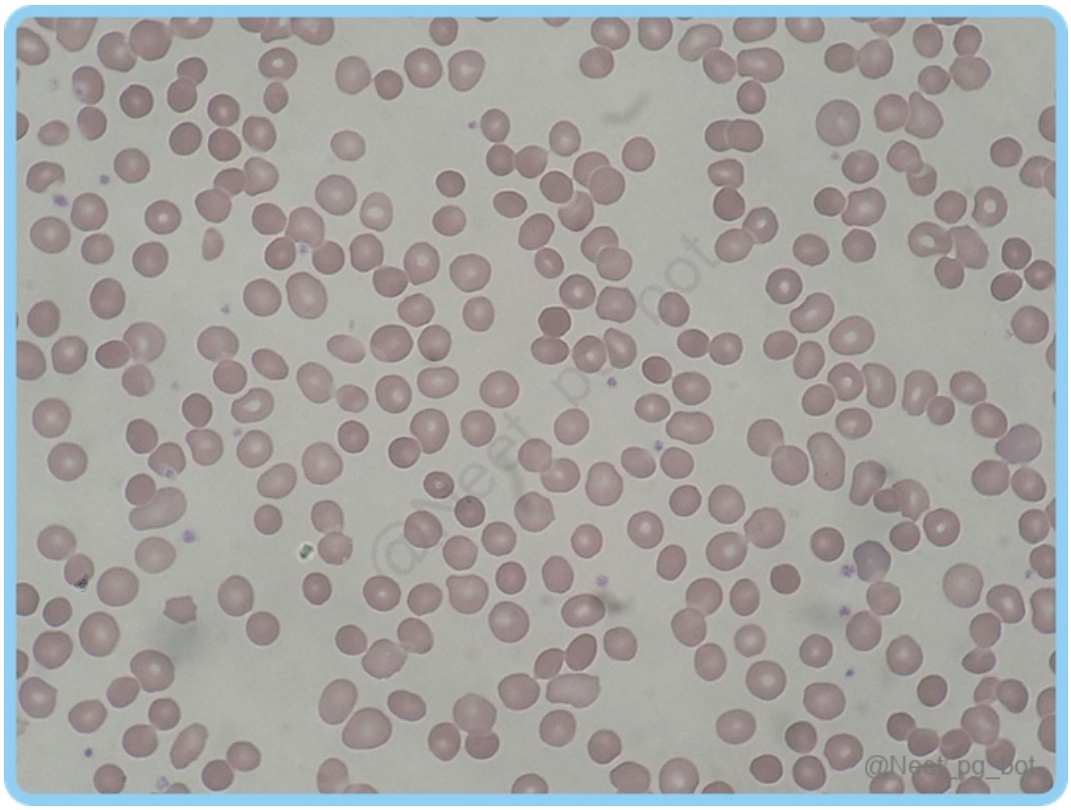
Q55: A child presents with intermittent jaundice and splenomegaly. There is a history of similar complaints in the elder brother. A peripheral smear shows the following findings. Which of the following is the most appropriate diagnostic test for this condition? (Q855398)

A. Osmotic fragility test - Hereditary spherocytosis

B. Coombs test - Autoimmune hemolytic anaemia

C. Genetic testing - G6PD deficiency

D. Flow cytometry - Paroxysmal nocturnal hemoglobinuria



Correct Answer: A. Osmotic fragility test - Hereditary spherocytosis

Explanation: The given clinical scenario and peripheral smear showing spherocytes most likely suggest a diagnosis of hereditary spherocytosis. The osmotic fragility test is used to diagnose hereditary spherocytosis, as spherocytes are more fragile and lyse in hypotonic solutions. Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. It has an autosomal dominant inheritance(75%) characterised by ankyrin mutation and an autosomal recessive inheritance characterised by spectrin mutation. Pathophysiology of hereditary spherocytosis: Mutations of ankyrin, band 3, spectrin, or band 4.2 ↓ Unstable RBC membrane with membrane loss ↓ The surface: volume ratio is reduced ↓ RBC takes up the shape of a sphere to compensate ↓ Spherical RBCs are trapped in splenic sinusoids due to large size ↓ Extravascular hemolysis {{caption_text}} The most specific morphologic finding is spherocytosis: Dark-staining (hyperchromic) spherocytes lacking the central zone of pallor. Other features include reticulocytosis. The characteristic clinical features are anemia, splenomegaly, jaundice, and an increased risk of gallstones. Severity ranges from asymptomatic to severe hemolytic anemia requiring transfusions. Early complications include neonatal jaundice and hemolytic crises. Late complications include gallstones and rarely iron overload.

@Neet_pg_bot

Q56: Serum transferrin saturation level is low. What is the most likely condition? (Q854695)

A. Iron Deficiency Anemia

B. Hemochromatosis

C. Sideroblastic anemia

D. Pernicious anemia

Correct Answer: A. Iron Deficiency Anemia

Explanation: Serum transferrin saturation is a key marker of iron status in the body. Low serum transferrin saturation indicates low iron stores , which is commonly seen in iron deficiency anaemia. Investigations for IDA

Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) indicates depleted iron stores. Serum Iron (Fe) Low levels are seen. Total Iron Binding Capacity (TIBC) Increased TIBC reflects the increased capacity of transferrin to bind iron in response to low iron stores. Transferrin saturation Is decreased, which refers to the percentage of transferrin that is bound to iron Red Cell Distribution Width (RDW) Increased RDW is often seen in iron deficiency anaemia Bone Marrow Aspiration and Iron Staining Confirmatory test Type of Anemia Serum Iron Transferrin saturation Serum Ferritin TIBC Sideroblastic Anemia (Option C ruled out) High High High Low Iron Deficiency Anemia Low Low Low High Hemochromatosis (Option B ruled out) High High High Low Pernicious anaemia (Option D) is an autoimmune condition that occurs when the body can't absorb enough vitamin B12. It does not primarily affect iron metabolism, and transferring saturation levels would not be low in this condition.

@Neet_pg_bot

Q57: Which of the following for Sickle cell anaemia is correct? (Q854687)

A. Low mechanical fragility, high osmotic fragility

B. High mechanical fragility, high osmotic fragility

C. Low mechanical fragility, low osmotic fragility

D. High mechanical fragility, low osmotic fragility

Correct Answer: D. High mechanical fragility, low osmotic fragility

Explanation: Sickle cell disease (SCD) is a hemoglobinopathy characterized by the presence of abnormal haemoglobin, known as haemoglobin S (HbS). Under low oxygen conditions, HbS polymerizes, causing RBCs to assume a sickle shape. Sickle-shaped RBCs are more rigid and less deformable, leading to high mechanical fragility , making them more likely to rupture under stress. Unlike normal RBCs, sickle-shaped RBCs have low osmotic fragility , meaning they are less prone to hemolysis in hypotonic solutions.

@Neet_pg_bot

Q58: A 45-year-old male patient with a history of chronic inflammatory conditions presents with fatigue, weakness, and pallor. Laboratory investigations reveal microcytic hypochromic anemia. Further evaluation suggests an underlying disorder affecting iron metabolism. Which cytokine is most likely inhibiting the activity of ferroportin in this patient? (Q820595)

A. IL-1

B. IL-6

C. IFN-gamma

D. TNF-Alpha

Correct Answer: B. IL-6

Explanation: Correct Option B - IL-6: IL-6 stands for Interleukin-6, which is a cytokine that plays a crucial role in inflammation and immune responses. In this scenario, the patient presents with microcytic hypochromic anemia, which is often caused by iron deficiency. Ferroportin is a protein that functions as an iron exporter, allowing iron to exit from cells into the bloodstream, where it can be utilized for various physiological processes including red blood cell production. When ferroportin is inhibited, it leads to reduced iron export from cells and contributes to iron retention within the cells.In chronic inflammatory conditions, such as the one mentioned in the question, there is an increased production of IL-6. IL-6 has been shown to stimulate the production of hepcidin, a peptide hormone synthesized in the liver. Hepcidin regulates iron homeostasis by binding to ferroportin and causing its internalization and degradation. This action reduces iron export from cells, leading to decreased iron availability for erythropoiesis (red blood cell production). Consequently, chronic inflammation-induced elevation of IL-6 and subsequent increase in hepcidin levels result in reduced iron absorption and availability for red blood cell formation, leading to microcytic hypochromic anemia. Incorrect Options: Option A - IL-1: Interleukin-1 is also involved in inflammation and immune responses, but it does not have a direct role in inhibiting ferroportin. It can contribute to inflammation-induced systemic responses. Option C - IFN-gamma: Interferon-gamma (IFN-gamma) is primarily involved in immune responses and has not been directly implicated in the inhibition of ferroportin. Option D - TNF-Alpha: Tumor Necrosis Factor-alpha (TNF-alpha) is another cytokine involved in inflammation. It does contribute to the inflammatory response, but it is not the primary cytokine responsible for inhibiting ferroportin.

@Neet_pg_bot

Q59: A 25-year-old female patient presents to the clinic with complaints of fatigue, weakness, and pale skin. On further investigation, her complete blood count reveals a

microcytic anemia. What is the likely diagnosis for this patient? (Q820581)

A. Alcoholism

B. Chronic Kidney disease

C. Hemolytic anemia

D. Iron deficiency anemia

Correct Answer: D. Iron deficiency anemia

Explanation: Correct Option D - Iron deficiency anemia: Iron deficiency anemia is characterized by a deficiency of iron, a key component required for hemoglobin synthesis in red blood cells. Microcytic anemia, where the red blood cells are smaller than normal, is a hallmark of iron deficiency. The patient's symptoms of fatigue, weakness, and pale skin are classic signs of anemia. Iron deficiency can be caused by inadequate dietary intake, chronic blood loss (such as from menstruation or gastrointestinal bleeding), or poor iron absorption. Based on the patient's presentation of microcytic anemia along with the symptoms of fatigue, weakness, and pale skin, the most likely diagnosis is D. Iron deficiency anemia. Incorrect Options: Option A - Alcoholism: Alcoholism can lead to various health issues, including anemia. However, in this case, the patient's presentation of fatigue, weakness, and pale skin along with microcytic anemia suggests a more specific cause related to iron deficiency. Option B - Chronic Kidney Disease: Chronic kidney disease can cause anemia due to reduced production of erythropoietin (a hormone that stimulates red blood cell production) by the kidneys. However, anemia caused by chronic kidney disease is usually normocytic or normochromic rather than microcytic. Option C - Hemolytic Anemia: Hemolytic anemia results from the destruction of red blood cells at a rate that exceeds their production. It can lead to a variety of symptoms, including fatigue and pale skin. However, microcytic anemia is typically associated with conditions related to impaired hemoglobin synthesis, like iron deficiency anemia, rather than hemolysis

@Neet_pg_bot

Q60: A patient reports to the outpatient department with complaints of fatigue. Investigation results indicate a Hb of 5.9, increased RDW and TIBC, and low ferritin. What is the most likely diagnosis? (Q860296)

A. Sideroblastic anemia

B. IDA

C. Anaemia of chronic disease

D. Hemolytic anemia

Correct Answer: B. IDA

Explanation: The patient's presentation with fatigue and investigations showing low haemoglobin, increased RDW, high TIBC, and low ferritin are consistent with a diagnosis of Iron Deficiency Anemia (IDA) . It results in inadequate haemoglobin synthesis. Causes: Dietary lack Impaired absorption Increased requirement Chronic blood loss Pathogenesis: Iron deficiency initially depletes iron stores (low ferritin) while maintaining normal serum iron and transferrin saturation. As depletion progresses, serum iron declines, leading to reduced haemoglobin synthesis. Hypochromic microcytic anaemia develops once iron stores are exhausted, with low serum iron, ferritin, and transferrin saturation, while total iron-binding capacity (TIBC) increases. Clinical features include koilonychia, alopecia, atrophic glossitis, esophageal webs, pica, malabsorption, fatigue, pale skin, shortness of breath, dizziness, headaches, tachycardia, cold extremities, and restless leg syndrome. Histopathology: Bone marrow aspiration: Increased erythroid progenitors and a lack of stainable iron in macrophages, best assessed by Prussian blue staining. Peripheral blood smears: Red cells are small (microcytic) and pale (hypochromic). {{caption_text}} Diagnosis: Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) (depleted iron stores). Serum Iron (Fe) Low levels Total Iron Binding Capacity (TIBC) Increased TIBC (increased capacity of transferrin to bind iron in response to low iron stores). Red Cell Distribution Width (RDW) Increased RDW (Red Cell Distribution Width) Bone Marrow Aspiration and Iron Staining Confirmatory test Lab parameters in various anaemia: Serum Iron Transferrin saturation Serum Ferritin TIBC Sideroblastic Anemia (Option A ruled out) High High High Low Iron Deficiency Anemia (Option B) Low Low Low High Anaemia of Chronic Disease (Option C ruled out) Low Low High Low Hemolytic Anemia (Option D ruled out) High Low High Low

@Neet_pg_bot

Q61: A 60-year-old woman presents with complaints of fatigue and dyspnea for 2 weeks. On examination, pallor is noted, and haemoglobin is found to be 6 gm/dL. What is the likely finding seen on the peripheral smear? (Q855962)

A. Poikilocytes

B. Microcytic hypochromic cells

C. Macrocytic cells

D. Target cells

Correct Answer: B. Microcytic hypochromic cells

Explanation: An elderly woman with fatigue, dyspnea, and severe anaemia (Hb 6 g/dL) suggests iron deficiency anaemia (IDA) . The peripheral smear typically shows microcytic hypochromic cells , the hallmark of IDA. While poikilocytosis can be present, microcytosis and hypochromia are more characteristic. Iron deficiency anaemia can result from dietary lack, impaired absorption, the increased iron requirement (pregnancy), or chronic blood loss (gastrointestinal bleeding). Clinical features: Koilonychia, alopecia, atrophic glossitis, oesophagal webs, pica and intestinal malabsorption, affecting overall nutritional status {{caption_text}} In iron deficiency anaemia (IDA), a peripheral blood smear can reveal characteristic changes. Hypochromic Red Blood Cells: The RBCs appear pale due to decreased haemoglobin content. Microcytic Red Blood Cells: RBCs are smaller than normal due to decreased haemoglobin synthesis. Anisocytosis: There is significant variation in the size of RBCs. Poikilocytosis: RBCs may show abnormal shapes, such as pencil cells, target cells (codocytes), and occasionally, elliptocytes.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 655,658

↑ *Back to this question in Part A*

@Neet_pg_bot

Q62: Which of the following cells are located in the centre of the lumen in a venule? (Q860262)

A. Lymphocytes

B. RBCs

C. Neutrophils

D. Platelets

Correct Answer: B. RBCs

Explanation: Red blood cells (RBCs) are located in the centre of the lumen in a venule. In venules with normal blood flow, red blood cells remain in the central axial column , while leukocytes are displaced toward the vessel wall . They are responsible for transporting oxygen from the lungs to the tissues and returning carbon dioxide from the tissues to the lungs. Lymphocytes (Option A) are white blood cells essential for immunity, comprising B cells (antibody production), T cells (immune regulation), and Natural Killer cells (targeting infected or cancerous cells).

They originate in the bone marrow, circulate in the blood and lymph, and typically adhere to the endothelium of blood vessels rather than residing within the venous lumen. Neutrophils (Option C) are white blood cells essential for bacterial defence . Produced in the bone marrow , they rapidly migrate to infection sites and eliminate pathogens via phagocytosis . During inflammation , like lymphocytes , they tend to localize near vessel walls rather than the lumen. Platelets (Option D) are small cell fragments produced in the bone marrow that play a key role in blood clotting. They aggregate at injury sites to form clots and stop bleeding, typically found near vessel walls rather than in the centre of the lumen.

@Neet_pg_bot

Q63: A 65-year-old patient presents with anaemia. Investigations show low serum iron and ferritin levels, along with increased TIBC. Which of the following is most likely to be present? (Q860216)

A. Iron Deficiency Anemia (IDA)

B. Myelodysplastic Syndrome

C. Aplastic Anemia

D. Anaemia of Chronic Disease

Correct Answer: A. Iron Deficiency Anemia (IDA)

Explanation: The pattern of low serum iron and ferritin levels, along with increased TIBC (total iron-binding capacity), is characteristic of Iron Deficiency Anemia (IDA) . It is the most common nutritional disorder in the world . It results in inadequate haemoglobin synthesis. Causes: Dietary lack Impaired absorption Increased requirement Chronic blood loss Pathogenesis: Iron deficiency initially depletes iron stores (low ferritin) while maintaining normal serum iron and transferrin saturation. As depletion progresses, serum iron declines, leading to reduced haemoglobin synthesis. Hypochromic microcytic anaemia develops once iron stores are exhausted, with low serum iron, ferritin, and transferrin saturation, while total iron-binding capacity (TIBC) increases. Clinical features include koilonychia, alopecia, atrophic glossitis, oesophagal webs, pica, malabsorption, fatigue, pale skin, shortness of breath, dizziness, headaches, tachycardia, cold extremities, and restless legs syndrome. Histopathology: Bone marrow aspiration: increased erythroid progenitors and a lack of stainable iron in macrophages, best assessed by Prussian blue staining. Peripheral blood smears: Red cells are small (microcytic) and pale (hypochromic). {{caption_text}} Diagnosis: Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) (depleted iron stores). (Option A) Serum Iron (Fe) Low levels (Option A) Total Iron Binding Capacity (TIBC) Increased TIBC (increased capacity of transferrin to bind iron in response to low iron stores). (Option A) Red Cell Distribution Width (RDW) Increased RDW Bone Marrow Aspiration and Iron Staining Confirmatory test Myelodysplastic Syndrome (MDS) (Option B) is a group of disorders where the bone

marrow produces dysfunctional blood cells, leading to cytopenias (anaemia, leukopenia, thrombocytopenia). It typically presents with multiple cytopenias, severe symptoms like infections or bleeding, and abnormal blood cell production. MDS often shows normal or elevated ferritin, not low iron and ferritin with high TIBC. Aplastic Anemia (Option C) is a rare condition where the bone marrow fails to produce enough blood cells, leading to pancytopenia (low red and white blood cells and platelets). It typically presents with pancytopenia, not just anaemia, and ferritin is usually normal or slightly elevated, not low with high TIBC. Anaemia of Chronic Disease (ACD) (Option D) occurs in chronic infections, inflammation, or kidney disease and is caused by impaired iron use and reduced red blood cell production. It typically presents with low serum iron and ferritin, but TIBC is decreased, not increased, due to iron sequestration and impaired utilisation in chronic inflammation.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 655-658.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q64: A 45-year-old patient visits a haematologist with symptoms of weakness and fatigue. Laboratory tests show low haemoglobin, a low reticulocyte count, and normal WBC and platelet counts. The bone marrow analysis reveals a selective reduction in erythroid precursors. What is the likely diagnosis? (Q860156)

A. Aplastic anemia

B. Pure red cell aplasia

C. Iron deficiency anaemia

D. Pernicious anemia

Correct Answer: B. Pure red cell aplasia

Explanation: The scenario of weakness, fatigue, low haemoglobin, low reticulocyte count, normal WBC and platelet counts, and bone marrow showing a selective reduction in erythroid precursors is consistent with Pure Red Cell Alasia (PRCA) , which is characterized by a marked reduction or absence of red blood cell precursors while other hematopoietic cell lines remain normal. It is a primary marrow disorder in which only erythroid progenitors are suppressed (red cell progenitors are completely absent in severe cases). Causes: Associated with neoplasms (thymoma and large granular lymphocytic leukaemia) Drug exposures Autoimmune disorders Parvovirus infection Clinical features: Fatigue, weakness, pallor, frequent infections, easy bruising or bleeding, and shortness of breath due to insufficient production of red blood cells, white blood cells, and platelets. It features a marked reduction or absence of red blood cell precursors while other hematopoietic cell lines remain normal . Aplastic anaemia (Option A) is a rare condition where the bone marrow fails to produce sufficient red blood cells, white blood cells, and platelets, leading to fatigue, infections, and bleeding. It can be caused by autoimmune diseases, infections, medications, or toxins. It involves a reduction in all hematopoietic cell lines and a hypocellular marrow with increased fat content on bone marrow biopsy. Iron deficiency anaemia (Option C) is a common type of anaemia caused by insufficient iron, leading to reduced haemoglobin production. Symptoms include fatigue, pallor, and weakness. It presents with low haemoglobin, low MCH, low MCV, low MCV, and high reticulocyte count , and it often shows signs of microcytic anaemia on blood smears. Pernicious anaemia (Option D) is a type of vitamin B12 deficiency anaemia caused by impaired absorption of B12 due to a lack of intrinsic factors. It leads to symptoms like fatigue, weakness, and neurological issues. It features low haemoglobin, high MCV, high MCH, and Erythroid hyperplasia on bone marrow biopsy .

↑ *Back to this question in Part A*

Q66: A 20-year-old female who is a known case of sickle cell anaemia was rushed to the emergency department with a complaint of extreme pain in the legs and fingers for the past 4 hours. Further examination revealed pain and tenderness in the right upper quadrant, and investigations showed sickle cells on peripheral blood smear and high bilirubin(indirect). What is the diagnosis? (Q860485)

A. IDA

B. Thalassemia

C. Anaemia of chronic disease

D. Sickle cell crisis

Correct Answer: D. Sickle cell crisis

Explanation: The patient, a known case of sickle cell anaemia, presenting with severe leg and finger pain for the past 4 hours, right upper quadrant tenderness, sickle cells on the peripheral blood smear, and elevated indirect bilirubin is likely undergoing a vaso-occlusive crisis (type of sickle cell crisis) , a common complication of Sickle Cell Disease (SCD) . Complications Acute Painful Episodes (Vaso-Occlusive Crisis) Characterised by unprovoked, severe, symmetrical pain often requiring strong opioids The most common acute event in sickle cell disease. Lasting from days to weeks. Sudden death during acute pain episodes can occur, possibly due to arrhythmias or pulmonary embolism. Acute Chest Syndrome: Symptoms include chest pain, cough, fever, hypoxia, and pulmonary infiltrates on x-ray. It can be mild in children (e.g., due to viral infections) or severe with multiple lobes affected. Thrombocytopenia, leukocytosis, and rapid anaemia suggest severe complications like acute respiratory distress syndrome (ARDS) and multiorgan failure. Osteonecrosis: Involves the hips bilaterally . Chronic pain can progress to severe disability; MRI detects early stages, while X-rays are less sensitive. Leg ulcer: Ulcers range from small and superficial to deep, covering most of the lower leg. Painful and difficult to treat if recurrent, long-standing and large ulcer. Other Complications: Priapism Stroke and silent infarction Gallstones/Surgery Hepatic disease Nephropathy Lung/pulmonary hypertension Retinopathy Aplastic crisis: Caused by parvovirus B19 infection Multiorgan failure IDA (Iron Deficiency Anemia) (Option A) presents with microcytic hypochromic anaemia, not sickle cells on the smear. It also lacks acute pain crises and indirect hyperbilirubinemia. Thalassemia (Option B) causes chronic anaemia with target cells, not acute vaso-occlusive pain. It is also associated with ineffective erythropoiesis rather than hemolysis-induced hyperbilirubinemia. Anaemia of chronic disease (ACD) (Option C) is linked to chronic inflammation and cytokine-mediated iron sequestration, typically presenting with normocytic or microcytic anaemia without acute pain crises or hemolysis.

@Neet_pg_bot

Q67: Which of the following is not seen after ileal resection? (Q844209)

A. Nuclear cytological asynchrony

B. Neurological manifestations

C. Microcytic hypochromic anemia

D. Reversible dementia

Correct Answer: C. Microcytic hypochromic anemia

Explanation: Ileal resection primarily affects vitamin B12 and bile acid absorption, since the terminal ileum is responsible for their absorption. Deficiency of vitamin B12 leads to megaloblastic anemia, nuclear-cytoplasmic

asynchrony, neurological manifestations (paresthesia, ataxia), and reversible dementia in severe cases. Microcytic hypochromic anemia (iron deficiency) is not typical, because iron is absorbed in the duodenum and proximal jejunum, which are not resected. Incorrect Options: Option A) Nuclear cytological asynchrony: Seen due to B12 deficiency affecting DNA synthesis. Option B) Neurological manifestations: Due to B12 deficiency, e.g., peripheral neuropathy. Option D) Reversible dementia: Severe B12 deficiency can lead to cognitive decline.

Q68: How is transferrin saturation affected by iron deficiency anemia? (Q844208)

A. Increased

B. Decreased

C. Normal

D. Dynamic

Correct Answer: B. Decreased

Explanation: Correct Option B – Decreased Transferrin saturation is decreased in iron deficiency anemia because there is less iron available to bind to transferrin despite increased transferrin levels. Incorrect Options: Options A, C, and D are incorrect.

FEATURE	IDA	AOCD	SIDEROBLASTIC ANEMIA
Serum iron	↓	↓	↑

@Neet_pg_bot

Q69: Which of the following statement is correct regarding Paroxysmal Nocturnal Hemoglobinuria? (Q844193)

A. Sucrose lysis test is used for confirmation

B. Flow cytometry is the best investigation

C. Most common cause of death is heart failure

D. It is an inherited disorder

Correct Answer: B. Flow cytometry is the best investigation

Explanation: Correct Option B - Flow cytometry is the best investigation: Flow cytometry is the confirmatory test for diagnosing Paroxysmal Nocturnal Hemoglobinuria (PNH). It detects the absence or reduction of GPI-anchored proteins like CD55 and CD59 on the surface of red blood cells. Incorrect Options: Option A - Sucrose lysis test is used for confirmation: Sucrose lysis testb is no longer the preferred diagnostic test. Option C - Most common cause of death is heart failure: Most common cause of death is heart failure: The most common cause of death in PNH is thrombosis, not heart failure. Option D - It is an inherited disorder: It is an inherited disorder: PNH is an acquired disorder, not inherited.

Q70: In a patient of hereditary spherocytosis, which of the following organisms is likely to attack progenitor cells, resulting in aplastic anemia? (Q844045)

A. CMV

B. EBV

C. Parvovirus B19

D. HSV

Correct Answer: C. Parvovirus B19

Explanation: Correct Option C - Parvovirus B19: Parvovirus B19 is responsible for causing aplastic crisis in hereditary spherocytosis. Incorrect Options: Options A, B, and D will not precipitate aplastic anemia.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q71: All are hereditary causes of thrombosis except: (Q853369)

A. PNH

B. Protein S deficiency

C. Antithrombin deficiency

D. Homocystinuria

Correct Answer: A. PNH

Explanation: Paroxysmal nocturnal hemoglobinuria (PNH) is a rare acquired condition marked by clonal expansion of hematopoietic stem cells lacking GPI anchor proteins and is not a hereditary cause of thrombosis. PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: CD55 (decay-accelerating factor) CD59 (membrane inhibitor of reactive lysis) C8-binding protein. Pathogenesis: It results from acquired mutations in the phosphatidylinositol glycan complementation group A gene (PIGA), an enzyme that is essential for the synthesis of certain membrane-associated complement regulatory proteins. Clinical features: It causes intravascular haemolysis and anaemia Haemoglobinuria (red-brown colour) (most noticeable in early morning urine) Hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome Management Transfusion Folate supplements Prophylaxis or treatment of thrombosis Anti-complement C5 monoclonal antibody. Incorrect Options: Protein S deficiency (Option B) is a genetic disorder that increases the risk of abnormal blood clotting (thrombosis). Protein C and its co-factor protein S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and thrombin generation. Deficiency can lead to deep vein thrombosis (DVT), pulmonary embolism (PE), and other thrombotic events. Antithrombin deficiency (Option C) is an autosomal dominant inherited disorder that heightens the risk of abnormal blood clotting (thrombosis). Antithrombin (AT) is a serine protease inhibitor (SERPIN) that inactivates activated coagulation factors IIa, IXa, Xa, and XIa. A deficiency in AT can result in deep vein thrombosis (DVT), pulmonary embolism (PE), and other thrombotic events. Heparins and fondaparinux enhance AT activity to exert their therapeutic effects. Homocystinuria (Option D) is an autosomal recessive disorder caused by mutations in the CBS gene, leading to cystathionine β-synthase deficiency that results in the accumulation of homocysteine and methionine in the blood. Symptoms include lens dislocation (ectopia lentis), intellectual disability, seizures, skeletal abnormalities similar to Marfan's syndrome, osteoporosis, thrombosis, and hyperpigmentation.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q72: A patient presents with fever, night sweats, and weight loss for 2 months. On examination, non-tender rubbery nodes are palpable in the supraclavicular and inguinal regions on both sides. A peripheral smear shows the presence of binucleated cells. Which of the following markers will be seen in this condition? CD15 CD30 CD19 CD3 (Q856019)

A. 1, 2, 4

B. 2, 3, 4

C. 2, 3

D. 1, 2

Correct Answer: D. 1, 2

Explanation: The clinical presentation of fever, night sweats, weight loss, and non-tender rubbery lymph nodes suggests Hodgkin lymphoma , supported by the presence of binucleated Reed-Sternberg cells in the peripheral smear. CD15 and CD30 are specific markers for Reed-Sternberg cells in Hodgkin lymphoma . {{caption_text}} CD19 and CD3 are typically markers for B cells and T cells , respectively, and are not characteristic of Hodgkin lymphoma. Hodgkin lymphoma typically spreads in an orderly, contiguous manner from one lymph node group to the next adjacent group without skipping areas. Feature Hodgkin Lymphoma (HL) Non-Hodgkin Lymphoma (NHL) Age of presentation Bimodal distribution peaks in young adults (15-35 years) and older adults (over 55). It is more common in older adults but can occur at any age. Localisation More often localised to a single axial group of nodes (cervical, mediastinal, para-aortic) More frequent involvement of multiple peripheral nodes. Pattern of Spread Orderly spread by contiguity. Non Contiguous spread Involvement of Mesenteric Nodes and Waldeyer Ring Mesenteric nodes and Waldeyer ring are rarely involved. Waldeyer ring and mesenteric nodes are commonly involved. Extranodal Presentation Extranodal presentation is rare. Extranodal presentation is common. WHO Classification of Hodgkin lymphoma: 1. Classical Hodgkin Lymphoma (CHL) Nodular Sclerosis Hodgkin Lymphoma Mixed Cellularity Hodgkin Lymphoma Lymphocyte-Rich Hodgkin Lymphoma Lymphocyte-Depleted Hodgkin Lymphoma 2. Non-classical lymphoma: Nodular Lymphocyte-Predominant Hodgkin Lymphoma (NLPHL) (CD20, CD45, and BCL-6 are expressed in Non-classical Nodular Lymphocyte-Predominant Hodgkin Lymphoma.

@Neet_pg_bot

Q73: Which of the following is not true about stem cells? (Q856476)

A. They can differentiate

B. They can replicate

C. They can divide without any regulatory stimulus

D. They can regenerate damaged tissues

Correct Answer: C. They can divide without any regulatory stimulus

Explanation: Stem cells can differentiate into various cell types, replicate, and regenerate damaged tissues. However, they do not divide uncontrollably or without regulatory stimuli. Their division is tightly regulated by signalling pathways to ensure proper function and prevent uncontrolled cell proliferation, which could lead to issues like cancer. Stem cells: Dual property: Stem cells can self-renew (Option B) and differentiate (Option A) into various cell types. Totipotent stem cells: Found during development, can generate all cell types in the body. Adult stem cells: Present in tissues, maintain cell populations, and repair damage (Option D) . Limited

differentiation capacity, typically producing cells within their respective tissues. Main types: Embryonic stem (ES) cells: Totipotent, can differentiate into all cell types. Adult (Tissue) stem cells: Limited to differentiating into specific tissue types, regulated by stem cell niches . Examples: Hematopoietic stem cells: Replenish blood cells in bone marrow, used in clinical treatments like leukaemia. Mesenchymal stem cells: Found in bone marrow and fat, they can differentiate into stromal cells (cartilage, bone, fat, muscle) and aid tissue regeneration.

@Neet_pg_bot

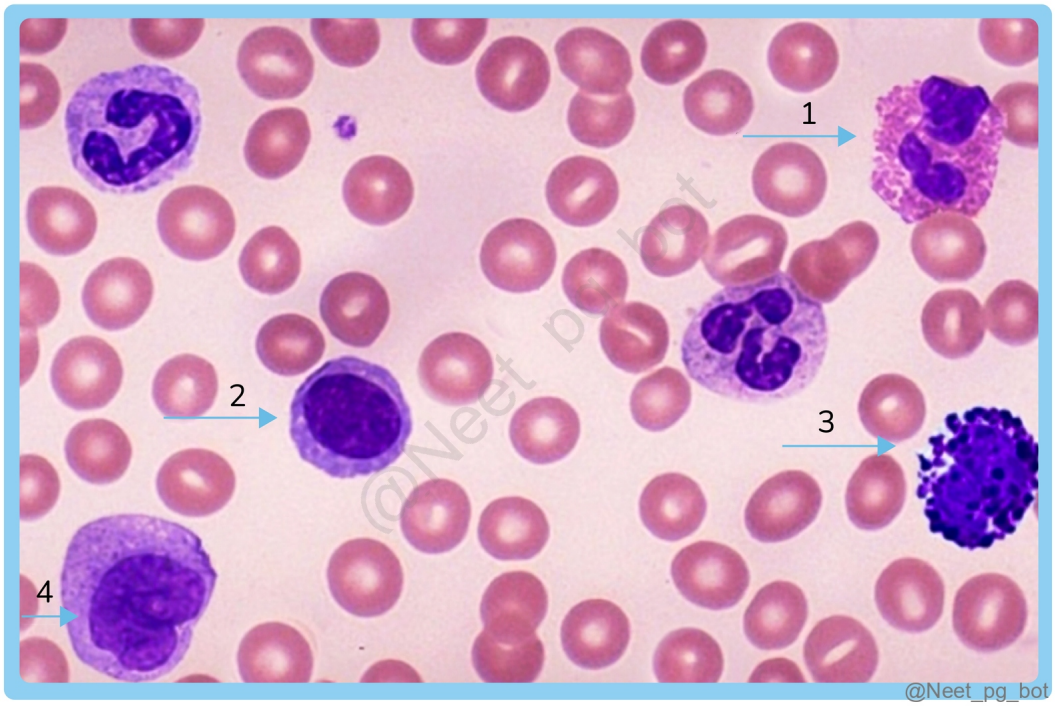
Q74: Identify the cells marked in the given image: (Q856905)

A. Lymphocyte-1, Monocyte-4, Eosinophil-2, Basophil-3

B. Lymphocyte-2, Monocyte-4, Eosinophil-1, Basophil-3

C. Lymphocyte-1, Monocyte-2, Eosinophil-3, Basophil-4

D. Lymphocyte-2, Monocyte-1, Eosinophil-3, Basophil-4



Correct Answer: B. Lymphocyte-2, Monocyte-4, Eosinophil-1, Basophil-3

Explanation: {{caption_text}} Neutrophils are granulocytes with a multilobed nucleus and pale cytoplasm containing fine pinkish granules. They are the most abundant white blood cells and play a key role in innate immunity through phagocytosis and enzyme release. Lymphocytes have a large, round nucleus, a small amount of cytoplasm & no granules. Monocytes are the largest cells with a kidney-shaped nucleus and a substantial cytoplasm. Eosinophils are granulocytes with a bilobed nucleus and prominent brick-red granules in their cytoplasm. Basophils are a type of granulocyte with a segmented nucleus and large bluish granules in their cytoplasm.

@Neet_pg_bot

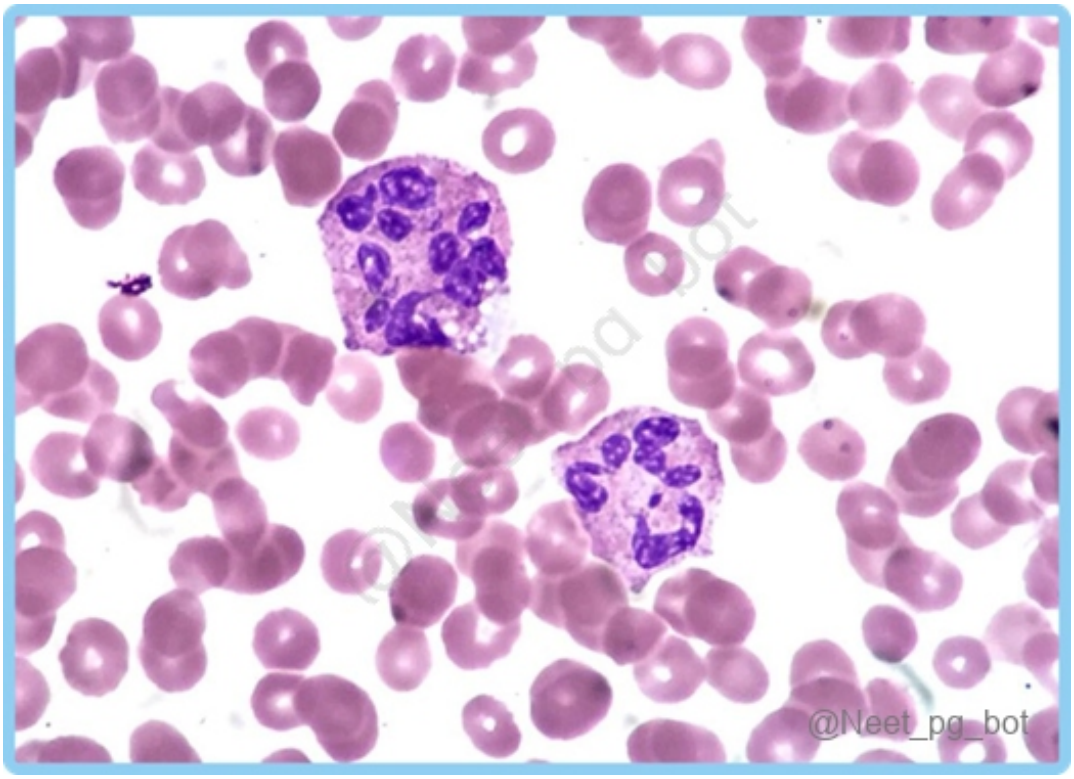
Q75: What is your diagnosis with respect to the findings shown in the peripheral smear: (Q856901)

A. Iron deficiency anaemia

B. Vitamin B12 deficiency

C. Hereditary spherocytosis

D. Acute myeloid leukemia



Correct Answer: B. Vitamin B12 deficiency

Explanation: The peripheral blood smear shows enlarged oval-shaped red blood cells (macro-ovalocytes) with hyperchromia and hypersegmented neutrophils , suggesting megaloblastic anaemia caused by B12 deficiency or folic acid deficiency. Causes of megaloblastic anaemia: Vitamin B12 deficiency Folate deficiency Other causes: Orotic aciduria, thiamine-responsive megaloblastic anaemia, arsenic poisoning, nitrous oxide inhalation, chemotherapy Lab findings in B12 deficiency: Bone Marrow Biochemical Tests Hypercellular bone marrow Erythroid Hyperplasia Sieve-like chromatin Hypersegmented neutrophils Reversal of myeloid: erythroid ratio 1:1 or less (Normal: 3:1) Nuclear-cytoplasmic asynchrony. {{caption_text}} Serum bilirubin: Increases Serum LDH: Increases Vitamin B12: Decreases Folic acid: Decreases Anti-intrinsic factor (IF) antibody: Present (Pernicious anaemia) Methylmalonyl CoA: Increases Homocysteine: Increases Schilling Test: Assess the cause of B12 deficiency.

@Neet_pg_bot

Q77: An 18-year-old male presented to the outpatient department with gum bleeding and fever for the past 2 months. The general examination showed pallor, and the systemic examination was unremarkable. Laboratory examination revealed a Hb level of 3 g/dl, a TLC of 1500/microL, and a platelet count of 15,000/microL. A peripheral smear shows macrocytes, and the reticulocyte count is 0.5%. A bone marrow examination revealed fatty streaks and absent megakaryocytes with no immature cells. What is the likely diagnosis? (Q856143)

A. Idiopathic acquired aplastic anaemia

B. Paroxysmal nocturnal hemoglobinuria

C. Myelodysplastic syndrome

D. Tuberculosis

Correct Answer: A. Idiopathic acquired aplastic anaemia

Explanation: The clinical presentation of gum bleeding, fever, pallor, severe anaemia, leukopenia, and thrombocytopenia, along with the findings of peripheral smear and bone marrow biopsy, strongly point toward idiopathic acquired aplastic anaemia (AAA). Aplastic Anemia is characterised by bone marrow failure, where the bone marrow does not produce enough blood cells, leading to Pancytopenia. In severe cases, the bone marrow may become hypocellular , making it difficult to aspirate sufficient material, leading to a dry tap. {{caption_text}} The absence of immature cells and the presence of fatty streaks in the bone marrow suggests bone marrow failure , typical of aplastic anemia, where normal hematopoiesis is replaced by fat. Paroxysmal nocturnal hemoglobinuria (Option B) is a rare disorder that causes red blood cells to prematurely break down by the complement system. It is characterised by hemolytic anemia and hemoglobinuria. The peripheral smear shows evidence of hemolysis, which is not the case here. Myelodysplastic syndrome (Option C) is a group of disorders characterised by ineffective hematopoiesis and dysplastic cells in the bone marrow. While MDS can cause pancytopenia, it would typically show dysplastic features in the marrow, including abnormal shapes of cells, which is not the case here. Tuberculosis (Option D) is an infectious disease caused by Mycobacterium tuberculosis that is not commonly associated with severe pancytopenia, fatty marrow, or absence of megakaryocytes. TB-related bone marrow suppression would usually have other findings like granulomas .

↑ *Back to this question in Part A*

@Neet_pg_bot

Q78: Which of the following is used in treating sideroblastic anaemia? (Q855432)

A. Vitamin B12

B. Vitamin B6

C. Vitamin B1

D. Iron

Correct Answer: B. Vitamin B6

Explanation: The treatment of Sideroblastic Anemia involves the use of vitamin B6 (pyridoxine). Sideroblastic Anemia It is a condition characterized by defective heme synthesis in the bone marrow, leading to the

accumulation of iron within the mitochondria of red blood cell precursors (sideroblasts). Causes Congenital causes: Due to enzyme deficiencies like ALA synthase, ferrochelatase, etc. Acquired causes Vitamin B6 deficiency Drugs like isoniazid and chloramphenicol Lead and alcohol poisoning Pathogenesis Vitamin B6 is crucial for the proper function of enzymes in heme synthesis. As a cofactor for aminolevulinic acid synthase, it aids in the first step of heme production. Ensuring sufficient vitamin B6 restores enzyme activity, supports heme synthesis, and helps alleviate symptoms of sideroblastic anaemia. Microscopy Peripheral Smear: Pappenheimer bodies Multiple basophilic iron aggregates Stain blue with Perl's/ Prussian blue Seen in sideroblastic anaemia, lead poisoning, or hemochromatosis {{caption_text}} Bone Marrow: Ringed Sideroblasts Blue granules form a full or partial ring Blasts have a nucleus Iron is present in mitochondria in the perinuclear region. Stain blue on Perl's/Prussian blue. Seen with Sideroblastic anemia and Myelodysplastic syndrome. Associated with SF3B1 mutation {{caption_text}} Vitamin B1 (Option C), or thiamine, plays a key role in carbohydrate metabolism and nerve function. Its deficiency causes conditions like Wernicke-Korsakoff syndrome and Beriberi, but it is not linked to sideroblastic anaemia. Vitamin B12 (Option A) deficiency causes megaloblastic anaemia and neurological symptoms. It results from poor diet, malabsorption, or lack of intrinsic factors. In sideroblastic anaemia, vitamin B6 is used instead of vitamin B12 because it helps correct the heme synthesis defect, while B12 is not involved in this process. Iron (Option D) deficiency presents with symptoms like pale skin, shortness of breath, dizziness or lightheadedness, brittle nails, headaches, restless legs syndrome, etc. In sideroblastic anaemia, treatment focuses on addressing the underlying cause, as the main issue is impaired heme synthesis. Iron supplementation is generally ineffective and may worsen the condition by increasing iron accumulation in tissues.

@Neet_pg_bot

Q79: Which of the following statements regarding the effect of glucose-6-phosphate dehydrogenase deficiency is correct? Decrease in reduced glutathione Decrease NADPH Decreased lipid peroxidation Decreased RBC membrane damage (Q855416)

A. Only 1 is correct

B. 1 & 2 are correct

C. 2 & 3 are correct

D. 1, 2 & 4 are correct

Correct Answer: B. 1 & 2 are correct

Explanation: 1 & 2 statements are correct regarding Glucose-6-phosphate Dehydrogenase (G6PD) Deficiency. It is an X-linked recessive disorder. Pathogenesis: It is characterized by a deficiency in the G6PD enzyme, which protects red blood cells from oxidative damage. This reduces the ability to generate NADPH (Statement 2) via the pentose phosphate pathway and impairs glutathione regeneration (Statement 1), exacerbating oxidative stress and

hemolysis. When exposed to oxidative stressors, there is an imbalance between the production of reactive oxygen species (ROS) and antioxidants that neutralize them. This leads to oxidative damage to red blood cell membranes and proteins, resulting in hemolysis. (Statement 4) {{caption_text}} Clinical features: Episodes of acute hemolytic anaemia triggered by oxidative stressors such as infections, certain medications (e.g., antimalarials, sulfonamides), or ingestion of certain foods (e.g., fava beans). Fatigue, pallor, jaundice, and dark urine (due to hemoglobinuria). The severity of hemolysis varies depending on the degree of enzyme deficiency and the magnitude of the oxidative insult, with some individuals experiencing life-threatening hemolytic crises. G6PD deficiency causes both intra and extravascular hemolysis. Decreased lipid peroxidation (Statement 3): G6PD deficiency does not directly lead to a reduction in lipid peroxidation. On the contrary, it can increase susceptibility to oxidative stress and the production of reactive oxygen species (ROS). The reduced levels of NADPH and glutathione in G6PD deficiency impair the cell's antioxidant defence mechanisms, resulting in enhanced lipid peroxidation and oxidative damage.

@Neet_pg_bot

Q80: A child presented with bilateral proptosis. From the peripheral smear, he was suspected to have chloroma. What is the next investigation of choice? (Q855410)

A. Platelet count

B. WBC count

C. Flow cytometry

D. Bone marrow biopsy

Correct Answer: D. Bone marrow biopsy

Explanation: The next investigation of choice for a child suspected to have Chloroma (also known as Granulocytic Sarcoma or Myeloblastoma) is a bone marrow biopsy. It is a localized extramedullary myeloid tumour composed of immature myeloid cells, which can occur in patients with acute myeloid leukaemia (AML) or myelodysplastic syndrome (MDS). It is not a benign tumour, but it has a greenish colour. Site: Soft tissue involvement in orbit leads to proptosis. Associated with AML M2 and M5. Bone marrow biopsy: Confirms the diagnosis by revealing the presence of abnormal myeloid cells infiltrating the bone marrow. (Option D) {{caption_text}} Peripheral smear findings: Myeloblasts. Arbiskov cells: Atypical monocytes/macrophages. Markers: MPO (green colour), CD 43, CD 45 and Lysozyme. {{caption_text}} {{caption_text}} Platelet count (Option A), WBC count (Option B) and Flow cytometry (Option C) might be done but they do not confirm the diagnosis of chloroma.

Robbins & Cotran Pathologic Basis of Diseases, 10th Edition, Page 618-620.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q81: All of the following are associated with massive splenomegaly, except: (Q855400)

A. Chronic myeloid leukemia

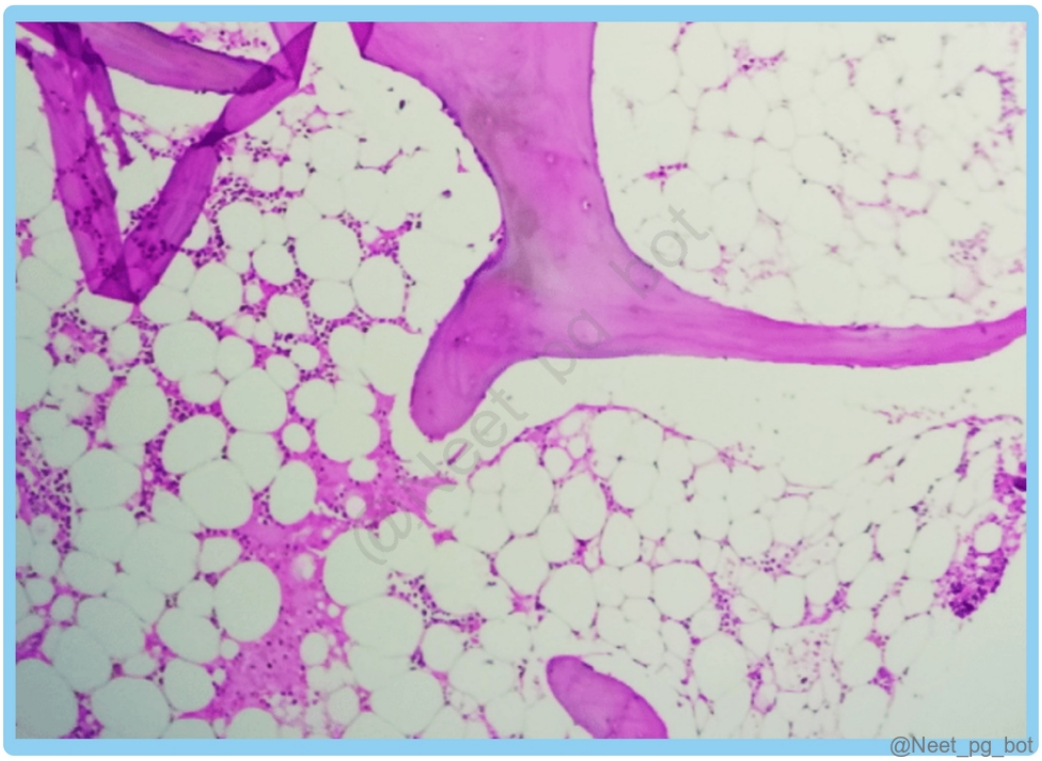
B. Aplastic anemia

C. Hairy cell leukemia

D. Lymphoma

Correct Answer: B. Aplastic anemia

Explanation: Massive splenomegaly, often linked to haematological disorders, is not typically associated with Aplastic Anemia, a bone marrow failure condition characterized by reduced production of blood cells. Aplastic Anemia It refers to a syndrome of chronic primary hematopoietic failure and attendant pancytopenia. Cause Acquired Idiopathic Acquired stem cell defects Immune-mediated Chemical agents Dose-related (Alkylating agents, antimetabolites, benzene, chloramphenicol, inorganic arsenicals) Idiosyncratic (Chloramphenicol, phenylbutazone, organic arsenicals, methylphenylethylhydantoin, carbamazepine, penicillamine, gold salts) Physical agents Whole-body irradiation Viral infections Hepatitis (unknown virus) Cytomegalovirus infections Epstein-Barr virus infections Herpes zoster (varicella zoster) Inherited Fanconi anemia Telomerase defects Pathogenesis The pathogenesis of aplastic anaemia is not fully understood. However, two major etiologies have been invoked: Extrinsic (immune-mediated suppression of marrow progenitors) Intrinsic (abnormality of stem cells) Clinical features Onset: Insidious. Pancytopenia Anaemia (progressive weakness, pallor, and dyspnea) Thrombocytopenia (petechiae and ecchymoses) Neutropenia (frequent and persistent infections or the sudden onset of chills, fever, and prostration). Splenomegaly is absent (Option B) The red cells are usually slightly macrocytic and normochromic. Microscopy Hypocellular bone marrow is largely devoid of hematopoietic cells; often, only fat cells, fibrous stroma, and scattered lymphocytes and plasma cells remain. Marrow aspirates often yield little material (a “dry tap”). {{caption_text}} Chronic myeloid leukaemia (Option A): Extensive extramedullary hematopoiesis often results in significant splenomegaly. Bone marrow findings typically include hypercellularity, an increased myeloid-to-erythroid ratio, and the presence of dwarf megakaryocytes. Additionally, sea-blue histiocytes, also known as pseudo-Gaucher cells, may be observed in the marrow. {{caption_text}} {{caption_text}} {{caption_text}} Hairy cell leukaemia (Option C) presents with fatigue, recurrent infections, easy bruising, and symptoms related to splenomegaly, such as early satiety and abdominal discomfort, along with pancytopenia. Peripheral smear typically shows "hairy cells" with round, oblong, or reniform nuclei and pale blue cytoplasm. Bone marrow findings often reveal hypocellular or fibrotic marrow with "hairy cells" and a characteristic "fried egg" appearance. {{caption_text}} Lymphoma (Option D) is cancer that originates in the lymphatic system, part of the immune system, and involves the uncontrolled growth of lymphocytes (a type of white blood cell). It can present with splenomegaly. The two main types are Hodgkin lymphoma (HL), characterized by Reed-Sternberg cells, and Non-Hodgkin lymphoma (NHL).



@Neet_pg_bot

Q82: A 45-year-old male patient was diagnosed with iron deficiency anaemia. Which of the following is true about the intracellular regulation of iron in iron deficiency anaemia? (Q855399)

A. Ferritin translation is increased by binding IRP to IRE

B. Ferritin translation is decreased by binding IRP to IRE

C. Transferrin receptor 1 translation is unaffected by binding IRP to IRE

D. Transferrin receptor 1 translation is decreased by binding IRP to IRE

Correct Answer: B. Ferritin translation is decreased by binding IRP to IRE

Explanation: Iron deficiency state → intracellular iron is low Iron regulatory proteins (IRPs) are key to maintaining iron homeostasis. When iron levels are low, IRPs bind to iron response elements (IREs) located in the untranslated regions (UTRs) of specific messenger RNAs (mRNAs) Ferritin regulation Ferritin mRNA has IRE in the 5′ UTR The binding of IRP to this 5' IRE physically blocks the ribosome from initiating translation, thus decreasing ferritin production . This action helps conserve the limited iron available by preventing its storage. Transferrin receptor 1 (TfR1) regulation TfR1 mRNA has IREs in the 3′ UTR The binding of IRP to the 3' IRE protects the mRNA from degradation, thereby increasing its stability and translation. This leads to increased production of TfR1 , which enhances iron uptake into the cells to compensate for the deficiency. Ferritin translation is increased by binding IRP to IRE (Option A) : Opposite of true; IRP binding inhibits ferritin translation Transferrin receptor 1 translation is unaffected by binding IRP to IRE (Option C): IRP binding increases TfR1 translation by stabilizing mRNA Transferrin receptor 1 translation is decreased by binding IRP to IRE (Option D): IRP binding actually enhances TfR1 expression

@Neet_pg_bot

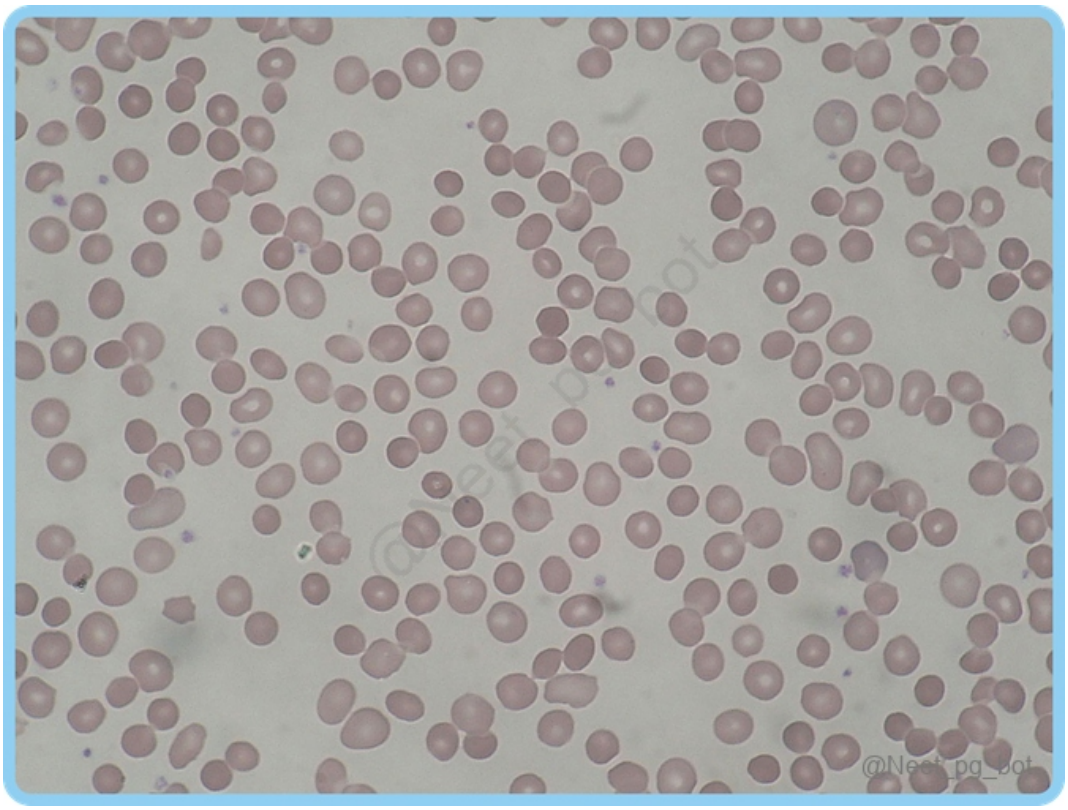
Q83: A 24-year-old male patient presents with anaemia. Both his father and paternal aunt experienced similar illnesses and were effectively treated with splenectomy. The patient's peripheral blood smear resembles the one depicted in the accompanying illustration, showing spherocytes. What other abnormalities can be anticipated? (Q857592)

A. Decreased osmotic fragility

B. Decreased reticulocytes

C. Heinz bodies

D. Howell-Jolly bodies



Correct Answer: D. Howell-Jolly bodies

Explanation: The clinical presentation, along with microscopic findings, indicates hereditary spherocytosis. Howell-Jolly bodies, remnants of nuclear material normally removed by the spleen, persist in red blood cells in splenectomised patients and can be seen on a peripheral blood smear. Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. It has an autosomal dominant inheritance(75%) characterised by ankyrin mutation and an autosomal recessive inheritance characterised by spectrin mutation. Pathophysiology of hereditary spherocytosis: {{caption_text}} {{caption_text}} The most specific morphologic finding is spherocytosis: Dark-staining (hyperchromic) spherocytes lacking the central zone of pallor. Other features include reticulocytosis. The characteristic clinical features are anaemia, splenomegaly, jaundice, and an increased risk of gallstones. Severity ranges from asymptomatic to severe hemolytic anaemia requiring transfusions. Early complications include neonatal jaundice and hemolytic crises. Late complications include gallstones and rarely iron overload. Decreased osmotic fragility (Option A): In hereditary spherocytosis, osmotic fragility increases , not decreases. Red blood cells are more prone to bursting in hypotonic solutions. Decreased reticulocytes (Option B): Reticulocyte count is typically increased in hereditary spherocytosis, especially in cases of hemolysis, as the bone marrow compensates by producing more immature red blood cells. Heinz bodies (Option C) are formed due to oxidative damage to haemoglobin and are typically seen in G6PD deficiency or other conditions involving hemoglobinopathy.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 638, 639

↑ *Back to this question in Part A*

@Neet_pg_bot

Q84: What is the most likely diagnosis for an 18-year-old male with gum bleeding, fever for two months, pallor, low haemoglobin (3 gm/dL), low TLC (1500/microL), low platelet count (15000/microL), macrocytes on peripheral smear, 0.5% reticulocyte count, and bone marrow examination showing fatty streaks and a lack of megakaryocytes but no immature cells? (Q857108)

A. Idiopathic acquired aplastic anemia

B. Paroxysmal nocturnal hemoglobinuria

C. Myelodysplastic syndrome

D. Tuberculosis

Correct Answer: A. Idiopathic acquired aplastic anemia

Explanation: The patient presents with gum bleeding, prolonged fever, pallor, and pancytopenia. Bone marrow examination shows fatty streaks, a lack of megakaryocytes, and no immature cells, suggesting idiopathic acquired aplastic anemia, where bone marrow failure leads to hematologic abnormalities. Aplastic anaemia is a condition of primary hematopoietic failure resulting in pancytopenia (anaemia, neutropenia, thrombocytopenia), often due to autoimmune mechanisms or inherited/acquired abnormalities in hematopoietic stem cells. Etiology: Common causes: Chemical and drug exposure (e.g., chemotherapy, benzene) Viral infections (e.g., hepatitis, linked to 5% of cases) Radiation exposure (e.g., therapeutic or nuclear accidents) Genetic causes: Fanconi anaemia : Rare autosomal recessive disorder with congenital anomalies (kidney, spleen hypoplasia, bone anomalies). Telomerase defects : Found in 5-10% of adult-onset cases, causing premature exhaustion of hematopoietic stem cells. Idiopathic cases: No identifiable cause in ~65% of cases. Morphology: Bone Marrow: Hypocellular marrow with fat cells, fibrous stroma, and scattered lymphocytes/plasma cells. "Dry tap" on marrow aspirates (due to lack of hematopoietic cells). Peripheral Blood: Macrocytic , normochromic red cells with reticulocytopenia . Granulocytopenia (leading to infections) and thrombocytopenia (leading to bleeding). Clinical features: Onset: Insidious, with progressive pancytopenia. Anaemia : Weakness, pallor, dyspnea. Thrombocytopenia : Petechiae, ecchymosis. Neutropenia : Frequent infections, chills, fever. Splenomegaly : Generally absent. Red Cells : Slightly macrocytic and normochromic. Diagnosis: Based on bone marrow biopsy , showing hypocellularity . Must differentiate from other causes of pancytopenia, like leukaemia or myelodysplastic syndrome, where the marrow is typically hypercellular. Paroxysmal nocturnal hemoglobinuria (PNH) (Option B) is a rare acquired disorder where red blood cells are destroyed by complement. It often presents with hemolysis and episodes of dark urine, especially at night. The peripheral smear in PNH shows evidence of hemolysis and pancytopenia, but bone marrow findings would not show fatty streaks with a lack of megakaryocytes, as in this case. Myelodysplastic syndrome (MDS) (Option C) typically presents with cytopenias and abnormal blood cell morphology. Bone marrow findings in MDS often show dysplastic changes in blood cells, which would not correlate with the lack of immature cells seen here. Additionally, the absence of megakaryocytes and the presence of fatty streaks suggest aplasia rather

than dysplastic hematopoiesis. Tuberculosis (TB) (Option D): While TB can cause systemic symptoms like fever and weight loss, it is not typically associated with pancytopenia, macrocytic anaemia, and bone marrow findings of fatty streaks with a lack of megakaryocytes. TB may affect bone marrow in disseminated forms, but the presentation and lab findings here point more to an intrinsic hematopoietic failure like aplastic anaemia.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 659-661

↑ *Back to this question in Part A*

@Neet_pg_bot

Q85: A 10-year-old boy presents with fatigue. Investigations reveal the following: Hemoglobin: 9 g/dL MCV: 80 fL MCH: 29 pg Serum ferritin: 185 µg/L TLC: Elevated with predominant lymphocytes and neutrophils. What is the likely diagnosis for this patient? (Q855124)

A. Thalassemia

B. Anemia of chronic disorder

C. Iron deficiency anaemia

D. Sickle cell anemia

Correct Answer: B. Anemia of chronic disorder

Explanation: The patient has normocytic, normochromic anaemia with normal MCV (80 fL) and MCH (29 pg). Elevated serum ferritin (185 µg/L) suggests adequate iron stores, ruling out iron deficiency anaemia. The elevated TLC with predominant lymphocytes and neutrophils indicates an underlying chronic inflammatory or infectious condition consistent with anaemia of chronic disease (ACD). Serum Iron Transferrin saturation Serum Ferritin TIBC Sideroblastic Anemia High High High Low Iron Deficiency Anemia Low Low Low High Anemia of Chronic Disease Low Low High Low Hemolytic Anemia High Low High Low Thalassemia (Option A) typically presents with microcytic anaemia and reduced MCV, which is not seen here. Iron deficiency anaemia (Option C) typically presents with low ferritin levels, which is not consistent with the patient's ferritin level. Sickle cell anaemia (Option D) usually results in normocytic anaemia but would typically show sickle-shaped cells on a peripheral blood smear, which is not described in this case.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 620,621,655,659

↑ *Back to this question in Part A*

@Neet_pg_bot

Q86: All of the following are seen in the anaemia of chronic disease, except: (Q855067)

A. High serum hepcidin

B. Low serum ferritin

C. Chronic infection

D. Normal iron stores

Correct Answer: B. Low serum ferritin

Explanation: In anaemia of chronic disease, ferritin levels are typically normal or elevated due to the inflammatory response, while hepcidin levels are increased, leading to impaired iron absorption and reduced availability of iron for erythropoiesis. Anaemia of Chronic Disease (AOCD): Interleukin-6 is the most important inflammatory mediator linked to the pathogenesis of anaemia of chronic disease (AOCD). In chronic conditions, Interleukin-6 will increase and act on the liver. Releases Hepcidin (Master regulator of Iron metabolism) Inhibits Fe absorption. Serum iron levels and transferrin saturation are decreased. Inhibits the release of Fe from ferritin. Therefore, ferritin levels increase . This leads to a decrease in TIBC. Anemia Serum Iron Transferrin saturation Serum Ferritin TIBC Sideroblastic Anemia High High High Low Iron Deficiency Anemia Low Low Low High Anaemia of Chronic Disease Low Low High Low Hemolytic Anemia High Low High Low

@Neet_pg_bot

Q87: A patient is diagnosed with B-cell leukaemia. Which of the following are poor prognostic factors? Hyperdiploidy Age <1 year t(9:22) t(4:11) (Q856031)

A. A, C, D

B. C, D

C. A, B, C, D

D. B, C, D

Correct Answer: D. B, C, D

Explanation: Hyperdiploidy is generally associated with a better prognosis in B-cell leukaemia, particularly in acute lymphoblastic leukaemia (ALL) Prognostic factors in ALL: Favorable Prognostic factors Unfavorable

prognostic factors Age: 1-10 years Leucocyte count < 50000/µl Hyperploidy t (12:21) L1 ALL Response to treatment Early Pre B-cell ALL Female Extreme age group : <1 year or >10 years Hypoploidy t(9:22) and t(4:11) L2 and L3 ALL and mature B cell ALL Total leukocyte count >50,000/cubic.mm Black males Organomegaly CNS Leukemia Absence of CD10 Remission> 14 days

@Neet_pg_bot

Q88: Which of the following is true about hereditary spherocytosis? (Q856004)

A. Gallstones develop by 4-5 years of age

B. Splenectomy does not protect against developing gallstones

C. Around 75% of cases show an autosomal dominant pattern

D. High MCH is pathognomonic of HS

Correct Answer: C. Around 75% of cases show an autosomal dominant pattern

Explanation: Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. It has an autosomal dominant inheritance (75%) characterized by ankyrin mutation and an autosomal recessive inheritance characterized by spectrin mutation . Gallstones develop by 4-5 years of age (Option A): Pigment gallstones form due to chronic hemolysis (excessive red blood cell breakdown). While a common complication, they usually appear in adolescence or adulthood , not as early as 4-5 years old. Splenectomy does not protect against developing gallstones (Option B): Splenectomy is performed precisely to stop the chronic hemolysis . By eliminating the major site of red blood cell destruction, it halts the overproduction of bilirubin and does protect against the formation of new bilirubin (pigment) gallstones. High MCH is pathognomonic of HS (Option D): The characteristic finding is a high MCHC, not MCH. This high MCHC occurs because the spherocytes lose cell membrane and cytoplasm, becoming dehydrated and "concentrating" the hemoglobin inside. Even a high MCHC is not pathognomonic. It is highly suggestive, but it can also be seen in other conditions, such as autoimmune hemolytic anemia.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 638, 639

↑ *Back to this question in Part A*

@Neet_pg_bot

Q89: Which of the following is not likely to be seen in a patient with paroxysmal nocturnal hemoglobinuria (PNH)? (Q855389)

A. Aplastic anemia

B. Leukaemia

C. Thrombosis

D. Hemolysis

Correct Answer: B. Leukaemia

Explanation: Leukaemia is not likely to be seen in a patient with Paroxysmal Nocturnal Hemoglobinuria (PNH). It is a rare acquired hematopoietic stem cell disorder characterized by a deficiency of glycosylphosphatidylinositol (GPI)-anchored proteins on the surface of blood cells, particularly red blood cells. PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: CD55 (decay-accelerating factor) CD59 (membrane inhibitor of reactive lysis) C8-binding protein. Pathogenesis: It results from acquired mutations in the phosphatidylinositol glycan complementation group A gene (PIGA), an enzyme that is essential for the synthesis of certain membrane-associated complement regulatory proteins. Clinical features: It causes intravascular hemolysis and anaemia. (Option D ruled out) Haemoglobinuria (red-brown colour) (most noticeable in early morning urine) Hypoplastic bone marrow failure, aplastic anaemia (Option A ruled out), thrombosis (Option C ruled out), and myelodysplastic syndrome Management Transfusion Folate supplements Prophylaxis or treatment of thrombosis Anti-complement C5 monoclonal antibody.

@Neet_pg_bot

Q90: Which of the following are features describing necrosis? Cell swelling Disrupted cell membrane Induces inflammation Physiological (Q857443)

A. 1 and 2

B. 1, 2 and 4

C. 1, 2 and 3

D. 1 and 3

Correct Answer: C. 1, 2 and 3

Explanation: Necrosis is a form of pathological cell death (Statement 4 ruled out) , often occurring due to various injuries, such as physical trauma, ischemia, infection, or exposure to toxic substances. It is characterized by cell swelling, membrane rupture, organelle damage, and nuclear changes (Pyknosis, Karyorrhexis, Karyolysis). Cell swelling occurs because of the loss of cellular integrity and failure of ion pumps (such as the Na+/K+ ATPase pump), leading to an influx of water into the cell. In necrosis, the plasma membrane of the cell is disrupted , allowing the release of intracellular contents. The released substances trigger an immune response, leading to an inflammatory reaction, which is a characteristic of necrosis.

@Neet_pg_bot

Q91: In which of the following conditions is macrocytic anemia seen? (Q793648)

A. Thalassemia

B. Anemia of chronic disease

C. Sideroblastic anemia

D. Liver disease

Correct Answer: D. Liver disease

Explanation: Correct Option D - Liver disease: There are several potential pathological mechanisms of macrocytic anemia associated with liver disease. First, patients with liver disease are more likely to have vitamin B12 or folate deficiencies, which directly result in macrocytic anemia. Vitamin B12 and folate coenzymes are required for thymidylate and purine synthesis; thus, their deficiencies result in retarded DNA synthesis and eventually will develop into macrocytic anemia. Second, macrocytic anemia in liver disease may be due to an increased deposition of cholesterol on the membranes of circulating RBCs. This deposition effectively increases the surface area of the erythrocyte. Incorrect Options: In options A, B, and C, macrocytic anemia is not seen.

@Neet_pg_bot

Q92: Which of the following stains is used for the detection of hemosiderin deposits? (Q793650)

A. Mason-Fontana stain

B. Oil Red O

C. Sudan black

D. Perls Prussian blue

Correct Answer: D. Perls Prussian blue

Explanation: Correct Option D - Perls Prussian Blue: Hemosiderin is an iron-containing pigment that is produced by the breakdown of hemoglobin. It is commonly found in macrophages and can accumulate in various tissues in the body under certain conditions, such as hemorrhage, inflammation, and iron overload disorders. Perls Prussian blue stain is a commonly used stain for the detection of hemosiderin. The stain is based on the reaction of potassium ferrocyanide and hydrochloric acid with iron in hemosiderin, which produces a blue color. The staining is often performed on tissue sections from biopsy or autopsy specimens. Incorrect Options: Option A - Mason-Fontana stain: This stain is based on the oxidation of melanin by potassium permanganate, which results in the formation of brown or black pigment. The stain is commonly used for the detection of melanin pigment in tissues, such as the skin, hair, and eyes. Option B - Oil Red O: This stain is a lipophilic dye that is used to detect lipids, such as triglycerides and cholesterol esters. The dye binds to the lipid droplets in tissues, producing a bright red color. The stain is commonly used for the detection of fat in frozen sections of tissue samples. Option C - Sudan black: This stain is a lipophilic dye that is used to detect lipids in tissues. The stain binds to the lipid droplets in tissues, producing a dark blue-black color. The stain is commonly used for the detection of fat in frozen sections of tissue samples.

@Neet_pg_bot

Q93: In iron deficiency anaemia, all of the following are increased except: (Q856136)

A. Transferrin saturation

B. RBC protoporphyrin

C. Total iron binding capacity

D. Ferritin soluble receptors

Correct Answer: A. Transferrin saturation

Explanation: Transferrin saturation is decreased in iron deficiency anaemia. This is because although TIBC is elevated, there is not enough iron to saturate the transferrin molecules, leading to low transferrin saturation. Iron Study Interpretation in Iron Deficiency Anemia Serum Ferritin Low (< 30 ng/mL) Serum Iron (Fe) Low Serum transferrin saturation (Option A) Low Total Iron Binding Capacity (TIBC) (Option C ruled out) Increased: TIBC reflects the increased capacity of transferrin to bind iron in response to low iron stores. Red Cell Distribution Width (RDW) Increased Ferritin soluble receptors (sTfR)(Option D ruled out) Increased RBC protoporphyrin (Option B ruled out) Increased Bone Marrow Aspiration and Iron Staining Confirmatory test for Iron deficiency anaemia.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 655

↑ *Back to this question in Part A*

@Neet_pg_bot

Q94: A child visited the hospital with her mother with complaints of severe fatigue, lethargy, pallor, and irritation. She has a known case of iron deficiency anemia and is on oral iron supplements. On reviewing the child, the physician in charge plans to start IV iron supplementation. What is the next best test to be done in assessing this child? (Q793752)

A. Blood hemoglobin

B. Total iron binding capacity

C. Serum ferritin

D. Hematocrit

Correct Answer: C. Serum ferritin

Explanation: Correct Option C - Serum ferritin: Serum ferritin is considered the most sensitive and specific test for the diagnosis of iron deficiency anemia. It reflects the amount of iron stored in the body and is considered an indirect measure of iron stores. A low serum ferritin level is the earliest indicator of iron deficiency anemia, and it can be used to monitor the effectiveness of iron therapy. Incorrect Options: Options A, B, and D are not specific to iron deficiency anemia.

References:

Prepladder Notes

↑ *Back to this question in Part A*

@Neet_pg_bot

Q95: A software engineer presents to the outpatient department with easy fatiguability. He gives a history of sitting in front of the computer for 12-14 hours. He consumes a lot of junk food with very few fruits and vegetables. Hb is 9 g/dl, and MCV is 80 fl. What is the most likely cause of this patient's anemia? (Q856150)

A. Cyanocobalamin deficiency

B. Iron deficiency

C. Folic acid deficiency

D. Hereditary spherocytosis

Correct Answer: B. Iron deficiency

Explanation: This patient's symptoms with a history of poor dietary habits and laboratory findings of Hb 9 g/dL with an MCV of 80 fl (microcytic anaemia) strongly suggest iron deficiency anaemia . Iron deficiency anaemia can result from dietary lack, impaired absorption, increased iron requirement (e.g., during pregnancy), or chronic blood loss (e.g., gastrointestinal bleeding). Clinical features include Koilonychia, alopecia, atrophic glossitis, esophageal webs, pica and intestinal malabsorption, affecting overall nutritional status. Cyanocobalamin deficiency (Option A) causes megaloblastic anemia , which typically presents with macrocytic anemia (elevated MCV), not the microcytic anemia seen in this patient. Folic acid deficiency (Option B) also causes megaloblastic anemia , which presents with macrocytic anemia (high MCV), not microcytic anemia . Hereditary spherocytosis (Option D) is a condition where red blood cells are abnormally shaped (spherocytes), leading to hemolysis and normocytic anemia (normal MCV).

@Neet_pg_bot

Q97: Metastatic calcification occurs in all except ? (Q793597)

A. Kidney

B. Fundus of the stomach

C. Pulmonary veins

D. Atheroma

Correct Answer: D. Atheroma

Explanation: Correct Option D - Atheroma: The type of calcification seen in atheroma is dystrophic calcification. Metastatic calcification: Metastatic calcification is caused by increased calcium phosphate in the blood and may result from hypercalcemia, hyperphosphatemia, or both. It is commonly associated with hyperparathyroidism, sarcoidosis, metastatic disease, and myeloma. Dystrophic calcification: The deposition of calcium salt in degenerated tissues in the absence of a systemic imbalance is called dystrophic calcification. It is mostly associated with trauma, inflammation, or infection. ■■■■■■■ Incorrect Options: Metastatic calcification occurs in options A, B, and C .

• [18_Hematology_ White Blood Cells] 071 Cml And Cll

« Back to Folder Directory

[18_Hematology_ White Blood Cells] 071 Cml And Cll — Quick Jump

Q1 (p. 2831) *Q2 (p. 2832)* *Q3 (p. 2833)* *Q4 (p. 2833)* *Q5 (p. 2839)* *Q6 (p. 2840)*
Q7 (p. 2842) *Q8 (p. 2843)* *Q9 (p. 2844)* *Q10 (p. 2845)* *Q11 (p. 2846)* *Q12 (p. 2847)*
Q13 (p. 2848)

Q1: A 45-year-old male complained of fatigue and weakness in daily activities associated with intermittent fever. A blood workup revealed ↑ TLC, ↑ Platelets, and↑ Differential leukocyte count. On further investigations, Chronic Myeloid Leukemia is diagnosed. Which of the following is correct regarding CML? (Q882174)

A. Philadelphia chromosome is present in a minority of cases

B. Tyrosine kinase inhibitors (TKIs) are the drug of choice

C. Most cases present in the blast phase

D. Methotrexate is the drug of choice for AML

Correct Answer: B. Tyrosine kinase inhibitors (TKIs) are the drug of choice

Explanation: Tyrosine kinase inhibitors (TKIs) are the drug of choice CML is the most common myeloproliferative neoplasm. It is caused by a reciprocal translocation between the long arms of chromosomes 9 & 22 [t(9;22)] , giving rise to shortened chromosome 22, which is referred to as the Philadelphia chromosome (Ph chromosome). CML progresses in three phases: 1) Chronic phase: Leukocytosis, < 10% blast cells, basophils <20% and monocytosis < 3% 2) Accelerated phase: 10%-19% blasts, ≥ 20% basophils in the peripheral blood or bone marrow Persistent or increasing WBC (>10 × 10^9/L) and splenomegaly, unresponsive to therapy Persistent thrombocytosis (>1000 × 10^9/L), unresponsive to therapy Persistent thrombocytopenia (<100 × 10^9/L) unrelated to therapy This phase often leads to the terminal blast crisis within 6-12 months 3) Blast Crisis: ≥20% blasts in peripheral blood or bone marrow In 50% of patients, the blast crisis occurs abruptly without an accelerated phase Extensive extramedullary hematopoiesis occurs to compensate for CML and leads to significant splenomegaly Transformation into AML is more predominant than ALL Patient present with hyperleukocytosis , massive splenomegaly Bone marrow is hypercellular with granulocytic hyperplasia. Sea-blue histiocytes can be seen. After a variable period, some patients may transform into an accelerated phase or blast crisis. Tyrosine kinase inhibitors are the drug of choice, e.g., Imatinib, Dasatinib, etc. Generation Drugs Activity 1st generation Imatinib BCR-ABL inhibitor 2nd generation Dasatinib, Nilotinib, Bosutinib More potent, used in resistance 3rd generation Ponatinib Active against T315I mutation Option A: Philadelphia chromosome is present in a minority of cases CML is caused by the reciprocal translocation between long arms of chromosomes 9 & 22 [t(9;22)] , giving rise to shortened chromosome 22, which is referred to as the Philadelphia chromosome (Ph chromosome). It is present in more than 90% of patients with CML. The presence of the Philadelphia chromosome confirms CML .

Option C: Most cases present in the blast phase Some patients with CML progress to blast crises in which the CML acts as acute leukaemia. It is the terminal phase of CML. Most patients with CML present with splenomegaly and are in the chronic phase of the disease. Option D: Methotrexate is the drug of choice for AML Methotrexate is a nucleotide synthesis inhibitor. It is used for the treatment of psoriasis, rheumatoid arthritis, breast cancer, and certain acute leukaemias.

Robbins & Cotran Pathologic Basis of Disease 10th ed pgs 622, 623

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 65-year-old woman presents with fatigue, night sweats and unintentional weight loss over the past few months. Physical examination reveals palpable lymph nodes and enlarged spleen. Lab tests show significant lymphocytosis (>20,000/μL) with small, mature-appearing lymphocytes. What is true regarding the origin and risk factors of the patient's condition? (Q842739)

A. B cells, no exposure to radiation

B. B-cells, exposure to radiation

C. Myeloid cells; BTK gene mutation

D. Myeloid cells; Philadelphia chromosome

Correct Answer: A. B cells, no exposure to radiation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the above scenario, the patient is most likely suffering from Chronic Lymphocytic Leukemia. CLL is one of the cancers not associated with radiation exposure and originates from B cells. Chronic Lymphocytic Leukemia Genetics: Trisomy 12, deletion 13q14 , and others Origin: Post–germinal center memory B cell or naive B Cells in the mantle zone of the lymph node (Option A) Etiopathogenesis Antiapoptotic protein BCL2 overexpression. CLL cell growth depends on Bruton Tyrosine kinase (BTK) activity. No association with radiation exposure (Options A and B) Myeloid cells and Philadelphia chromosomes are seen in Chronic Myeloid Leukemia (Options C and D) .

References:

Robbin's and Cotran Pathological Basis of Disease, 10th Edition, Page 597

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 65-year-old male presents with generalised fatigue and night sweats. Lab tests reveals Hemoglobin (Hb) 12 g/dL Platelet count 150,000/µL Absolute lymphocyte count (ALC) 45,000/µL Total leukocyte count (TLC) 70,000/µL Differential leukocyte count (DLC) 70% lymphocytes, 20% neutrophils, 5% monocytes, and 5% eosinophils Based on these lab findings, what is the most likely diagnosis? (Q842740)

A. ALL

B. AML

C. CML

D. CLL

Correct Answer: D. CLL

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The diagnosis is CLL due to the following laboratory findings: Absolute lymphocyte count (ALC) is significantly elevated (45,000/µL), a characteristic finding in CLL. Diagnostic ALC >5000/mm3. Total leukocyte count (TLC) is elevated (70,000/µL), consistent with leukemia. The differential leukocyte count (DLC) shows 70% lymphocytes, further supporting the CLL diagnosis. In CLL, there is a proliferation of mature-appearing lymphocytes. Definitive criterias for confirmation of CLL: Persistent lymphocytosis> 5000/µL On flow cytometry: Dual positivity for CD5 and CD23 On bone marrow examination: Lymphocyte count > 30% ALL (Option A): ALL is characterised by the presence of a high blast count in the peripheral blood. AML (Option B): AML involves the rapid proliferation of myeloid blasts in the bone marrow, often leading to high leukocyte counts. CML (Option C): CML is characterised by the presence of the Philadelphia chromosome and the overproduction of mature and immature granulocytes.

@Neet_pg_bot

Q4: Match the following peripheral smear images with the respective diagnosis: A. 1. Acute Myeloid Leukemia (AML) B. 2. Chronic Myeloid Leukemia (CML) C. 3. Acute Lymphoblastic Leukemia (ALL) D. 4. Chronic Lymphocytic Leukemia (CLL)

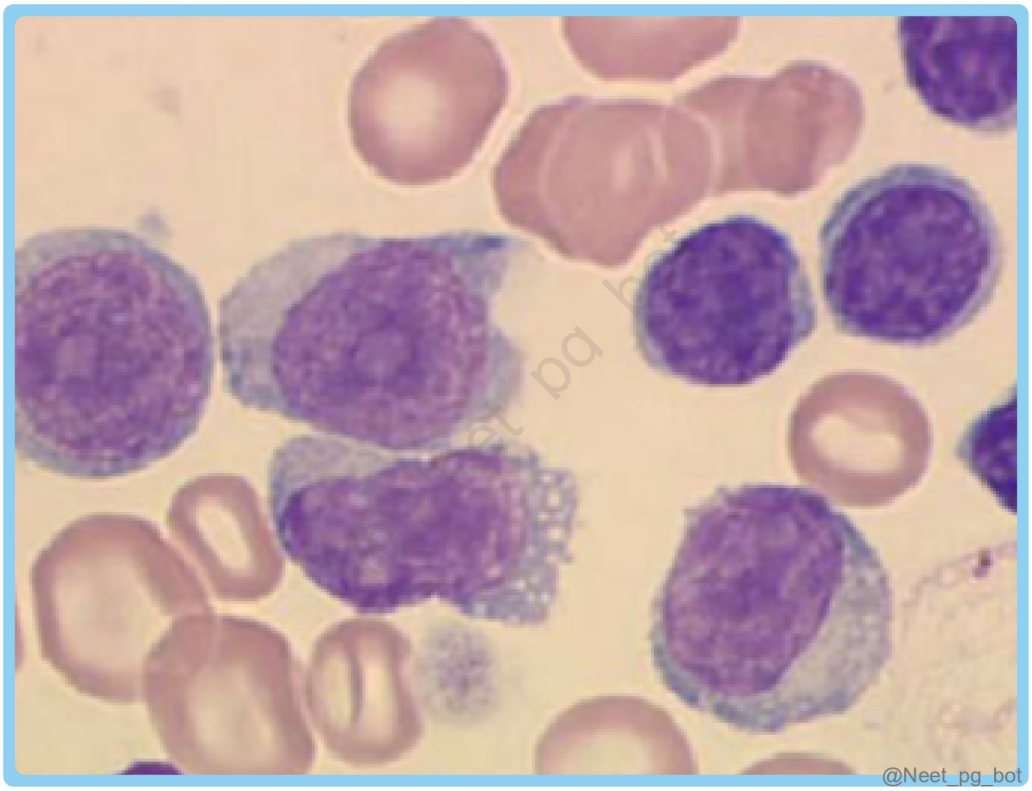
(Q842741)

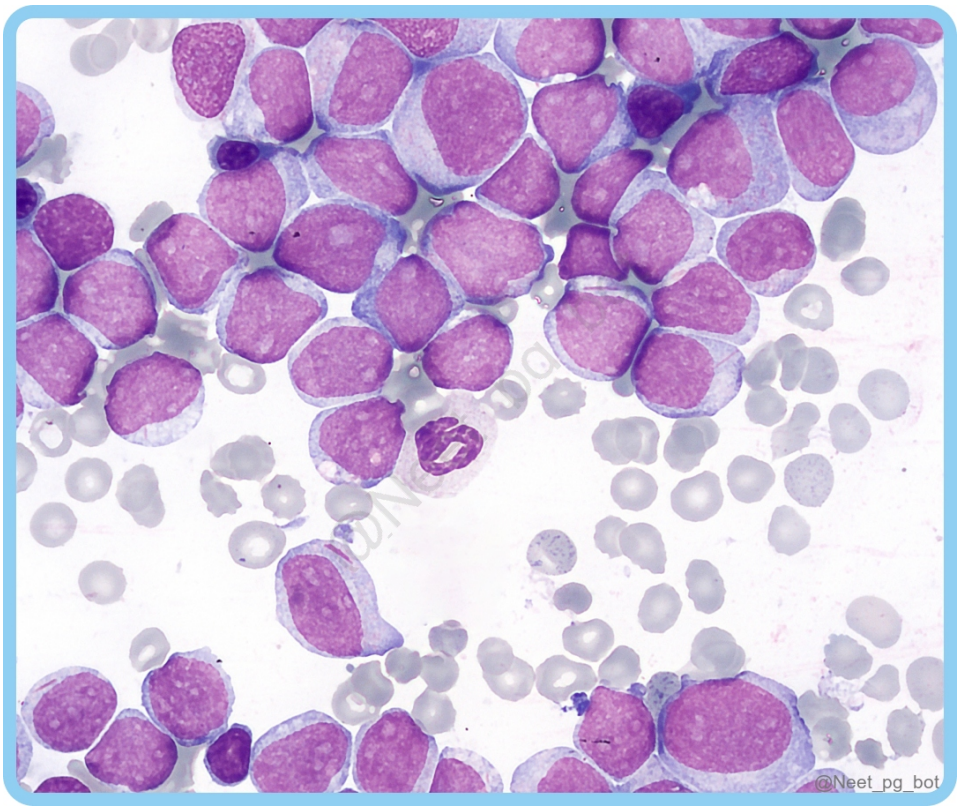
A. 1-B, 2-A, 3-D, 4-C

B. 1-B, 2-C, 3-D, 4-A

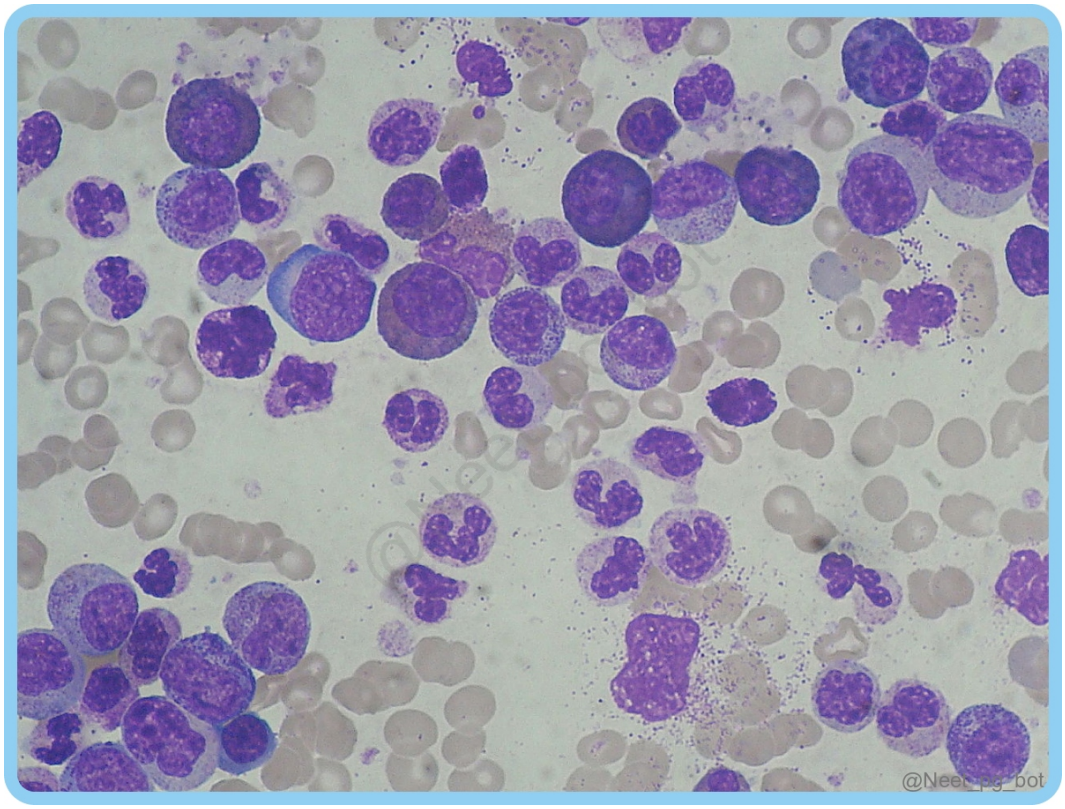
C. 1-C, 2-D, 3-B, 4-A

D. 1-D, 2-C, 3-A, 4-B

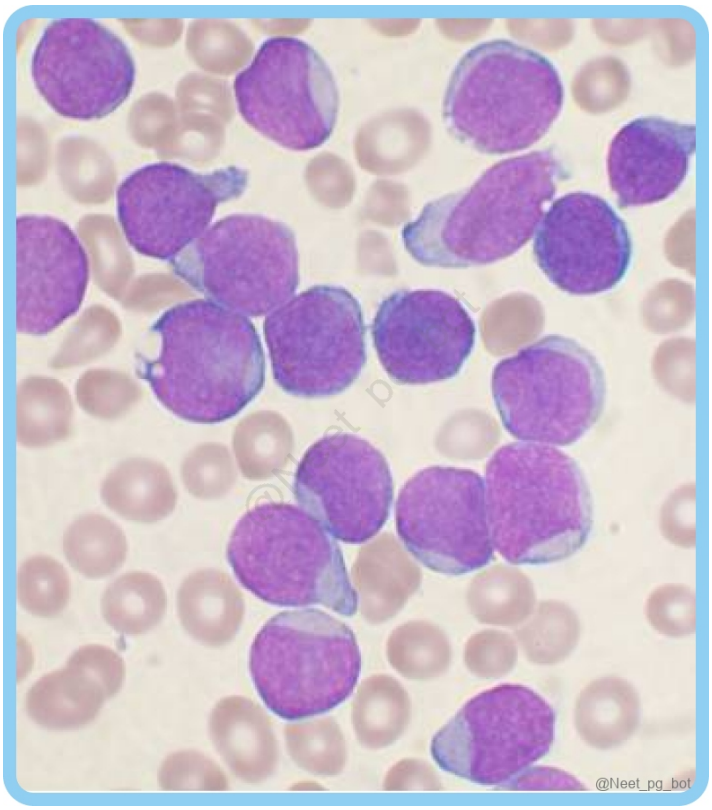




@Neet_pg_bot



@Neet_pg_bot



Correct Answer: B. 1-B, 2-C, 3-D, 4-A

- *Listen (English)*
- *Listen (Hindi)*

Explanation: 1. Acute Lymphoblastic Leukemia (ALL): Lymphoblasts in bone marrow ≥ 20% Cytoplasmic vacuolations They contain fat (Oil Red O Positive) Hand mirror -shaped cells 2. Acute Myeloid Leukemia (AML): Blasts ≥ 20% Myeloblasts with Auer Rods in cytoplasm. 3. Chronic Lymphocytic Leukemia (CLL): Smudge cells (or parachute/basket cell): Due to the fragility of lymphocytes during slide preparation Convent Girl Appearance: Lot of homogenous, small, mature-like, round lymphocytes with scant cytoplasm 4. Chronic Myeloid Leukemia (CML): Leukocytosis Cell Types: Neutrophils(multilobed nucleus), metamyelocytes (indented nucleus), myelocytes (D-shaped nucleus), and eosinophils (orange cells) College girl/garden party appearance: Due to the variety of cell appearances Shift to the Left: Presence of immature cells, mainly immature neutrophils types in the blood.

↑ *Back to this question in Part A*

@Neet_pg_bot

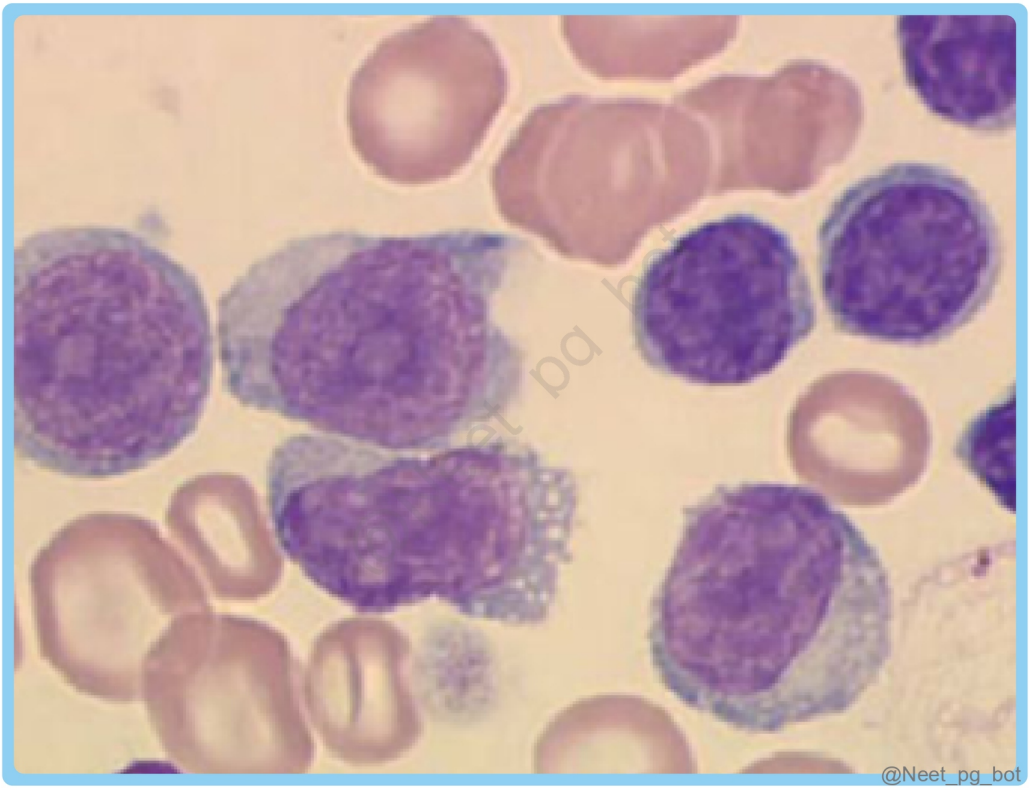
Q5: A 60-year-old man presents with fatigue, night sweats, and unintentional weight loss over the past several months. Examination reveals generalised lymphadenopathy and mild splenomegaly. Peripheral blood smear is shown below. Which of the following is not typically associated with the patient's condition? (Q842742)

A. Autoimmune hemolytic anemia (AIHA)

B. Evan’s syndrome

C. Richter’s syndrome

D. Di Guglielmo Disease



Correct Answer: D. Di Guglielmo Disease

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the clinical presentation, laboratory findings, and HPE image, the patient's diagnosis is Chronic Lymphocytic Leukemia (CLL). CLL is not associated with Di Guglielmo Disease. Di Guglielmo Disease, or acute erythroid leukemia, represents a subtype of acute myeloid leukemia (AML-M6 in FAB classification.) characterised by the proliferation of erythroid precursors in the bone marrow. ≥50% erythroid precursors in bone marrow ≥20% myeloblasts among non-erythroid cells Autoimmune hemolytic anemia (AIHA) (Option A): AIHA

is associated with CLL, sometimes occurring independently or in Evan’s syndrome, along with immune thrombocytopenia. Peripheral smear may reveal spherocytes (round, hyperchromatic RBCs). Evan’s syndrome (Option B): Evan’s syndrome is associated with CLL. In Evan's syndrome, RBCs, WBCs and Platelets are affected in bone marrow: RBCs: Autoimmune hemolytic anemia (AIHA) (Coomb’s positive) WBCs: CLL Platelets: Immune thrombocytopenic purpura (ITP) Richter’s syndrome (Option C): Richter’s syndrome is associated with CLL and occurs when CLL transforms to small lymphocytic lymphoma (SLL) in the lymph nodes. The transition from SLL to diffuse large B-cell lymphoma (DLBCL) is known as Richter's syndrome.

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC7049379/

↑ *Back to this question in Part A*

@Neet_pg_bot

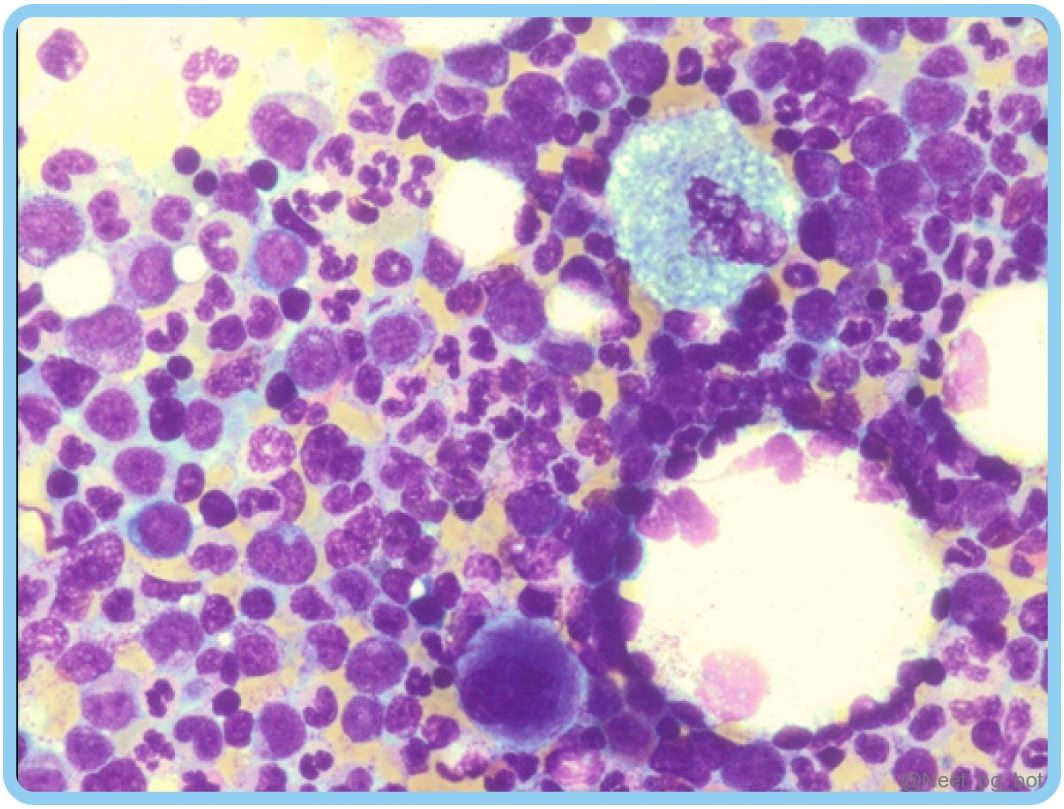
Q6: A 52-year-old male presents with complaints of fatigue, abdominal fullness, and night sweats. His complete blood count shows WBC count of 120,000/μL. A peripheral blood smear shows an increased number of granulocytes at different stages of maturation. A bone marrow aspirate is shown below. Which of the following features can be seen in this condition? (Q842743)

A. Diffusely effaced lymph node architecture with proliferation centres

B. Presence of Reed-Sternberg cells

C. Normal marrow cellularity with increased blast cells

D. Hypercellular bone marrow with decreased erythroid precursors



Correct Answer: D. Hypercellular bone marrow with decreased erythroid precursors

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The features described in the scenario are consistent with Chronic Myeloid Leukemia (CML). CML typically presents with splenomegaly, high white blood cell counts, and a characteristic peripheral blood smear showing increased granulocytes at different stages of maturation. Bone Marrow aspirate findings of CML: Presence of scattered macrophages with abundant wrinkled, green-blue cytoplasm, called sea-blue histiocytes or pseudo-Gaucher cells . The marrow is markedly hypercellular due to massively increased numbers of maturing granulocytic precursors (elevated eosinophils and basophils) Increased megakaryocytes, commonly with small, dysplastic forms called dwarf megakaryocytes. Normal or slightly decreased erythroid progenitors (increased myeloid: erythroid ratio). Increased deposition of reticulin fibers.

@Neet_pg_bot

Q7: A 62-year-old woman presents with fatigue, unintentional weight loss, and occasional night sweats over the past few months. On physical examination, cervical lymphadenopathy is noted. A complete blood count reveals leukocytosis with an absolute lymphocyte count of 10,000/mm3. Which of the following flow cytometry marker profiles is most consistent with this form of leukemia? (Q842744)

A. CD5+, CD19+, CD23+, CD10-

B. CD20+, CD79a+, CD5+, CD25-

C. CD3+, CD5+, CD19+, CD20-

D. CD10+, CD19+, CD22+, CD23-

Correct Answer: A. CD5+, CD19+, CD23+, CD10-

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Lab investigations with CBC showing leukocytosis with ALC >=5000/mm3 points towards diagnosis of Chronic Lymphocytic Leukemia (CLL). It is seen in elderly and is characterised by specific cell surface markers detected via flow cytometry: CLL shows dual positivity for CD5 and CD23. The typical CLL immunophenotype

includes CD5+, CD10-, CD19+, CD20+ (with dim expression), and CD23+. CD19 and CD20 are B-cell markers, with CD20 typically appearing dim in CLL. CD23 is also commonly found on CLL cells. CD20+, CD79a+, CD5+, CD25-: Seen in Mantle cell lymphoma, along with other CD markers such as SIgD, CD 5, cyclin D1 (Option B) . CD3+, CD5+, CD19+, CD20-: CD3 indicates a T-cell lineage, CD 19+ denotes B-cell lineage, seen in Mixed Phenotype Acute Leukemia (MPAL) (Option C) . CD10+, CD19+, CD22+, CD23-: CD10 and CD22 expression is more typical of precursor B-cell lymphoblastic leukemia/lymphoma (Option D) . Cell Type CD Markers Common lymphoid progenitor cell CD 34, HLA DR Pro-B cell CD 19, CD 34, HLA DR, PAX 5 Pre-B cell CD 10 (CALLA antigen), Tdt, CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b Immature B cell CD 19, CD 20, CD 21, CD 22, CD79a, CD 79b, SIgM Naive B cell CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, +/- CD5 Polyclonal Plasma cell CD 19, CD 38, CD 138 Chronic Lymphocytic Leukemia CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, CD 5, CD 23 Mantle Cell Lymphoma CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, SIgD, CD 5, cyclin D1 Diffuse Large B-cell Lymphoma CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, SIgD, CD 10, CD 23, BCL-6 Burkitt's Lymphoma CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, SIgD, CD 10, CD 23, BCL-6 Follicular Lymphoma CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, SIgD, CD 10, CD 23, BCL-2 Marginal Zone Lymphoma CD 19, CD 20, CD 21, CD 22, CD 79a, CD 79b, SIgM, SIgD T-cell CD 3 Anaplastic Large Cell Lymphoma CD 3, CD 30

@Neet_pg_bot

Q8: Which of the following are the good prognostic factors of CLL? (Q842745)

A. NOTCH1 mutations

B. CD38+

C. Expression of Zap 70

D. Expression of MiR-15/16

Correct Answer: D. Expression of MiR-15/16

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Most common deletion occuring in CLL is deletion of chromosome 13 which has a good prognosis. Good prognostic factors Poor prognostic factors Deletion of MicroRNA15 and 16 (acts as tumor suppressors) (Option D) Deletion of 13q14 Post GC B cell Naive B-cell NOTCH 1 mutation (commonly associated with Trisomy 12) (Option A) Deletion of 11q, 17p Richter's transformation (DLBCL transformation) Expression of ZAP 70 (Option C) Increased CD38 expression High β2-microglobulin levels Lack of somatic hypermutation High LDH levels

@Neet_pg_bot

Q9: A 45-year-old man presents with purulent nasal discharge, headache, sore throat, and nonproductive cough. He has maxillary sinus tenderness, pharyngeal erythema, and tender anterior cervical lymphadenopathy. Laboratory results are as follows: Leukocytes 58,000/mm3 Neutrophils 42% Myelocytes 30% Metamyelocytes 8% Band forms 1% Blast cells 1% Eosinophils 6% Basophils 4% The leukocyte alkaline phosphatase score is low. Which of the following is the most likely diagnosis and its appropriate management/drug for treatment? (Q842746)

A. Leukemoid reaction and Amoxicillin

B. CML and Imatinib mesylate

C. ALL and vincristine

D. AML and stem cell transplant

Correct Answer: B. CML and Imatinib mesylate

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This scenario is suggestive of chronic myelogenous leukemia (CML) as the patient has a markedly elevated white blood cell (WBC) count, increased myeloid precursor forms , basophilia, and eosinophilia in the peripheral blood smear, and a low LAP score . CML Genetics: Philadelphia chromosome (t(9;22)) Origin: Myeloid lineage Etiopathogenesis: BCR-ABL fusion gene, due to t(9;22), causes tyrosine kinase activity much above normal Radiation exposure Clinical features: Occurs in adults. Often presents with splenomegaly, fatigue, weight loss, night sweats, and abdominal discomfort. Can progress to a blast crisis with features of acute leukemia. Diagnosis: Bone marrow aspirate to confirm diagnosis FISH - presence of BCR ABL fusion gene product. Management: Tyrosine kinase inhibitors such as Imatinib mesylate (Option B) Generation Drugs Target Details 1st Generation Imatinib BCR-ABL First-line in CML 2nd Generation Dasatinib, Nilotinib, Bosutinib BCR-ABL resistant mutations More potent than imatinib 3rd Generation Ponatinib T315I mutation Used in resistant CML 4th Generation Asciminib STAMP inhibitor (ABL myristoyl pocket) Used in resistant disease Leukemoid reaction (Option A): LAP score is increased in leukemoid reaction, and basophilia is not seen. It is usually due to

underlying infections and treated with antibiotics. ALL and vincristine (Option C): Typically, acute lymphoblastic leukemia, which is more common in young children, is characterised by having over 20% bone marrow lymphoblasts and is treated with chemotherapy. AML and stem cell transplant (Option D): Most patients present with a WBC count of approximately 15,000-20,000/mm³ and a significant increase in blast cells (e.g., >20%), unlike the 1% seen in this patient and treated with stem cell transplant. Types of Philadelphia Chromosome based on breakpoint: Type Fusion Protein Associated Disease p210 BCR-ABL p210 CML (most common) p190 BCR-ABL p190 ALL (especially B-ALL) p230 BCR-ABL p230 Chronic neutrophilic leukemia (rare)

https://pubmed.ncbi.nlm.nih.gov/28273028/

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6415732/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 55-year-old man who is a known case of chronic phase CML presents with increasing fatigue, weight loss, and abdominal discomfort. His physical examination reveals splenomegaly. Lab tests show a persistent decline in platelet counts, increased circulating basophils, and a blast count of 12%. What is the most likely explanation for the patient's clinical presentation and laboratory findings? (Q842747)

A. Progression to accelerated phase CML

B. Development of acute lymphoblastic leukemia

C. Entry into the blast crisis phase of CML

D. Development of secondary myelofibrosis

Correct Answer: A. Progression to accelerated phase CML

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This patient's increasing anemia and thrombocytopenia, accompanied by a rise in the number of basophils in the blood and a blast percentage of 12%, is consistent with the accelerated phase of CML. The 3 phases of CML and their characteristics are: 1) Chronic phase: Leukocytosis, < 10% blast cells , basophils <20% and monocytosis < 3% 2) Accelerated phase: 10%-19% blasts , ≥ 20% basophils in the peripheral blood or bone marrow Persistent or increasing WBC (>10 × 10^9/L) and persistent splenomegaly , unresponsive to therapy Persistent thrombocytosis (>1000 × 10^9/L), unresponsive to therapy Persistent thrombocytopenia (<100 × 10^9/L) unrelated to therapy This phase often leads to the terminal blast crisis within 6-12 months 3) Blast Crisis: ≥20% blasts in peripheral blood or bone marrow In 50% of patients, the blast crisis occurs abruptly without an accelerated phase Extensive extramedullary hematopoiesis occurs to compensate for CML and leads to significant

splenomegaly Transformation into AML is more predominant than ALL

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 50-year-old male presents with fatigue, abdominal discomfort, and splenomegaly. Lab tests reveal a markedly elevated WBC count with a left shift and increased myeloid precursor forms on peripheral blood smear. Which of the following statements regarding the leukocyte (neutrophil) alkaline phosphatase (LAP) score in this condition is correct? (Q842748)

A. Normal LAP score

B. Increased due to excessive myeloid cell production

C. Decreased due to cytochemical abnormal WBCs

D. LAP score is relevant only in acute leukemia

Correct Answer: C. Decreased due to cytochemical abnormal WBCs

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The leukocyte (neutrophil) alkaline phosphatase (LAP/NAP) score is typically decreased in CML . This is because the WBCs in CML are abnormal, which are formed after philadelphia chromosome mutation, reducing LAP activity. Nomal LAP count: 40-100 neutrophils Alkaline phosphatase activity is found predominantly in mature segmented neutrophils. Conditions with Increased and Decreased LAP Score: Increased LAP score Decreased LAP score Leukemoid reaction Neutrophilia / Sepsis Pregnancy OCP Down’s syndrome Chronic Myeloid leukemia Paroxysmal nocturnal hemoglobinuria

References:

https://www.ncbi.nlm.nih.gov/books/NBK531464/

↑ *Back to this question in Part A*

@Neet_pg_bot

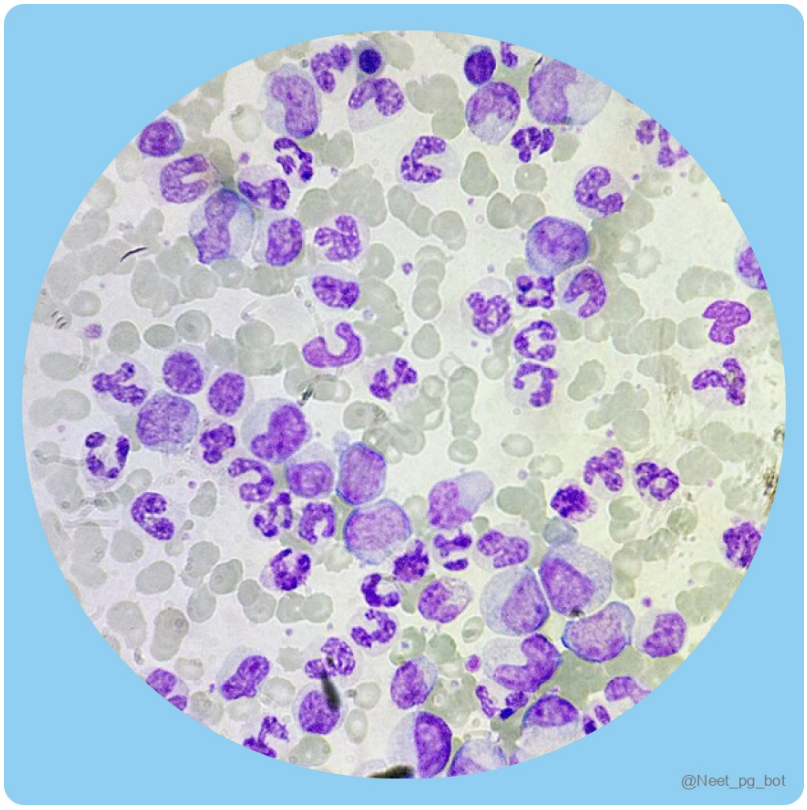
Q12: A 55-year-old patient presents with fatigue, weight loss, and abdominal discomfort. Labs reveal a markedly elevated WBC count with a left shift and increased myeloid precursor forms on peripheral blood smear as shown below. Which of the following is the investigation of choice to confirm the diagnosis? (Q842749)

A. Bone Marrow Aspiration and Biopsy

B. Flow Cytometry Analysis of Peripheral Blood

C. Fluorescent in situ hybridisation (FISH)

D. Serum Lactate Dehydrogenase (LDH) Levels



Correct Answer: C. Fluorescent in situ hybridisation (FISH)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The investigation of choice to confirm the diagnosis of Chronic Myelogenous Leukemia is Fluorescence In-Situ Hybridisation (FISH) , which makes a cytogenetic analysis of the Philadelphia chromosome. CML shows garden party/college girl appearance. The presence of the Philadelphia chromosome, resulting from the reciprocal translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)], or detection of the BCR-ABL1

fusion gene on mRNA, confirms the diagnosis of CML. Fluorescence In-Situ Hybridisation (FISH): Uses fluorescently labeled DNA probes that bind to specific chromosomal sequences to detect translocations, deletions and amplifications, done in Interphase cells (vs. metaphase in karyotyping). Types of FISH: Type of FISH Probe Design Detects Classic Example Dual fusion FISH Two probes on different chromosomes Translocations BCR-ABL in CML Break-apart FISH Probes flanking a gene Gene rearrangements ALK in lymphoma Centromeric (CEP) FISH Targets centromere Aneuploidy Trisomy detection Locus-specific FISH Targets a specific gene Deletion/amplification HER2 in breast cancer Telomeric FISH Targets chromosome ends Structural abnormalities Rarely used Multicolor FISH (M-FISH/SKY) Whole chromosome painting Complex karyotypes Complex leukemias Bone Marrow Aspiration and Biopsy (Option A) : Showing myeloid cells at different stages of maturation can support the diagnosis, it is not the investigation of choice for confirming the diagnosis. Flow Cytometry Analysis of Peripheral Blood (Option B) : can help characterise the immunophenotypic features of leukemic cells (cell surface markers) but is not the primary investigation for confirming the diagnosis of CML. Serum Lactate Dehydrogenase (LDH) Levels (Option D) : Not specific for the diagnosis. It is used more as a marker of disease activity rather than a diagnostic tool .

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5656269/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 60-year-old male presents with fatigue and abdominal discomfort. Laboratory investigations reveal a markedly elevated WBC count with a left shift and increased myeloid precursor forms on peripheral blood smear. Which of the following features would help differentiate Chronic Myelogenous Leukemia (CML) from a leukemoid reaction? (Q842750)

A. Massive splenomegaly

B. High LAP score

C. History of recent antibiotic use

D. Resolution of neutrophilia after treating the underlying cause

Correct Answer: A. Massive splenomegaly

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Extensive extramedullary hematopoiesis in CML frequently leads to significant splenomegaly, with the spleen often containing infarcts of various ages. In contrast, leukemoid reaction does not cause splenomegaly. Differences between leukemoid reaction and CML: Characteristics CML (Blood cancer) Leukemoid Reaction (Leukaemia-like reaction) Cause t (9:22) BCR/ABL fusion gene Sepsis Spleen Massive Splenomegaly No splenomegaly TLC High High but not as high as CML LAP score (Normal: 40-100) Decreased (Option B) Increased Basophils > 20% in accelerated phase (Basophilia) No basophilia Peripheral smear Garden party appearance _

@Neet_pg_bot

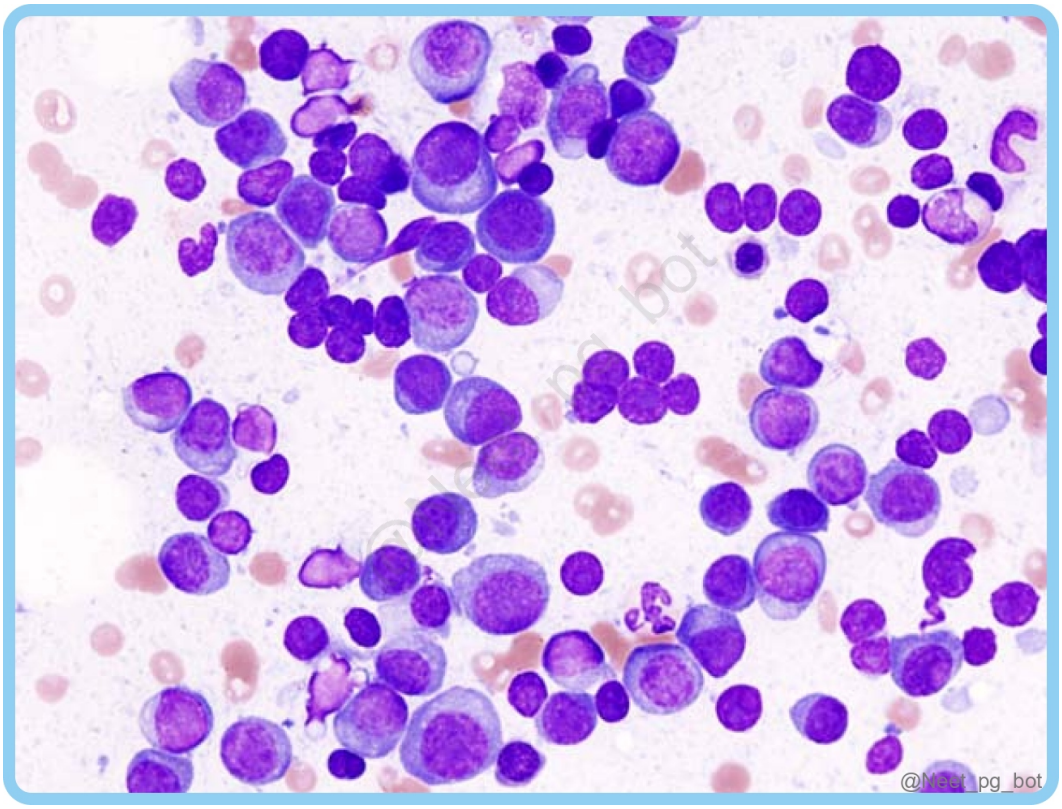
Q2: A 55-year-old woman presents with 6 months of persistent fatigue, lower back pain and recurrent infections. Laboratory tests show hypercalcemia, elevated creatinine, and normocytic anemia. Serum protein electrophoresis indicates a monoclonal spike. Bone marrow biopsy shows atypical plasma cells with eccentric nuclei and perinuclear halos, as shown in the image below. Which of the following cytogenetic abnormalities is not typically associated with this condition? (Q845747)

A. Deletion of chromosome 13q

B. Translocation t(11;14)

C. Trisomy 21

D. Deletion of chromosome 17p



Correct Answer: C. Trisomy 21

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient most likely has Multiple myeloma (MM) , a plasma cell neoplasm associated with hyper c alcemia, r enal failure, a naemia, lytic b one lesions (CRAB features) and immune abnormalities. Trisomy 21 is associated with Down's syndrome and not multiple myeloma. It is seen in patients 60-70 years of age. There are 3 main cytogenetic abnormalities seen in MM. Deletion of chromosome 13q (also seen in CLL) (Option A) Translocation t (11;14) (also seen in mantle cell lymphoma) (Option B) Deletion of chromosome 17p (TP53) (Option D) IL-6 essential for plasma cell growth , elevated IL-6 linked to poor prognosis. Risk Stratification in Multiple Myeloma: Standard Risk Intermediate Risk High Risk Trisomies (Hyperdiploidy) t(4;14) 17p deletion t(11;14) Gain 1q21 t(14;16) t(6;14) t(14;20)

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 607, 608

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 68-year-old man presents with complaints of persistent bone pain, particularly in his lower back and ribs, along with fatigue and recurrent infections over the past few months. Further workup demonstrates Bence Jones proteinuria. What temperature does it precipitate at? (Q845748)

A. 100°C

B. 60°C

C. 0°C

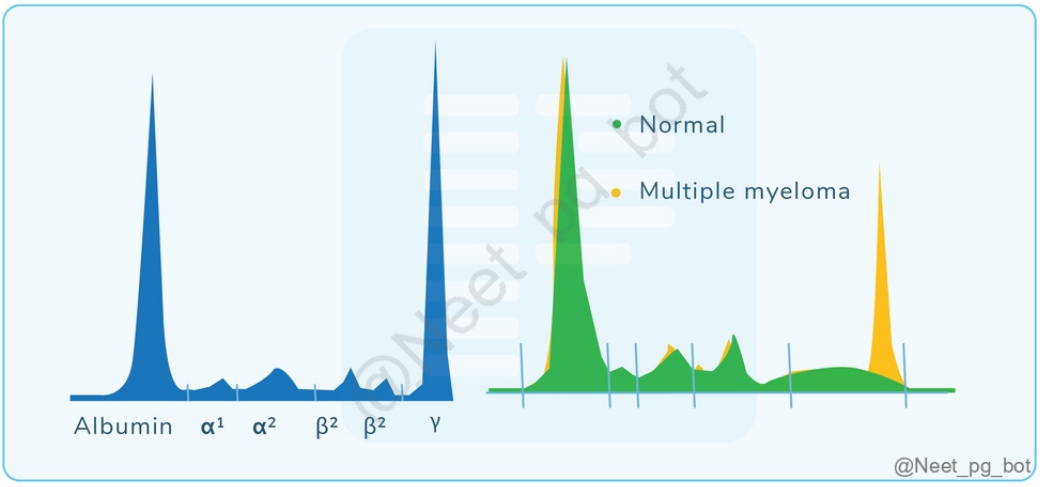
D. 30°C

Correct Answer: B. 60°C

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and Bence Jones proteinuria are consistent with Multiple myeloma Multiple myeloma cells produce excess free light chains, either alongside complete immunoglobulins or independently. Due to their small size, free light chains (Bence Jones proteins) can pass through the glomeruli of the kidneys and appear in urine. This is a diagnostic marker for multiple myeloma. Bence Jones Proteinuria: The presence of Bence Jones proteins in urine contributes to myeloma kidney, a form of renal damage. These light chains exert toxic effects on renal tubular epithelial cells, leading to renal impairment. It is a kappa or lambda light chain immunoglobulin that precipitates in the urine at 40-60°C . When boiling, it disappears and reappears when cooling. Urine and serum electrophoresis show a characteristic M spike due to increased levels of monoclonal IgG.



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 609

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: A 55-year-old woman presents with bone pain, recurrent infections, elevated serum calcium levels, renal dysfunction, and anaemia. Laboratory tests reveal an M spike on serum protein electrophoresis and the presence of Bence Jones proteins in the urine. Based on this presentation, which of the following is not a criterion for a myeloma-defining event in the diagnostic criteria for this condition? (Q845749)

A. Hypercalcemia

B. Anemia

C. Renal failure

D. Bence jones proteinuria

Correct Answer: D. Bence jones proteinuria

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario is consistent with Multiple myeloma in which Bence jones proteinuria is not a diagnostic criterion for a myeloma-defining event according to the current diagnostic criteria for the condition Diagnostic Criteria for Multiple Myeloma: ≥10% clonal bone marrow plasma cells (or) a biopsy-proven bony or extra medullary plasmacytoma + (PLUS) Evidence of one or more multiple myeloma defining events (MDE): (CRAB features) Hyper C alcemia (S.Ca2+ >11g/dl) (Option A) R enal failure (S. Creatinine >2mg/dl) (Option C) A naemia (Hb <10gm) (Option B) Lytic B one lesions are attributable to the plasma cell disorder. (OR) One or more biomarkers of malignancy (SLIM criteria) Bone marrow clonal plasmacytosis ≥60% (S ixty per cent) Serum involved/uninvolved free Li ght chain (FLC) ratio ≥ 100 (provided involved FLC is ≥100 mg/L) >1 focal lesion on M RI.

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 609

www.ncbi.nlm.nih.gov/pmc/articles/PMC9387011/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 70-year-old woman is being evaluated for monoclonal gammopathy. Bone marrow examination showed abnormal proliferation of plasma cells with evidence of certain microscopic features. Match the following structures with corresponding

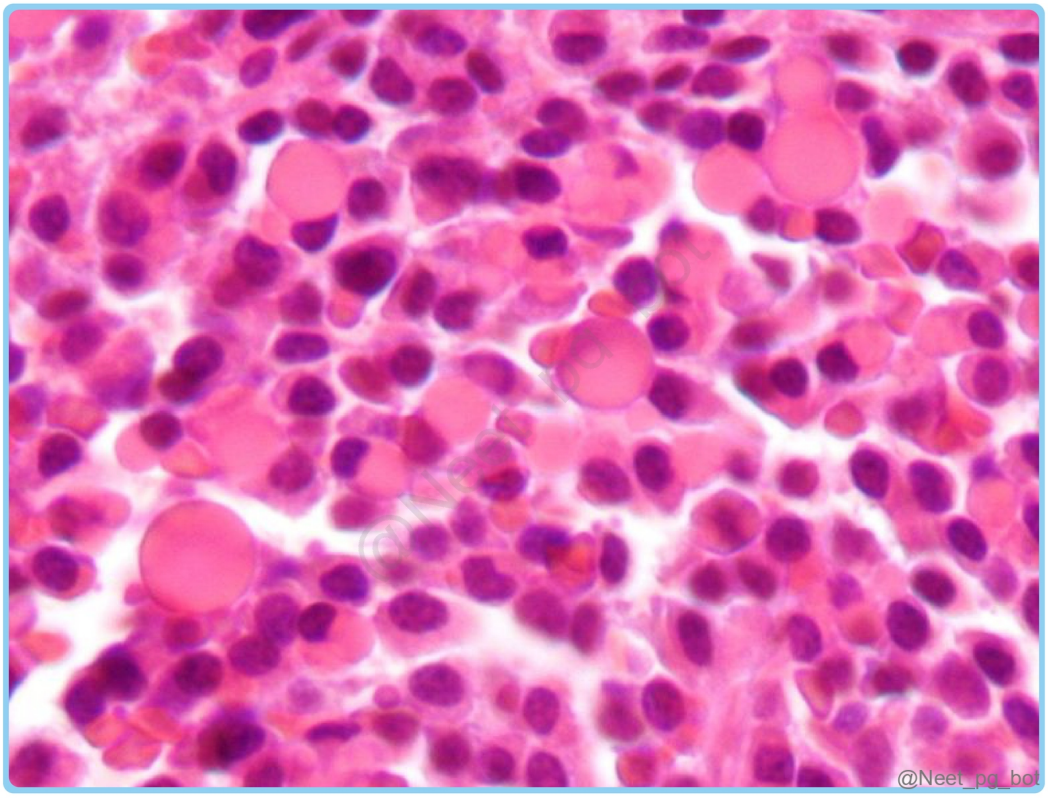
histopathological images regarding this condition. 1. Flame Cell a) 2. Mott cell b) 3. Russel bodies c) 4. Dutcher bodies d) (Q845750)

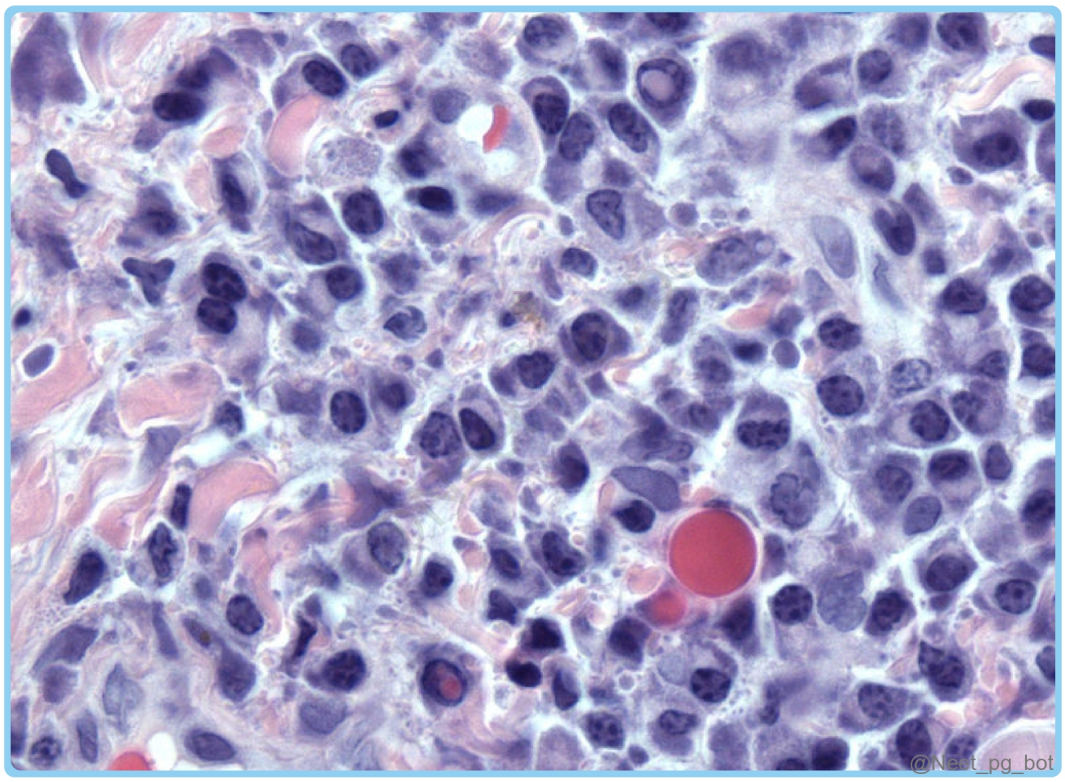
A. 1-d; 2-a; 3-c; 4-b

B. 1-d; 2-c; 3-a; 4-b

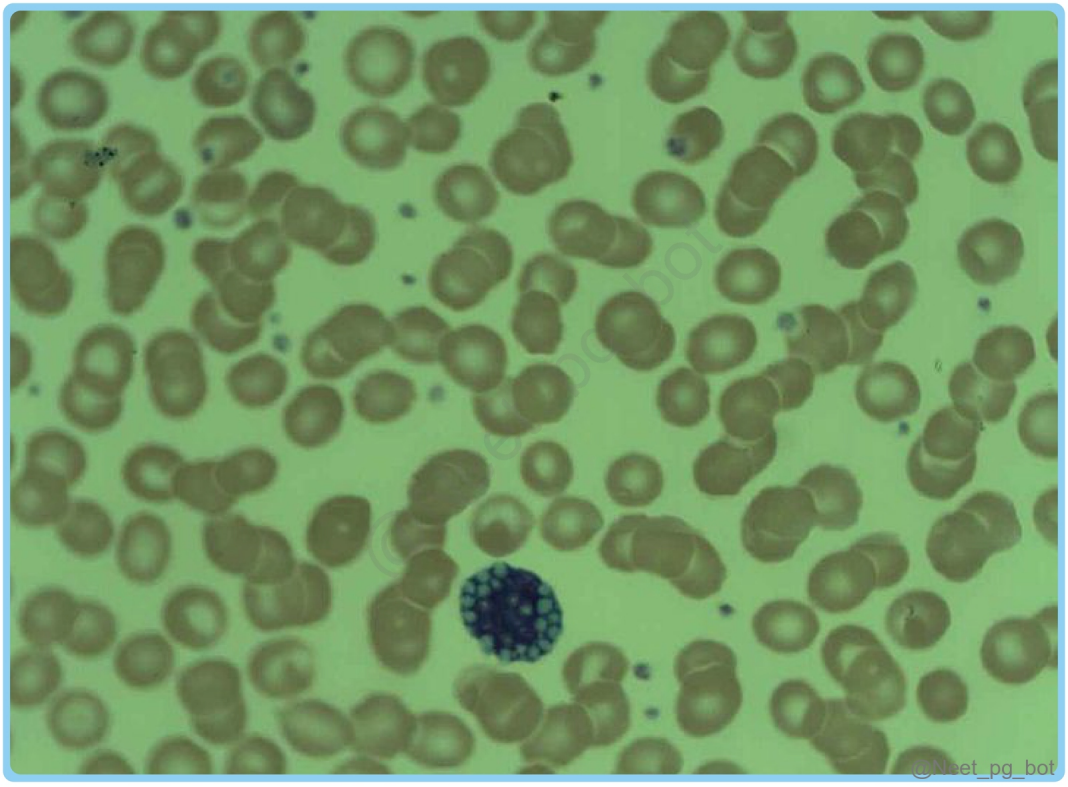
C. 1-c; 2-d; 3-a; 4-b

D. 1-c; 2-d; 3-b; 4-a

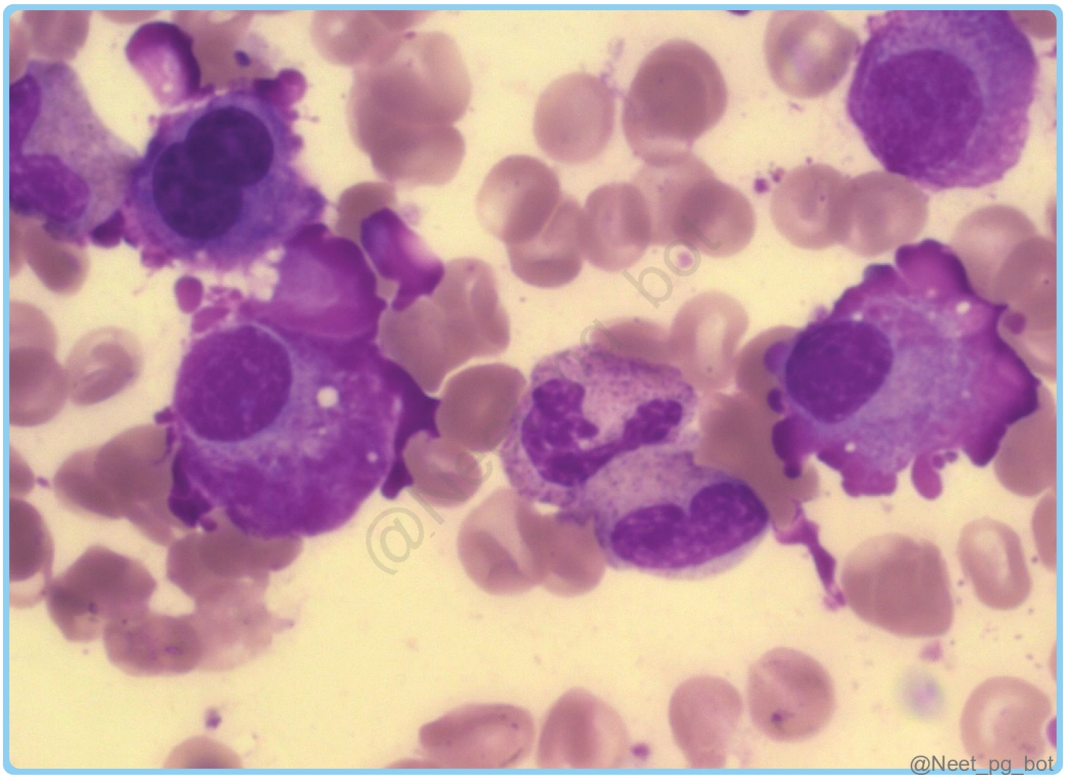




@Neet_pg_bot



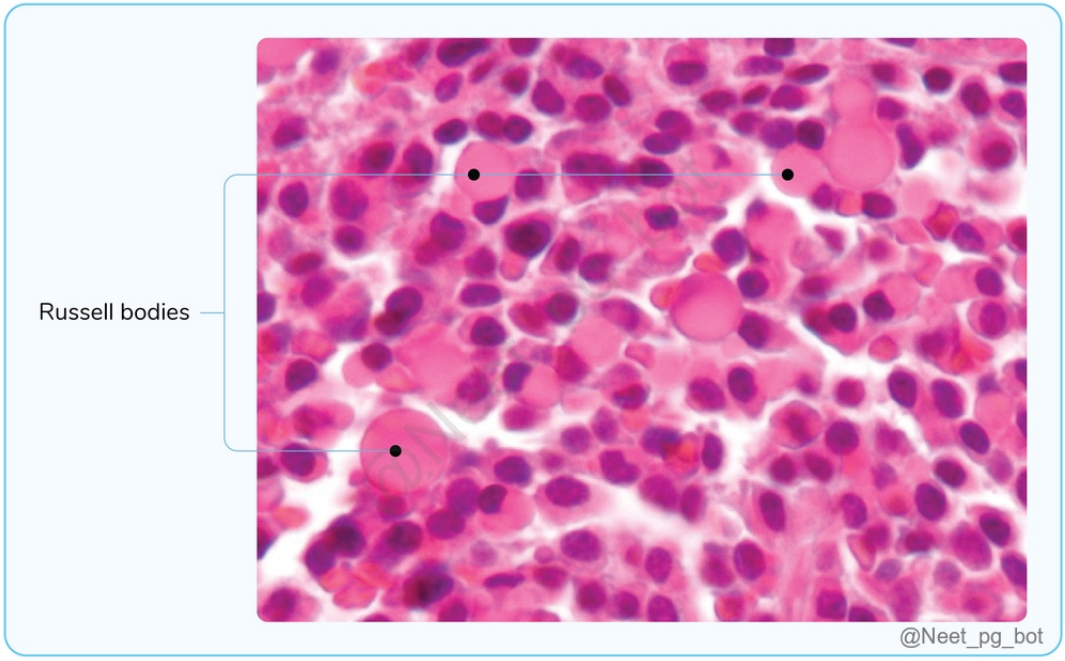
@Neet_pg_bot



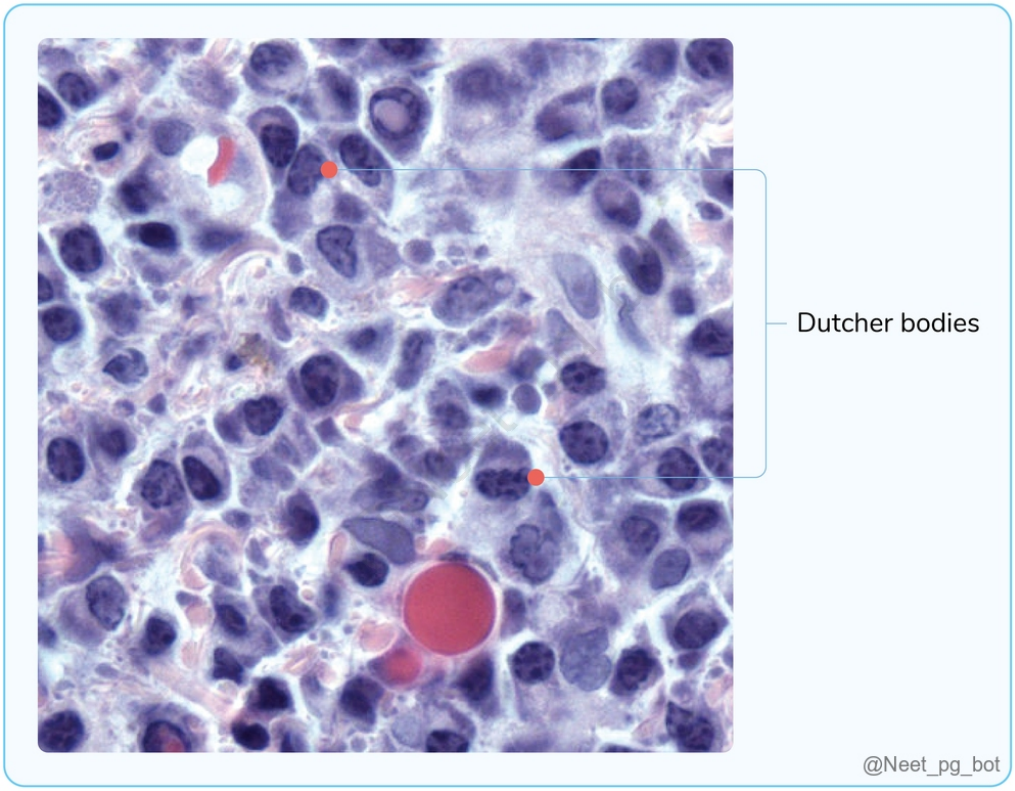
Correct Answer: B. 1-d; 2-c; 3-a; 4-b

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The patient most likely has multiple myeloma, a plasma cell neoplasm, and can present with characteristic histopathological features such as: INCLUSION BODIES SEEN IN MULTIPLE MYELOMA Russel bodies Location: Intracytoplasmic Composition: Eosinophilic Round Dilated endoplasmic reticulum cisternae filled with condensed immunoglobulin. . Dutcher bodies Location: Intranuclear. Composition: Globular inclusions containing accumulated immunoglobulin. PLASMA CELL VARIANTS IN MULTIPLE MYELOMA Mott cells Contain Grape-like cytoplasmic droplets. Composition: Inclusion bodies, fibrils, crystalline rods, and globules. Flame cells Appearance : Fiery red cytoplasm. Cause : High concentration of immunoglobulin as bright red granules within the cytoplasm. Often seen in IgA subtype myeloma.



Russell bodies
@Neet_pg_bot



Dutcher bodies
@Neet_pg_bot

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 607, 608, 609

Multiple myeloma cells with asurophillic granules

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 65-year-old male presents with fatigue, bone pain, and recurrent infections. Laboratory tests show elevated IL-6 and beta-2 microglobulin levels, while imaging reveals multiple lytic bone lesions. Bone marrow biopsy showed a high percentage of plasma cells, and cytogenetic analysis revealed a deletion of chromosome 17p. Flow cytometry is performed to distinguish abnormal plasma cells from normal ones in this patient. Which marker commonly shows increased expression on plasma cells in multiple myeloma, aiding in this differentiation? (Q845751)

A. CD19

B. CD38

C. CD56

D. CD117

Correct Answer: C. CD56

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario is consistent with Multiple myeloma with poor prognosis. CD56 is a marker commonly overexpressed on plasma cells in multiple myeloma, and it helps to differentiate malignant cells from normal plasma cells. Prognostic factors of Multiple myeloma Good prognostic factors Poor prognostic factors ↓ Beta-2 Microglobulin Level Normal Lactate Dehydrogenase (LDH) Levels Low Serum Free Light Chain Ratio Chromosomal abnormalities like t(11;14) ↑ Beta-2 Microglobulin Level ↑ IL-6 ↑ Lactate Dehydrogenase (LDH) Levels High Serum Free Light Chain Ratio Deletions of chromosome 17p Flow cytometry Markers Normal plasma cells Multiple myeloma plasma cells CD19 + - CD45 + - CD 38 + + CD138 (Syndecan-1) + + CD56 - + CD19 (Option A): It is a pan-B cell marker, absent on malignant plasma cells in multiple myeloma but may be expressed on normal plasma cells. CD 38 (Option B): A marker highly expressed on plasma cells, both normal and malignant. High levels of CD38 are a characteristic feature of multiple myeloma plasma cells. However, CD38 is also found on other cells, so it is combined with other markers like CD138 to identify malignant plasma cells specifically. CD 117 (Option D): CD117, or c-kit, is a receptor tyrosine kinase that is sometimes expressed on hematopoietic stem cells and progenitor cells. CD117 can be expressed in multiple myeloma and is associated with a poorer prognosis. However, its presence is less common than CD56 in multiple myeloma cells. When positive, it can indicate a more aggressive disease course.

Normal plasma cells vs myeloma cells

Multiple myeloma prognosis

Multiple myeloma prognosis- NCBI

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 68-year-old man presents with fatigue, bone pain, and recurrent infections. Laboratory tests reveal hypercalcemia and increased beta-2 microglobulin; imaging shows multiple lytic bone lesions. Which biochemical test is most commonly used to assess renal function and evaluate kidney damage in patients with multiple myeloma? (Q845752)

A. Serum protein electrophoresis (SPEP)

B. Serum creatinine levels

C. Serum calcium levels

D. Urine protein electrophoresis

Correct Answer: B. Serum creatinine levels

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient presents with multiple myeloma features in which renal involvement is common due to factors like hypercalcemia and the deposition of monoclonal light chains in the renal tubules (light chain cast nephropathy). Serum creatinine levels are the most commonly used biochemical test to assess renal function and detect kidney damage. Biochemical tests useful in the diagnosis of Multiple Myeloma Serum Protein Electrophoresis (SPEP): Detects and measures M-proteins in blood, aiding in multiple myeloma diagnosis and monitoring. But does not help in assessing kidney damage. (Option A) Urine Protein Electrophoresis (UPEP): Identifies Bence Jones proteins in urine, supporting multiple myeloma diagnosis. (Option D) Serum Free Light Chain Assay: Measures free kappa and lambda light chains, useful for diagnosis and treatment monitoring. Serum creatinine: Elevated levels indicate renal impairment. Serum calcium: Commonly elevated due to bone resorption. But does not assess renal function (Option C) CBC: Look for anaemia, leukopenia, or thrombocytopenia. Albumin to globulin ratio - reversed Serum Beta 2 microglobulin - Increased Peripheral blood: Rouleaux formation due to high serum protein (M-protein), red blood cells stack like coins in a roll.

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 609

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 62-year-old male with a routine health check-up is found to have a serum M protein level of 3.5 g/dL and plasma cells making up 25% of the marrow cellularity. He reports no bone pain, normal kidney function, normal calcium levels, and no lytic bone lesions on imaging. What is the most likely diagnosis? (Q845753)

A. Monoclonal Gammopathy of Undetermined Significance (MGUS)

B. Plasma Cell Leukemia

C. Multiple Myeloma

D. Smouldering Myeloma

Correct Answer: D. Smouldering Myeloma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical findings suggest Smouldering Myeloma . It is a precursor condition to multiple myeloma, lying between Monoclonal Gammopathy of Undetermined Significance (MGUS) and symptomatic multiple myeloma. It is characterised by the presence of monoclonal protein in the absence of end-organ damage , with bone marrow plasma cell infiltration of ≥10% and <30% without myeloma-defining events. Plasma cell leukemia (Option B) is a rare and aggressive form of multiple myeloma associated with myc gene mutations. Criteria MGUS (most common plasma cell abnormality) (Option A) Plasma Cell Leukemia (Option B) Multiple Myeloma (Option C) Smouldering Myeloma (Option D) Serum M Protein Level Typically < 3 g/dL Variable Variable, often > 3 g/dL > 3 g/dL Plasma Cells in Bone Marrow < 10% Variable Variable, often > 10% 10% to 30% Symptoms Absent Present Present (bone pain, anemia, hypercalcemia) Absent Organ Damage Absent Present Present (renal impairment, bone lesions) Absent

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 610

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 70-year-old male presents with blurred vision, dizziness, and epistaxis. Physical examination reveals engorged retinal veins and signs of haemorrhage. Laboratory tests show an elevated serum viscosity. Serum protein electrophoresis reveals a monoclonal IgM spike. What is the most likely cause of the patient's symptoms? (Q845754)

A. Multiple Myeloma

B. Chronic Lymphocytic Leukemia

C. IgA Myeloma

D. Waldenstrom’s Macroglobulinemia

Correct Answer: D. Waldenstrom’s Macroglobulinemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation suggests Waldenstrom’s macroglobulinemia, a lymphoproliferative disorder characterised by the presence of monoclonal IgM antibodies . Waldenström Macroglobulinemia (WM) is due to increased association with Lymphoplasmacytic Lymphoma (LPL) associated with: MYD88 Mutation: Present in >90% of Waldenström patients (a high-yield molecular marker). CD40-CD40L Interaction: The interaction between CD40 on B-cells and CD40L (CD154) on T-cells drives B-cell proliferation and class-switching.

Aberrant signaling here contributes to the lymphoplasmacytic expansion. Patients may present with symptoms of hyperviscosity syndrome , such as blurred vision, dizziness, and bleeding tendencies. It is d iagnosed by the monoclonal IgM gammopathy seen on serum protein electrophoresis (SPEP) or immunofixation electrophoresis (IFE). Multiple Myeloma (Option A): Multiple myeloma is characterised by the presence of monoclonal IgG or IgA antibodies, not IgM . Chronic Lymphocytic Leukemia (Option B): CLL is a B-cell malignancy characterised by the accumulation of monoclonal B lymphocytes and not IgM antibodies. IgA Myeloma (Option C): A subtype of multiple myeloma that primarily produces monoclonal IgA. While it can cause hyperviscosity syndrome, it is not characterised by an IgM spike.

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 607

www.ncbi.nlm.nih.gov/pmc/articles/PMC3659998/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 55-year-old male presents with recurrent infections and fatigue. Palatal edema is noted. Laboratory tests show hypogammaglobulinemia and serum protein electrophoresis reveals an absence of normal immunoglobulins but a monoclonal spike in the gamma region. Bone marrow biopsy reveals large lymphoid cells with intracytoplasmic inclusions. Which type of heavy chain disease is most likely causing the patient's symptoms? (Q845755)

A. Alpha Heavy Chain Disease

B. Gamma Heavy Chain Disease

C. Mu Heavy Chain Disease

D. Delta Heavy Chain Disease

Correct Answer: B. Gamma Heavy Chain Disease

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical scenario is consistent with Gamma heavy chain disease (Franklin’s Disease). Heavy-chain diseases are rare monoclonal gammopathies characterized by the production and secretion of free heavy-chain fragments. These diseases can be associated with various disorders, including: Lymphoplasmacytic Lymphoma Small Bowel Marginal Zone Lymphoma Gamma heavy chain disease (Franklin's disease): (Option B) Present with systemic symptoms & sometimes palatal and uvular swelling. Involves the production of abnormal monoclonal gamma heavy chains without associated light chains , resulting in hypogammaglobulinemia and recurrent infections. Serum protein electrophoresis (SPEP) reveals a monoclonal spike in the gamma region. Alpha

heavy chain disease (Seligmann's Disease) (Option A): The most common type. Often presents as a gastrointestinal immunoproliferative small intestinal disease (IPSID). Mu heavy chain disease (Option C): A very rare subtype that resembles chronic lymphocytic leukaemia/small lymphocytic leukaemia Delta heavy chain disease (Option D): Extremely rare subtype.

Robbins and Cotran Pathological Basis of Disease, 10th Edition, Page 607

www.uptodate.com/contents/the-heavy-chain-diseases

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following represents the normal serum free κ:λ light chain ratio? (Q889647)

A. 0.01 - 0.10

B. 0.26 - 1.65

C. 1.65 - 3.50

D. 3.50 - 5.00

Correct Answer: B. 0.26 - 1.65

Explanation: 0.26 - 1.65 is the normal reference range for the serum free κ:λ light chain ratio . This range reflects balanced polyclonal production of κ and λ light chains by plasma cells. A high ratio suggests excess κ light chain production (e.g., κ-restricted monoclonal gammopathy). A low ratio suggests excess λ light chain production. Marked deviations from the normal range raise suspicion for monoclonal plasma cell disorders , such as multiple myeloma, MGUS, or light chain amyloidosis.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 67-year-old man presents with back pain and anaemia. Skull radiograph shows multiple punched-out lytic lesions. He is diagnosed with multiple myeloma. Which of the following is the most common location of lytic bone lesions in multiple

myeloma? (Q889652)

A. Vertebral column

B. Femur

C. Skull

D. Pelvis

Correct Answer: A. Vertebral column

Explanation: Multiple myeloma characteristically involves the axial skeleton , with the vertebral column being the most commonly affected site . Vertebral involvement frequently leads to back pain and compression fractures , which are common presenting features. Bone destruction in myeloma occurs due to: Increased osteoclast activity (via RANKL and cytokine stimulation) Suppressed osteoblast function (mediated by inhibitors such as DKK1) This imbalance produces the classic “punched-out” lytic lesions seen on radiographs. Commonly affected bones include the vertebrae, ribs, skull, pelvis, and proximal long bones .

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 553

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A 66-year-old man with multiple myeloma presents with bone pain and hypercalcemia. Imaging shows multiple punched-out lytic lesions. The increased bone resorption in this condition is primarily mediated by which of the following factors produced by neoplastic plasma cells? (Q889654)

A. Interleukin-2

B. MIP-1α

C. Erythropoietin

D. Transforming growth factor-β

Correct Answer: B. MIP-1α

Explanation: In multiple myeloma, bone destruction results from an imbalance between osteoclast activation and osteoblast suppression. Neoplastic plasma cells produce MIP-1α (macrophage inflammatory protein-1 alpha, also known as CCL3) , which is a key mediator of osteoclast differentiation and activation . MIP-1α stimulates osteoclast precursors and enhances osteoclast formation, leading to increased bone resorption and the

characteristic punched-out lytic lesions . The resulting bone breakdown also contributes to hypercalcemia . Although additional factors such as RANKL (from stromal cells) and DKK1 (which inhibits osteoblast differentiation) participate in myeloma bone disease, MIP-1α is a principal osteoclast-activating factor produced directly by myeloma cells. Interleukin-2 (Option A): Primarily promotes T-cell proliferation and is not involved in osteoclast activation in multiple myeloma. Erythropoietin (Option C): Stimulates erythroid progenitor cells in the bone marrow and does not mediate bone resorption. Transforming growth factor-β (Option D): Involved in tissue remodelling and fibrosis, but is not the primary mediator of osteoclast-driven bone destruction in multiple myeloma.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 553

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Excessive production of which of the following proteins is most commonly associated with hyperviscosity in multiple myeloma? (Q889661)

A. IgG3

B. IgG

C. IgM

D. IgG2

Correct Answer: A. IgG3

Explanation: IgG3 is the immunoglobulin subtype among the given options most strongly associated with hyperviscosity in multiple myeloma. Hyperviscosity syndrome results from markedly elevated levels of monoclonal immunoglobulin (M protein), which increases plasma viscosity and impairs microcirculation. In multiple myeloma, hyperviscosity is most commonly associated with IgA myeloma because IgA forms dimers and polymers that significantly increase serum viscosity. However, since IgA is not listed in the options, IgG3 is the best answer among those provided. IgG3 has a long hinge region and a greater tendency for self-aggregation , increasing its effective molecular size and its contribution to plasma viscosity compared to other IgG subclasses. Clinical features of hyperviscosity include: Headache Blurred vision Mucosal bleeding Retinal venous engorgement Neurological symptoms IgG (Option B): Although IgG is the most common immunoglobulin subtype in multiple myeloma overall, it is less strongly associated with hyperviscosity compared to IgG3. IgM (Option C): IgM is the classic cause of hyperviscosity in Waldenström macroglobulinemia , not multiple myeloma. IgG2 (Option D): Does not demonstrate the aggregation tendency seen with IgG3 and is less associated with hyperviscosity.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 554

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which type of multiple myeloma is most commonly associated with a higher risk of renal insufficiency? (Q889663)

A. IgG myeloma

B. IgA myeloma

C. IgD myeloma

D. IgE myeloma

Correct Answer: C. IgD myeloma

Explanation: IgD myeloma is most commonly associated with a higher risk of renal insufficiency. IgD myeloma characteristically produces large amounts of free light chains (Bence Jones proteins) . These light chains are filtered by the kidneys and precipitate within renal tubules, leading to light chain cast nephropathy (myeloma kidney) . Tubular obstruction and inflammation result in progressive renal dysfunction. IgD myeloma is rare but often presents with high tumour burden and advanced renal impairment at diagnosis. Renal injury in multiple myeloma is primarily mediated by excessive free light chain production. IgG myeloma (Option A): Most common subtype of multiple myeloma; renal failure may occur, but is not disproportionately associated compared to IgD myeloma. IgA myeloma (Option B): Second most common subtype; can cause renal involvement but is less frequently associated with severe renal insufficiency compared to IgD myeloma. IgE myeloma (Option D): Extremely rare subtype and not classically associated with a higher incidence of renal failure.

« Back to Folder Directory

[18_Hematology_ White Blood Cells] 073 Wbc Basics And Instruments — Quick Jump

Q1 (p. 2870) *Q2 (p. 2873)* *Q3 (p. 2874)* *Q4 (p. 2877)* *Q5 (p. 2878)* *Q6 (p. 2883)*
Q7 (p. 2884) *Q8 (p. 2887)* *Q9 (p. 2891)*

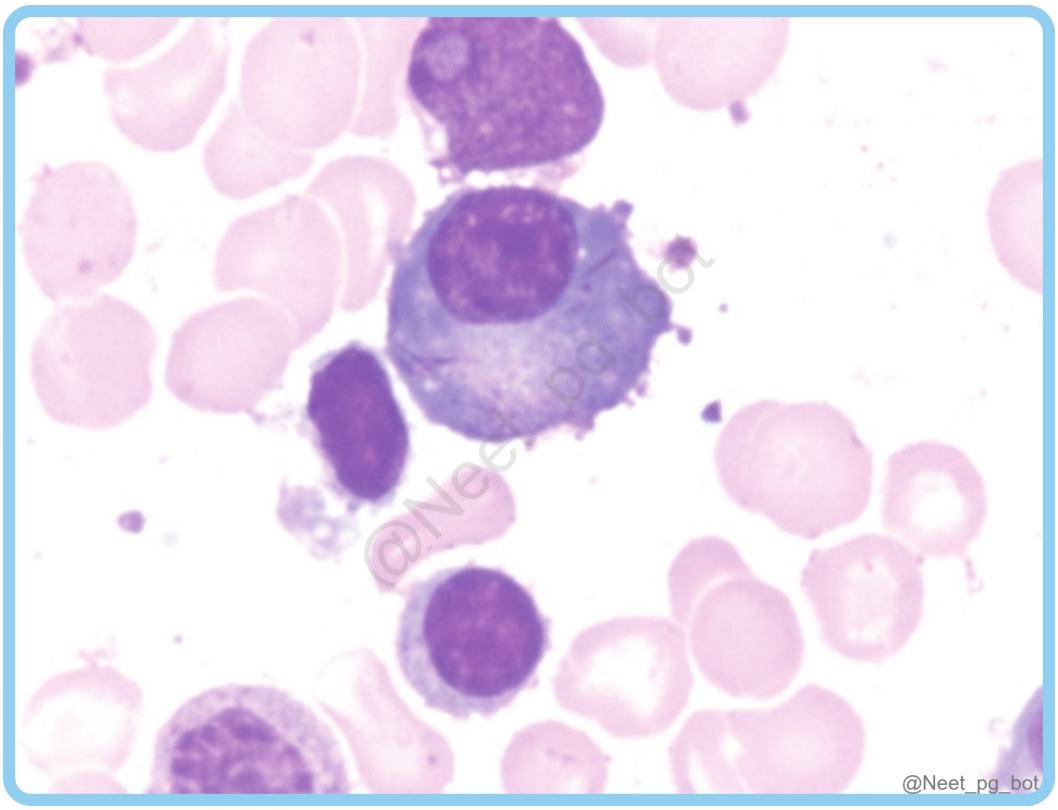
Q1: A 50-year-old man presents with complaints of fatigue, easy bruising, and recurrent nosebleeds over the past month. Laboratory investigations reveal leukopenia and thrombocytopenia. Peripheral blood smear examination demonstrates the presence of cells with Auer rods. In which stage of myelopoiesis are Auer rods typically found? (Q845756)

A. Myeloblast

B. Myelocyte

C. Metamyelocyte

D. Monoblast



Correct Answer: A. Myeloblast

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The patient most likely has Acute Myeloid Leukemia (AML) , characterised by Myeloblasts with Auer rods, which are needle-like granules in the cytoplasm. Because they are formed from the fusion of primary granules (azurophilic granules), they can also be found in promyelocytes . Myelopoiesis is the process of WBC formation, which starts with the Pluripotent Stem Cells, which are CD34+.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 45-year-old man presents with complaints of persistent fever, chills, and generalized weakness for the past week. Lab reports revealed leukocytosis with a left shift, and peripheral blood smear examination shows cells with kidney-shaped nuclei and parasites in ring forms inside RBCs. What is the cell called? (Q845757)

A. Monocyte

B. Neutrophil

C. Basophil

D. Eosinophil

Correct Answer: A. Monocyte

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The patient most likely has malaria which presents initially with fever, chills and weakness. On smear examination, there is monocytosis (cells with kidney-shaped nuclei) and parasites in ring forms within RBCs. Different types of WBC a) Granulocytes Neutrophils: 3-5 lobes and are involved in the acute inflammatory response to bacterial infection and the removal of the bacteria by phagocytosis. (Option B) Eosinophils : They have orange-red granules and a bilobed nucleus and are involved in chronic inflammation, allergic reactions, and host defence against parasitic infections. (Option D) Basophils: They have blue-black granules and their primary function is inflammation and allergic reaction. They act similar to Mast cells. (Option C) b) Agranulocytes Lymphocytes: They are part of the adaptive immune system. They are circulating immunocompetent cells that develop the ability to recognise and react to antigens. Monocytes: They have a kidney-shaped nucleus. In tissues, they differentiate into phagocytes , such as macrophages, osteoclasts and Kupffer cells and phagocytose bacteria, cells, and debris and function as antigen-presenting cells.

@Neet_pg_bot

Q3: A 6-year-old child is brought up due to concerns about persistent fever, fatigue, and frequent infections over the past few weeks. There is generalised lymphadenopathy. Laboratory investigations reveal leukocytosis with lymphoblasts on peripheral smear examination. Which of the following stains are used to visualise lymphoblasts? (Q845758)

A. Periodic Acid Schiff (PAS) stain

B. Myeloperoxidase stain

C. Sudan Black stain

D. Wright stain

Correct Answer: A. Periodic Acid Schiff (PAS) stain

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The child most likely has Acute lymphoblastic leukemia (ALL) which is a neoplasm composed of immature B or T cells, referred to as Lymphoblasts which is visualised by Periodic Acid Schiff (PAS) stain. ALL lymphoblasts show a block or coarse granular positivity. Symptoms related to depression of marrow function and neoplastic infiltration include fatigue (anaemia), fever(infections due to neutropenia), bleeding

(thrombocytopenia), generalised lymphadenopathy, splenomegaly, and hepatomegaly, most of which are seen in this patient. Features Lymphoblast Myeloblast Monoblasts Cell Features No Auer rods Auer rods present Lobulated nuclei differentiate it from myeloblasts. Stains Periodic Acid Schiff (PAS) stain Acid phosphatase for T-lymphoblasts Myeloperoxidase stain (Option B) Sudan Black stain (Option C) HPE Nucleus with clumped, dark purple chromatin Nucleus with opened up, homogeneous, lighter chromatin Wright's stain (Option D): Wright’s stain is a mixture of eosin (red) and methylene blue dyes and is used in blood smears and bone marrow aspirates to detect RBCs, WBCs and platelet abnormalities.

@Neet_pg_bot

Q4: A 55-year-old male presents with persistent fatigue, significant weight loss, and night sweats over the past few months. Examination revealed massive splenomegaly. CBC shows elevated white blood cell count. A bone marrow biopsy confirms the diagnosis of CML. Which of the following types of leukocytosis is most commonly associated with this condition? (Q845760)

A. Neutrophilia

B. Eosinophilia

C. Lymphocytosis

D. Basophilia

Correct Answer: D. Basophilia

Explanation: Chronic Myeloid Leukemia (CML) is a myeloproliferative neoplasm characterised by the unregulated proliferation of myeloid cells. It is defined by the presence of the Philadelphia chromosome, a balanced translocation t(9;22)(q34;q11), which creates the BCR-ABL1 fusion gene. While a generalised increase in myeloid cells (neutrophilia) is always present, the presence of basophilia is a distinct, high-yield, and classic peripheral blood finding in CML. Clinical and Laboratory Pointers: Splenomegaly: Massive splenic enlargement is common due to extramedullary hematopoiesis and sequestration of cells. Peripheral Blood: Shows a wide spectrum of myeloid precursors (the "leukemic hiatus" is absent) and frequently includes an absolute increase in basophils and eosinophils. Basophilia: A characteristic feature that helps distinguish CML from other causes of reactive neutrophilia. Disease Course: Typically progresses from a chronic phase to an accelerated phase and eventually to a terminal blast crisis, resembling acute leukemia. Neutrophilia (Option A): While CML does present with neutrophilia, it is a non-specific finding seen in various reactive states, infections, and other malignancies. Eosinophilia (Option B): While eosinophilia can occur in CML, it is less consistent and less diagnostic than basophilia. Lymphocytosis (Option C): Lymphocytosis is characteristic of lymphoid malignancies like Chronic Lymphocytic Leukemia (CLL).

@Neet_pg_bot

Q6: A 17-year-old boy presented with complaints of a sore throat, fever, and extreme fatigue for the past two weeks. On examination, he has enlarged cervical lymph nodes and an enlarged spleen. A complete blood count reveals lymphocytosis with atypical lymphocytes and is diagnosed as infectious mononucleosis. Which of the following statements is NOT correct? (Q845762)

A. Caused by Epstein-Barr Virus (EBV)

B. The Monospot test is a common diagnostic tool

C. Downey cells are characteristic histopathological features.

D. Also known as Haemophagocytic Lymphohistiocytosis.

Correct Answer: D. Also known as Haemophagocytic Lymphohistiocytosis.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Hemophagocytic lymphohistiocytosis (HLH) is a reactive condition marked by cytopenias and systemic inflammation due to macrophage activation. It is a Cytokine Storm syndrome. EBV-induced HLH occurs when the immune system (T-cells/NK cells) becomes hyper-activated but ineffective, causing macrophages to phagocytose blood elements (RBCs, WBCs, platelets). Epstein-Barr virus infection is a common trigger. Clinical features include acute febrile illness, splenomegaly, hepatomegaly, anaemia, thrombocytopenia, elevated ferritin and IL-2 receptor levels, and liver dysfunction. Types: Primary (Familial): Usually caused by genetic defects in cytotoxic T-cell/NK cell function (e.g., PRF1, UNC13D genes). Secondary (Acquired): Triggered by infections (most commonly EBV), malignancies, or rheumatological conditions. Diagnostic Criteria (HLH-2004): Requires 5 out of 8: Fever. Splenomegaly. Cytopenias (affecting ≥ 2 cell lines). Hypertriglyceridemia and/or hypofibrinogenemia. Hemophagocytosis in bone marrow, spleen, or lymph nodes. Low/absent NK-cell activity. Ferritin >500 µg/L. Soluble CD25 (sIL-2 receptor) >2400 U/mL. Infectious mononucleosis, primarily caused by Epstein-Barr Virus (Option A), presents with fever, sore throat, lymphadenopathy, and splenomegaly, predominantly affecting late adolescents and young adults. Diagnosis relies on lymphocytosis with atypical lymphocytes, known as Downey cells (Ballerina skirt appearance) (Option C), which are activated CD8 T lymphocytes responding to EBV-infected cells. Positive heterophile antibody reaction (Monospot test) (Option B) and rising specific antibodies for EBV antigens aid in diagnosis.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 358

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 58-year-old patient presents with fatigue, night sweats, and significant weight loss. Physical examination reveals generalized lymphadenopathy and splenomegaly. Blood tests show a markedly elevated white blood cell count. Based on the clinical scenario, which diagnosis is most likely if the bone marrow biopsy reveals over 20% blasts? (Q845763)

A. Chronic Lymphocytic Leukemia (CLL)

B. Acute Myeloid Leukemia (AML)

C. Hodgkin’s Lymphoma (HL)

D. Non-Hodgkin’s Lymphoma (NHL)

Correct Answer: B. Acute Myeloid Leukemia (AML)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the clinical scenario and the bone marrow findings, the most likely diagnosis is Acute Myeloid Leukemia (AML). Blasts in the bone marrow are a pivotal factor in diagnosing different types of leukaemia. When the bone marrow contains over 20% blasts, it indicates acute leukaemia rather than a chronic condition. Acute Myeloid Leukemia (AML) is characterised by the rapid proliferation of abnormal myeloid blasts (Myeloblasts are identified by the presence of Auer rods), crowding out normal cells and leading to the symptoms observed. Chronic Lymphocytic Leukemia (CLL) (Option A): CLL typically presents with mature lymphocytes , not blasts, in the bone marrow, distinguishing it from AML. Histopathology reveals smudge cells. The elevated blast count seen in the bone marrow biopsy is not characteristic of CLL. Hodgkin's Lymphoma (Option C): HL is diagnosed via lymph node biopsy revealing Reed-Sternberg cells , not through a bone marrow biopsy showing high blast counts. The hallmark of HL is the presence of specific large abnormal lymphocytes, not blasts.HL primarily involves lymph nodes, with systemic symptoms such as night sweats and weight loss. Non-Hodgkin's Lymphoma (NHL) (Option D): The diagnosis of NHL involves malignant lymphoid cells in affected tissues, not an increased blast percentage in the bone marrow.

Q8: A 45-year-old female is undergoing routine blood work. The laboratory technician uses different Vacutainers for various tests. Which Vacutainer colour is used for coagulation studies, such as PT and aPTT? (Q845764)

Correct Answer: Unknown

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The light blue Vacutainer contains sodium citrate as an anticoagulant and is specifically used for coagulation studies, such as Prothrombin Time (PT) and Activated Partial Thromboplastin Time (aPTT) . The anticoagulant preserves the coagulation factors for accurate testing. Colour Anti-coagulants Uses Purple/Lavender (Option D) EDTA (Ca2+ chelating anticoagulant) CBC, Peripheral Smear, ESR Light Blue (Option B) Citrate (Ca2+ chelating anticoagulant) ESR, PT, aPTT Red (Option A) No anti-coagulant is added Serum studies (Proteins, enzymes, hormones) Yellow Clot activator/Gel separator Serum studies (Proteins, enzymes, hormones)

Grey Sodium Fluoride Blood Glucose Green (Option C) Heparin ABG, Osmotic fragility, flow cytometry, immunophenotyping

@Neet_pg_bot

Q9: Which of the following diluting fluids correctly matches its specific use in haematology? (Q845767)

A. Turk's Solution - Platelets

B. Hayem's Solution - WBCs

C. Gower's Solution - RBCs

D. 1% Ammonium Oxalate - WBCs

Correct Answer: C. Gower's Solution - RBCs

Explanation: Gower's solution is specifically designed for the counting of RBCs. It provides a suitable environment for diluting blood samples while preserving the integrity and morphology of red blood cells. This solution ensures accurate counting of RBCs under a microscope without altering their appearance or function. Turk's Solution - Platelets (Option A): Turk's solution causes hemolysis of red blood cells and stains white blood cells for microscopic examination, not for platelet counting. Hayem's Solution - WBCs (Option B): Hayem’s solution is used for RBC counting rather than WBC due to its isotonicity preventing hemolysis, fixation, maintaining cell shape, and prevention of agglutination, with a longer shelf life. 1% Ammonium Oxalate - WBCs (Option D): Ammonium oxalate is used to prevent clotting in blood collection tubes and does not directly aid in white blood cell count in haematology.

Q13 (p. 2906) *Q14 (p. 2907)*

Q1: As per FAB classification, what percentage of blast cells in bone marrow biopsy is required to diagnose a patient with acute leukaemia? (Q845765)

A. 10

B. 20

C. 25

D. 30

Correct Answer: D. 30

Explanation: According to the FAB classification , 30% of blast cells must be present in the bone marrow and peripheral smear to diagnose acute leukaemia. Classification for diagnosis of acute lymphoblastic leukaemia: WHO classification FAB (French-American-British) classification Basis of classification It incorporates genetics, immunophenotypic, and morphological features. It is primarily based on morphology and cytochemistry Subtypes B-cell ALL, NOS (not otherwise specified). B-cell ALL with recurrent genetic abnormalities. T-cell ALL. ALL-L1- small uniform cells ALL-L2- large cells with irregular nuclei ALL-L3- large cells with regular nuclei Clinical utility Used for diagnosis, treatment, and prognostication. Less commonly used in clinical practice and more historical. Diagnosis threshold >20% blasts in the bone marrow. >30% blasts in the bone marrow.

References:

WHO Classification of Tumors of Haematopoietic and Lymphoid Tissues 2017, Page 77

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Which is not included in the FAB classification of acute lymphoblastic leukaemia (ALL) L3 subtype? (Q845766)

A. Presence of lymphoblasts with vacuoles and cytoplasmic blebs

B. Expression of surface immunoglobulins

C. Association with Epstein-Barr virus (EBV)

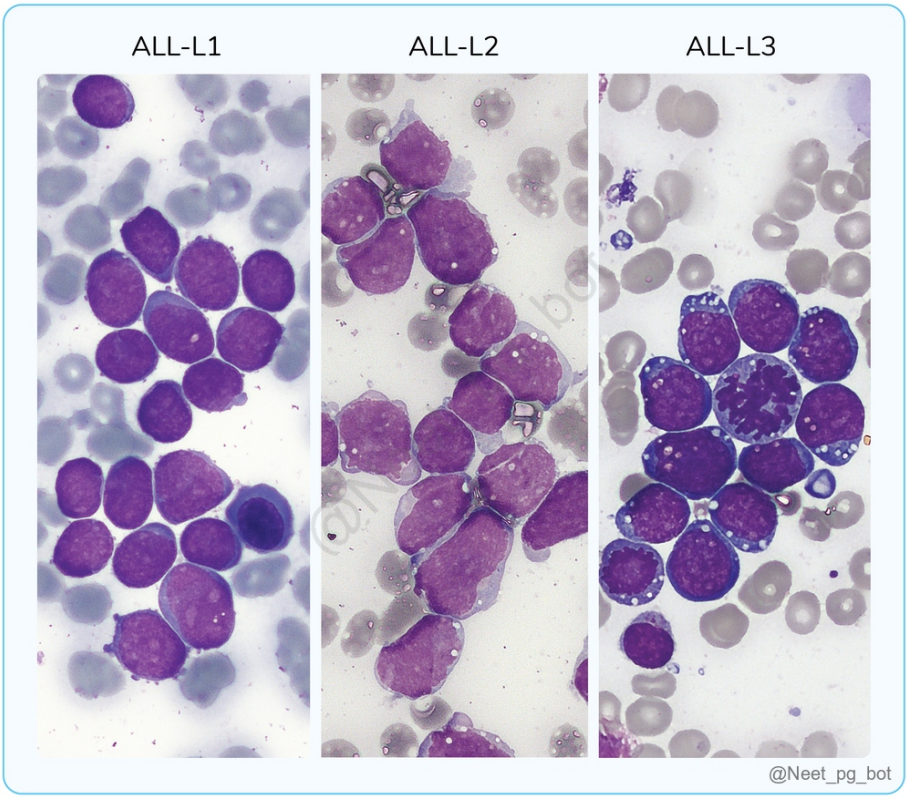
D. t(9;22) Philadelphia chromosome

Correct Answer: B. Expression of surface immunoglobulins

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Unlike Burkitt lymphoma cells, which typically express surface immunoglobulins, the lymphoblasts in ALL L3 subtype do not express surface immunoglobulins. Instead, they express other markers, such as CD10 and CD19. Immunoglobulin and Monoclonality are fetures of B-ceels and Plasma cells seen in Multiple myeloma. ALL-L3 is similar to Burkitt's lymphoma. The image below shows the FAB types of ALL. Presence of lymphoblasts with vacuoles and cytoplasmic blebs (Option A): The presence of lymphoblasts with vacuoles and cytoplasmic blebs is a characteristic feature of L3 subtype ALL. Association with Epstein-Barr virus (Option C): Burkitt lymphoma is strongly associated with Epstein-Barr Virus (EBV) infection. However, while EBV infection may be present in some ALL cases, it is not a defining characteristic of the ALL L3 subtype. t(9;22) Philadelphia chromosome (Option D): The Philadelphia chromosome, resulting from the translocation t(9;22), is associated with a different subtype of ALL (Philadelphia chromosome-positive ALL, or Ph+ ALL) rather than the L3 subtype. Ph+ ALL is characterised by the BCR-ABL1 fusion gene. If weight of BCR-ABL1 fusion gene protein is 190 kDa: ALL If weight of BCR-ABL1 fusion gene protein is 210 kDa: CML FAB classification of ALL: L1 L2 L3 Occurrence More common - Less common Morphology Small homogenous blasts Large heterogenous blasts Large homogenous blasts Cytoplasm Scant blue Moderately weak basophilic Abundant basophilic with prominent vacuoles Nucleus Regular Irregular nuclear outlines - Nucleoli Small & indistinct Prominent - Chromatin Coarse & dark purple Pink - Prognosis Best - Poor



References:

www.ncbi.nlm.nih.gov/pmc/articles/PMC4235437/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: Which of the following is not associated with acute lymphoblastic leukaemia (ALL) regarding chromosomes? (Q845768)

A. t(9;22)

B. t(12;21)

C. t(1;19)

D. t(15;17)

Correct Answer: D. t(15;17)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: t(15;17) translocation is not associated with ALL; rather, it is seen in acute promyelocytic leukaemia (APML) , a type of acute myeloid leukaemia , where t(15;17) translocation leads to the formation of a PML-RAR■ fusion protein (Option D) . Genetic abnormalities associated with ALL: Most common genetic abnormality seen in ALLs is Hyperdiploidy. B-cell ALL with recurrent cytogenetic abnormalities: t(12;21): ETV6-RUNX1 (Option B ruled out) . t(5,11) (KMT2A-MLL). t(9;22): BCR-ABL1 (Option A ruled out) . It produces a 190 kDa fusion protein. t(5;14): IgH-IL3. B-cell ALL with hyperdiploidy. B-cell ALL with hypodiploidy. B-cell ALL t(1;19): TCF3-PBX1. (Option C ruled out) . T-cell ALL: NOTCH1 mutations are most common (50-70% of the cases).

@Neet_pg_bot

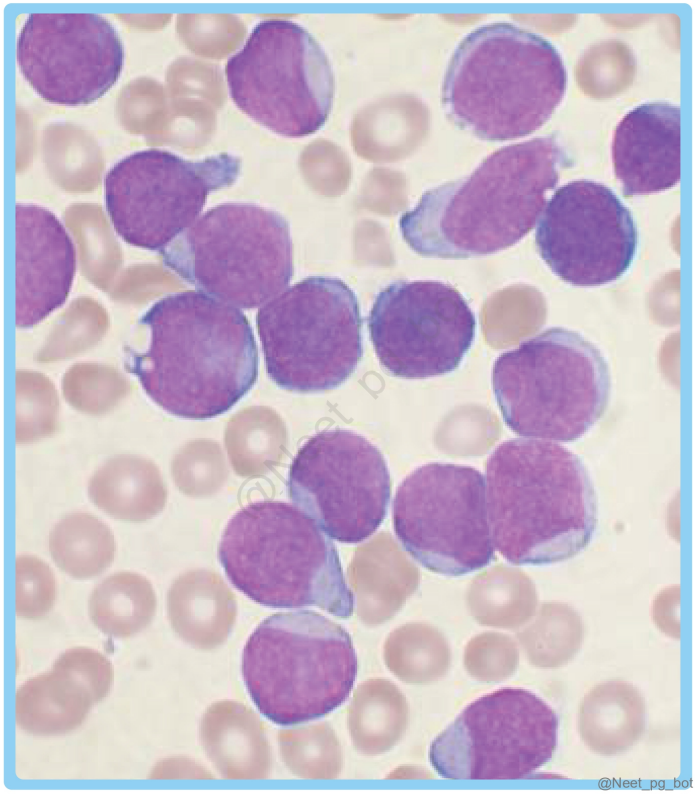
Q4: A 4-year-old male presents with fever, bleeding gums, and fatigue for 5 days. CBC shows Hb of 8g%, TLC 30,000/µL, and platelet count of 40,000/µL. A differential count shows an increased number of immature white blood cells. A bone marrow aspiration is done, as shown below. What is the most likely diagnosis? (Q845769)

A. Chronic myeloid leukaemia.

B. Acute lymphoblastic leukaemia.

C. Acute promyelocytic leukaemia.

D. Aplastic anaemia



Correct Answer: B. Acute lymphoblastic leukaemia.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation of fatigue , fever , and bleeding gums , along with anaemia , thrombocytopenia , leukocytosis with a high proportion of immature white blood cells , and bone marrow aspirate showing lymphoblasts is indicative of acute lymphoblastic leukaemia (ALL) . Acute lymphoblastic leukaemia: It is the most common cancer among children. Symptoms Due to decline in normal marrow function. Fatigue - anaemia. Infections - neutropenia. Bleeding - thrombocytopenia Mass effects Bone pain. Generalised lymphadenopathy. Hepatosplenomegaly. Testicular enlargement. Mediastinal mass in T-ALL (Superior mediastinal syndrome). CNS manifestations Headache. Vomiting. Nerve palsies. Morphology : Hypercellular bone marrow. Lymphoblasts show characteristic Hand-mirror morphology where the cytoplasm extends out like the handle of a hand-mirror.

@Neet_pg_bot

Q7: A 9-year-old boy presents with fever, fatigue, and worsening shortness of breath. On examination, he has a large anterior mediastinal mass causing respiratory distress . Laboratory findings shows leukocytosis and blasts on peripheral smear. Flow cytometry of blasts reveals the positivity for CD3, CD5, CD7 along with variable expression of CD10. What is the most likely diagnosis? (Q845772)

A. Acute Myeloid Leukemia (AML)

B. T cell Acute Lymphoblastic Leukemia

C. B cell Acute Lymphoblastic Leukemia

D. Chronic Lymphocytic Leukemia (CLL)

Correct Answer: B. T cell Acute Lymphoblastic Leukemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: T cells mature in thymus located in anterior mediastinum This young boy with mass in anterior mediastinum is classic for T-cell acute lymphocytic leukaemia (ALL). CD3 - definitive pan T cell marker, CD5,7 - T cell marker, CD10- may be expressed in early T-cell precursors Important features of different types of leukaemia: ALL AML (Option A) CML (Option D) B cell -ALL (Option C) T cell -ALL (Option B) Most common Less common (15%) M2 (M/C) - Age Children Teenagers Adults (15-40 years) Middle-Elderly Mutation Loss of function PAX5, E2A, EBF Gain of function NOTCH1 t(15:17) in M3, t (8:21) in M2 t(9:22) BCR-ABL fusion gene. Prognosis Good Poor Good Good Organ Involvement No tissue involvement T-ALL shows tissue infiltration: CNS Mediastinum Testes Bone pain Hepatosplenomegaly, gum hyperplasia, chloroma Massive splenomegaly, hepatomegaly Stain PAS+ Acid Phosphatase MPO+, NSE + Decreased NAP/LAP score Markers

CD 19,20,21 CD 1,2, 3 , 5 ,7, 10 (CALLA antigen) CD 13, 33, and 117 CD 25

@Neet_pg_bot

Q8: Which of the following statements regarding the M4 subtype of AML based on FAB classification is true? (Q845773)

A. It is associated with t(8:21), called AML with maturation.

B. It is associated with t(15:17), called acute promyelocytic leukaemia

C. It is associated with CBF-MYH fusion, called acute myelomonocytic leukaemia

D. It is associated with MPO positivity, called AML without maturation.

Correct Answer: C. It is associated with CBF-MYH fusion, called acute myelomonocytic leukaemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Acute myelocytic leukemia (M4) type, also called acute myelomonocytic leukaemia, is associated with the CBF-MYH fusion gene. FAB classification of AML Subtype Name Features AML-M0 AML undifferentiated MPO negative AML-M1 AML without maturation (Option D) MPO + AML-M2 AML with maturation (Option A) Most common t(8:21) RUNX1-RUNX1T1 fusion Associated with chloroma. AML-M3 Acute promyelocytic leukaemia (Option B) t(15:17) - PML-RAR■ fusion Blocks promyelocyte → myelocyte transformation Bone marrow: Auer rods form criss-cross called faggot cell Can cause DIC PAS+ AML-M4 Acute myelomonocytic leukaemia (Option C) Associated with inversion 16 chromosome and CBF-MYH fusion gene (CBF = Core binding factor) Gums - gum hypertrophy Skin - leukaemia cutis MPO+, NSE + AML-M5 Acute monocytic leukaemia Gums - gum hypertrophy Skin - leukaemia cutis MPO-, NSE + AML-M6 Acute erythroid leukaemia Also called DI Guglielmo Disease Diffuse PAS+, CD71 AML-M7 Acute megakaryocytic leukaemia Bone Marrow aspiration gives a dry tap PAS+, CD41 and CD61

Robbins and Cotran, Pathologic Basis of Disease, 10th Edition, Pages 617-620

↑ *Back to this question in Part A*

@Neet_pg_bot

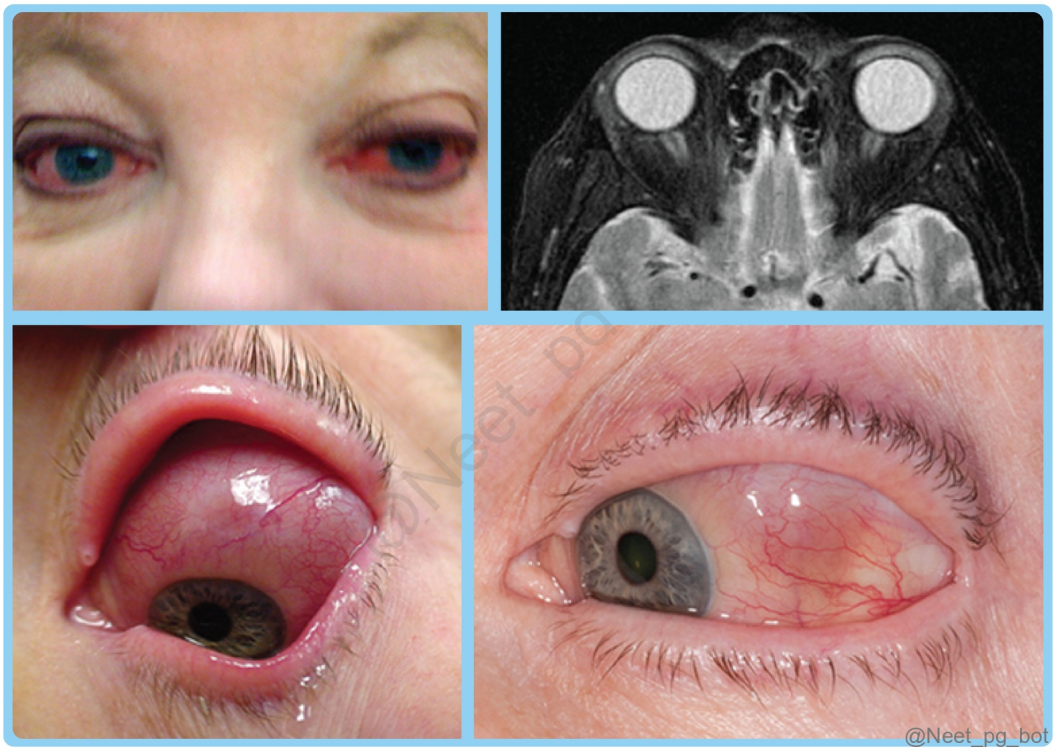
Q9: A 12-year-old boy presents with fatigue, bruising, and intermittent fevers for the past few weeks. Physical examination reveals the following findings. Immunophenotyping of the biopsy specimen shows CD43 and MPO positivity. What is the most likely diagnosis? (Q845774)

A. Acute Lymphoblastic Leukemia (ALL)

B. AML with maturation

C. Acute promyelocytic leukaemia

D. Non-Hodgkin Lymphoma



Correct Answer: B. AML with maturation

- *Listen (English)*
- *Listen (Hindi)*

Explanation: This young child with nonspecific systemic symptoms, MPO positivity, and an image showing orbital swelling and proptosis suggests chloroma associated with AML with maturation (AML-M2). Chloroma : A.k.a Myeloblastoma/Granulocytic Sarcoma. It is not a benign tumour, but it has a greenish colour. Site: Soft tissue involvement in orbit leads to proptosis. Associated with AML M2 and M5 . Peripheral smear findings: Myeloblasts . Arbiskov cells: Atypical monocytes/macrophages. Markers: MPO (green colour), CD 43, CD 45 and Lysozyme .

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 618-620

↑ *Back to this question in Part A*

@Neet_pg_bot

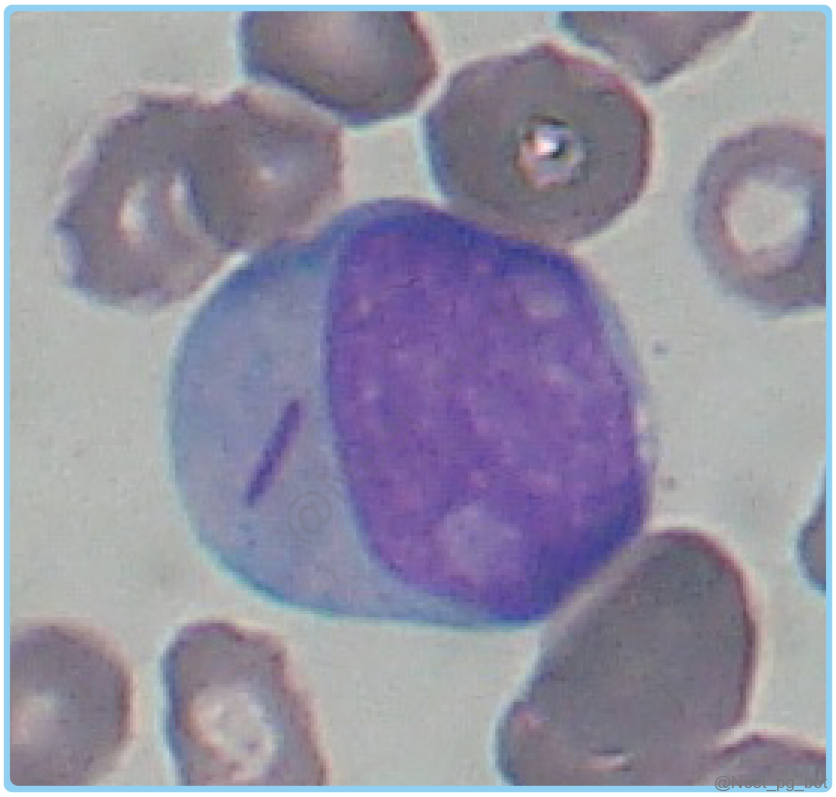
Q10: A 28-year-old female was admitted to the hospital with complaints of frequent nosebleeds, reports of sudden onset chest pain and dyspnea. On examination, she has petechiae and ecchymoses on her skin. Laboratory tests revealed WBC 15,000/µL, haemoglobin 8 g/dL, platelets 20,000/µL and elevated prothrombin time. A peripheral blood smear shows the following findings. Further testing confirms which of the following associated conditions? (Q845775)

A. t(12:21) translocation

B. t(15:17) translocation

C. t(9:22) translocation

D. t(8:21) translocation



Correct Answer: B. t(15:17) translocation

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: This patient's history of sudden onset symptoms with pancytopenia, high prothrombin time, and Auer-rods on blood smear suggests disseminated intravascular coagulation secondary to acute promyelocytic leukaemia (AML M3) associated with t(15:17) translocation . A key morphological feature is the presence of faggot cells , which are promyelocytes containing bundles of Auer rods . Genetics of M3 AML/ Acute promyelocytic leukemia: t(15:17) translocation causes PML-RARA (retinoic acid receptor alpha) fusion protein formation. Blocks promyelocyte → myelocyte maturation. Accumulation of abnormal promyelocytes with procoagulant granules. These granules trigger DIC , which is the most common cause of early mortality Diagnosis of choice: FISH Management ATRA (All-trans retinoic acid): Drug of choice; start immediately (even before confirmation) Induces differentiation of promyelocytes → reverses coagulopathy Arsenic Trioxide: Used with ATRA Promotes apoptosis of leukemic cells Improves survival significantly t(12:21) translocation (Option A) is seen in ALL and has a good prognosis. They are negative for auer rods. t(9:22) translocation (Option C): Philadelphia chromosome associated with CML and ALL (worse prognosis). ALL (Acute Lymphoblastic Leukemia) : t(9;22) results in a BCR-ABL fusion protein of 190 kDa CML (Chronic Myeloid Leukemia) : t(9;22) results in a BCR-ABL fusion protein of 210 kDa . CNL (Chronic Neutrophilic Leukemia) : t(9;22) results in a BCR-ABL fusion protein of 230 kDa t(8:21) translocation (Option D): t(8:21) translocation is seen in the M2 subtype of AML (most common).

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 617-620

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following types of AML, according to the FAB classification, is associated with Down's syndrome? (Q845776)

A. Acute erythroid leukaemia

B. Acute myelomonocytic leukaemia

C. Acute megakaryocytic leukaemia

D. Acute monocytic leukaemia

Correct Answer: C. Acute megakaryocytic leukaemia

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Acute megakaryoblastic leukaemia (AML M7) is notably associated with Down's syndrome. Down's syndrome associated disorders: Overall most common leukemia associated with Down's syndrome is ALL . In less than 3 years old child, most common leukemia associated with Down's syndrome is AML-M7 . Most common haematological abnormality associated with Down's syndrome is TAM (Transient Abnormal Myelopoiesis) Transient: Lasts for only a few months Abnormal Myelopoiesis: Some abnormal WBC lineage cells are found circulating in bone marrow and peripheral blood. Reduced incidence of: Breast cancer Lung cancer Prostate cancer Neuroblastoma Medulloblastoma

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 618

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following is associated with a good prognosis according to WHO classification of AML? (Q845777)

A. AML: Therapy-related

B. AML with MDS-like features

C. AML with recurrent genetic abnormality

D. AML not otherwise specified

Correct Answer: C. AML with recurrent genetic abnormality

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: AML defined by specific genetic abnormalities are associated with a good prognosis due to the presence of targetable mutations and the availability of specific therapies, such as ATRA for APL. AML having good prognosis: t(8;21): AMLM2 t(15;17): AMLM3 inv(16): AMLM4 WHO Classification of AML: AML with Recurrent Genetic Abnormalities (good prognosis): t(8;21)(q22;q22.1); RUNX1-RUNX1T1 inv(16) (CBFB-MYH11) t(15;17)(q24.1;q21.1); PML-RARA. t(1;22) AML with Myelodysplasia-Related Changes (bad prognosis) Therapy-Related Myeloid Neoplasms (bad prognosis) AML, Not Otherwise Specified (NOS) (bad prognosis) AML with minimal differentiation AML without maturation AML with myelocytic maturation AML with myelomonocytic maturation. AML with monocytic maturation. AML with erythroid maturation. AML with megakaryocytic maturation. AML associated with Down's syndrome - AMLM7.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 617

↑ *Back to this question in Part A*

@Neet_pg_bot

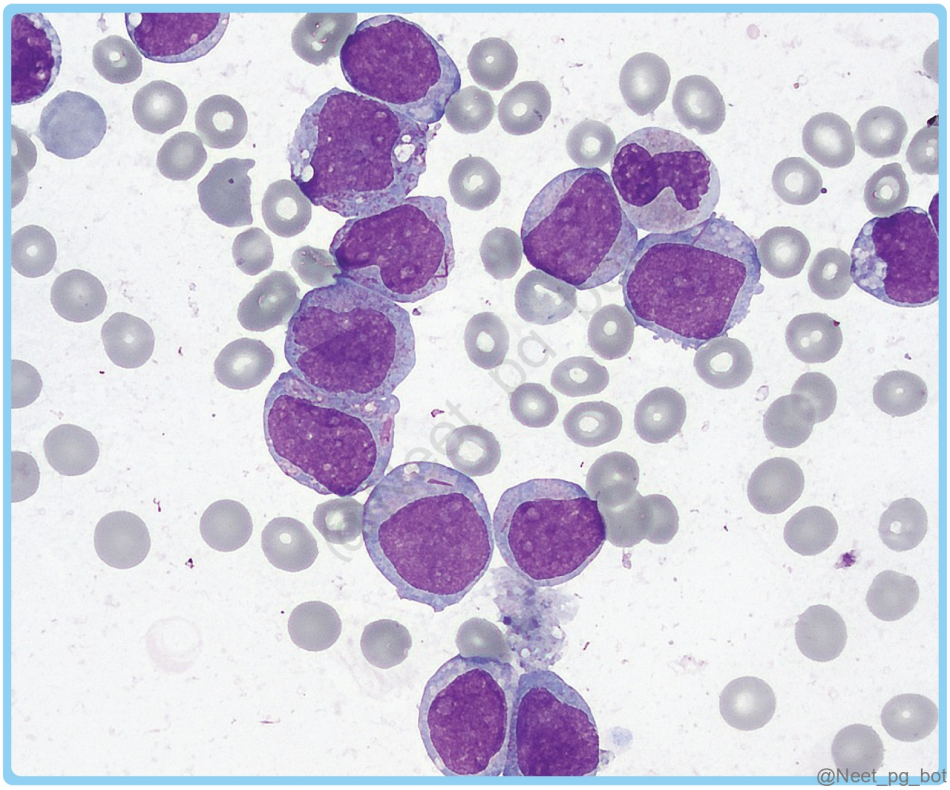
Q13: What is the most likely immunophenotype associated with the condition indicated by the peripheral blood smear shown below? (Q845778)

A. CD13+, CD33+, CD34+, HLA-DR+

B. CD19+, CD20-, CD22+, CD79a-

C. CD3+, CD4+, CD8+, CD5-

D. CD10+, CD19+, CD20+, CD22-



Correct Answer: A. CD13+, CD33+, CD34+, HLA-DR+

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The peripheral smear shows myeloblasts (large, irregularly shaped cells with prominent nuclei and moderately granular cytoplasm), and needle-like inclusions in the cytoplasm of blasts (Auer rods) , suggesting acute myeloid leukaemia (AML). The immunophenotype associated with AML is CD13+, CD33+, CD34+, and HLA-DR+. AML is characterised by the presence of myeloid lineage markers. Myeloid lineage markers: Myeloperoxidase, CD13 , and CD33 . TdT, HLA-DR , and CD34 are expressed on AML blasts.. CD19+, CD20-, CD22+, CD79a- (Option B): Suggestive of B-cell ALL. CD3+, CD4+, CD8+, CD5- (Option C): Suggestive of T-cell ALL. CD10+, CD19+, CD20+, CD22- (Option D): Suggestive of B-cell Chronic Lymphocytic Leukemia (B-CLL).

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 593-619

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: A 55-year-old female presented with fatigue, easy bruising, and recurrent infections over the past few months. On examination, there is mild splenomegaly, but

no lymphadenopathy is noted. Laboratory tests reveal pancytopenia. A peripheral blood smear shows normocytic normochromic red blood cells and bone marrow shows blast count >20%. What is the most likely diagnosis? (Q845779)

A. Aplastic anemia

B. Myelodysplasia

C. Aleukemic leukaemia

D. Myeloproliferative disorder

Correct Answer: C. Aleukemic leukaemia

Explanation: The patient shows pancytopenia, fatigue, bruising, and infections with no lymphadenopathy, mild splenomegaly, >20% blast count in bone marrow, indicating aleukemic leukemia. Aplastic anemia (Option A): Aplastic anemia causes pancytopenia from bone marrow failure with no splenomegaly. Myelodysplasia (Option B): Myelodysplastic syndrome (MDS) has <20% blasts by definition Myeloproliferative disorder (Option D): Myeloproliferative disorders (MPDs) typically has features of elevated blood counts, only late spent phase causes cytopenias with <20% blast counts

« Back to Folder Directory

[18_Hematology_ White Blood Cells] 075 Myeloid Disorders — Quick Jump

Q1 (p. 2909) *Q2 (p. 2910)* *Q3 (p. 2911)* *Q4 (p. 2912)* *Q5 (p. 2914)* *Q6 (p. 2915)*
Q7 (p. 2919) *Q8 (p. 2921)* *Q9 (p. 2922)* *Q10 (p. 2923)* *Q11 (p. 2924)* *Q12 (p. 2925)*
Q13 (p. 2926) *Q14 (p. 2926)*

Q1: A 45-year-old female presents with complaints of occasional headaches and blurred vision. Laboratory tests reveal isolated thrombocytosis without significant leukocytosis or erythrocytosis. Bone marrow biopsy shows increased megakaryocytes. Which of the following types of myeloproliferative neoplasm (MPN) is most likely to be diagnosed based on these findings? (Q845780)

A. Polycythemia Vera (PV)

B. Essential Thrombocytosis (ET)

C. Chronic Myeloid Leukemia (CML)

D. Primary Myelofibrosis (PMF)

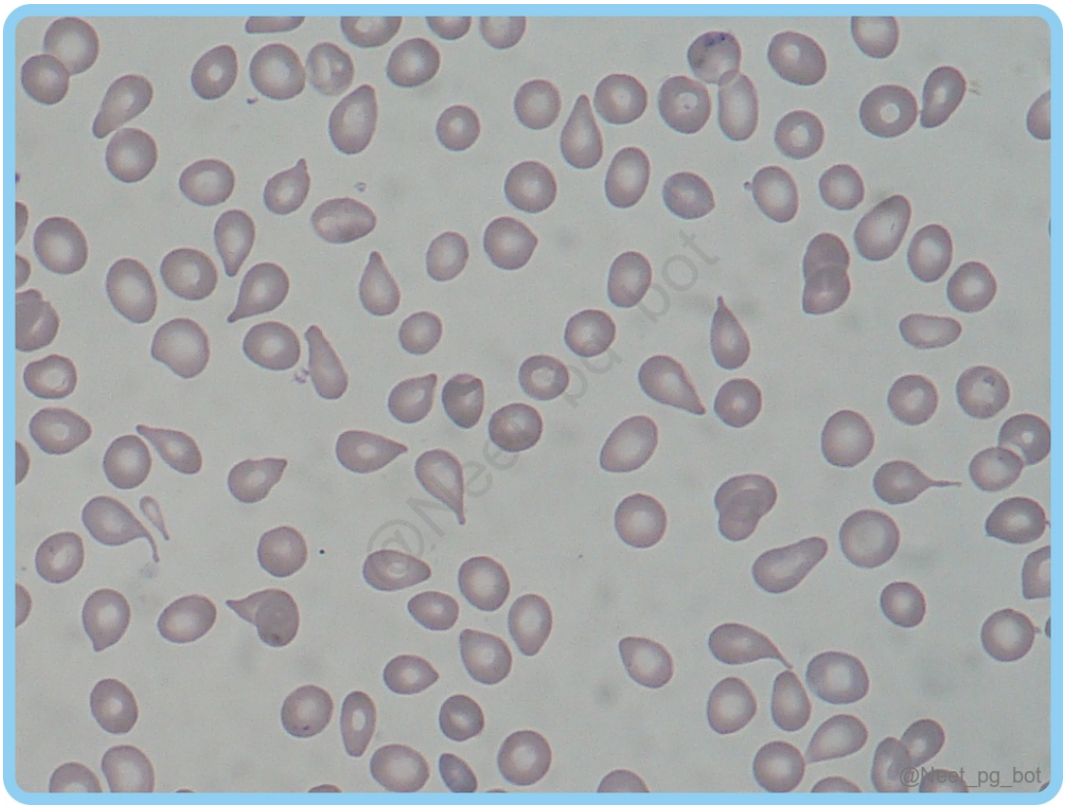
Correct Answer: B. Essential Thrombocytosis (ET)

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Essential thrombocytosis is a type of myeloproliferative neoplasm which is characterized by isolated thrombocytosis without any without significant leukocytosis or erythrocytosis , along with increased megakaryocytes in bone marrow biopsy It is asymptomatic in more than half of the cases and is usually diagnosed incidentally Less than 50% patients have symptoms related to thrombosis or hemorrhage Symptoms include Bleeding tendency Microvascular occlusion Thrombosis of major arteries (leading to CVA and transient ischemic attacks), and vasomotor symptoms such as headache, visual disturbances, and syncope. Mild splenomegaly and rarely hepatomegaly and lymphadenopathy Diagnosis Criteria for Early/Prefibrotic ET Sustained platelet count ≥ 450 x 10^9/L Megakaryocyte proliferation Absence of criteria for other myeloid neoplasms Absence of JAK2, CALR, or MPL mutation Bone Marrow: Shows megakaryocytic hyperplasia with large, hyperlobulated (staghorn) megakaryocytes in clusters. Polycythemia Vera (PV) (Option A): It is characterized by increased red blood cell mass, leading to erythrocytosis. Associated with JAK2 mutation Symptoms : headaches, dizziness, and pruritus due to hyperviscosity. Laboratory findings typically include elevated hemoglobin and hematocrit levels, leukocytosis, and thrombocytosis. Bone marrow biopsy shows hypercellularity with increased erythropoiesis Chronic Myeloid Leukemia (Option C): CML is characterized by the Philadelphia chromosome (BCR-ABL fusion gene). Patients present with leukocytosis, predominantly neutrophils, and may have splenomegaly. Laboratory

findings- elevated white blood cell count, left-shifted granulocytes, and basophilia. Treatment often involves tyrosine kinase inhibitors targeting the BCR-ABL fusion protein. Primary Myelofibrosis (PMF) (Option D): It is characterized by bone marrow fibrosis, leading to cytopenias and splenomegaly. Symptoms- fatigue, weight loss, and abdominal discomfort due to splenomegaly. Laboratory findings: anemia, leukoerythroblastosis, and teardrop-shaped red blood cells (dacrocytes) on peripheral smears. JAK2 mutation is commonly found in PMF Bone marrow biopsy shows fibrosis with increased megakaryocytes.



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 625

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 50-year-old male presents with complaints of headaches, dizziness, and pruritus. Physical examination reveals a plethora and splenomegaly. Laboratory tests show elevated hemoglobin and hematocrit levels. Which of the following criteria are consistent with the Polycythemia Vera (PV) diagnosis? (Q845781)

A. Sustained platelet count ≥ 450 x 10^9/L

B. Increased red blood cell mass

C. Presence of JAK2 mutation

D. Presence of CALR or MPL mutation

Correct Answer: B. Increased red blood cell mass

Explanation: Diagnostic Criteria of Polycythemia Vera: Major criteria: Hb: > 16.5 g/dL in men and 16 g/dL in women. Hct: > 49% in men and > 48% in women. BM Trilineage myeloproliferative with pleomorphic megakaryocytes. Presence of JAK2 mutation. Minor Criteria: Subnormal serum erythropoietin level. Clinical features: Increased Hb causes stasis and neurological abnormalities. Increased TLC causes itching after a hot water bath and flushing. A high platelet count causes bleeding tendencies. Hepatosplenomegaly. Sustained platelet count ≥ 450 x 10^9/L (Option A): This criterion is not indicative of polycythemia vera (PV). Instead, it is a characteristic of Essential Thrombocytosis (ET), which is characterized by isolated thrombocytosis without significant erythrocytosis or leukocytosis. Presence of JAK2 mutation (Option C): While the presence of JAK2 mutation is a major diagnostic criterion for PV, it is not the only criterion. The presence of JAK2 mutations may also be observed in other myeloproliferative neoplasms like Essential Thrombocythemia (ET) or Primary Myelofibrosis (PMF). Presence of CALR or MPL mutation (Option D): CALR and MPL mutations are typically associated with other myeloproliferative neoplasms, such as Essential Thrombocythemia (ET) or Primary Myelofibrosis (PMF), and are not specific to Polycythemia Vera (PV).

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 624

↑ *Back to this question in Part A*

@Neet_pg_bot

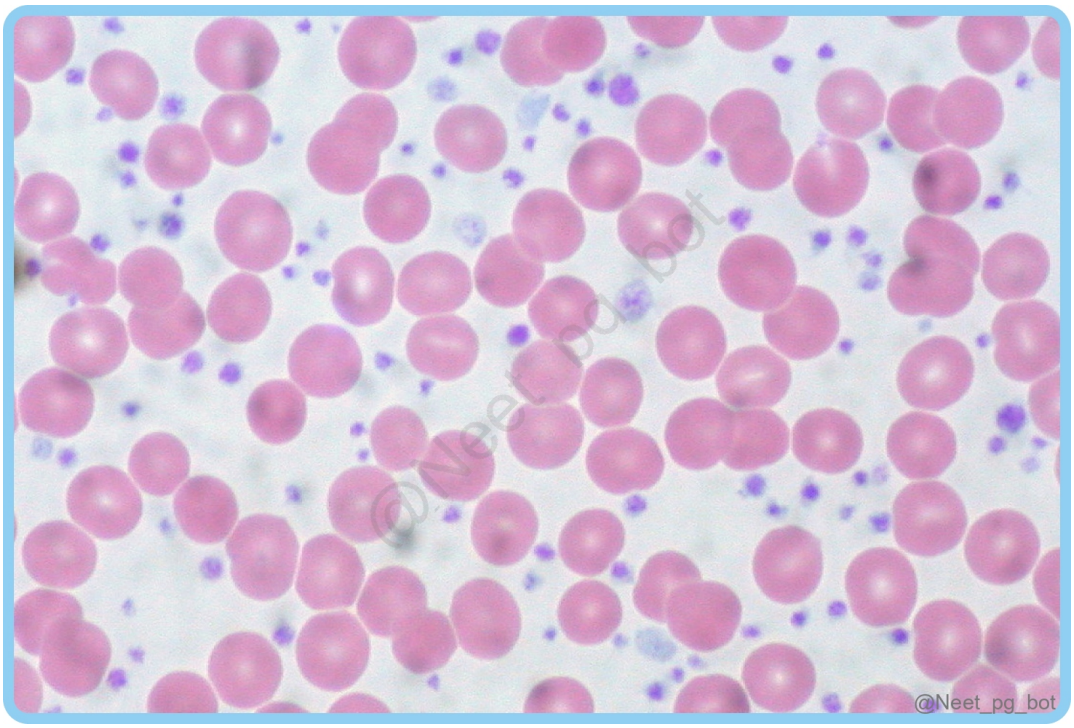
Q3: A 55-year-old female presents to the clinic with complaints of frequent headaches, dizziness, and occasional burning pain in her hands and feet. Examination reveals splenomegaly. Her complete blood count shows a platelet count of 12,00,000/µL. The peripheral blood smear shows marked thrombocytosis with giant platelets. Which of the following is not true regarding this condition? (Q845783)

A. Characterized by the presence of megakaryocytic hyperplasia.

B. Associated with JAK2, CALR, or MPL mutations.

C. Bone marrow biopsy typically shows increased reticulin fibrosis.

D. Increased risk of thrombotic and hemorrhagic events.



Correct Answer: C. Bone marrow biopsy typically shows increased reticulin fibrosis.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation is consistent with Essential Thrombocytosis, which typically does not show a significant increase in reticulin fibers in the bone marrow at diagnosis. Increased reticulin fibrosis is more characteristic of primary myelofibrosis. WHO diagnostic criteria of Essential thrombocytosis Major criteria Platelet count greater than or equal to 450,000/microliter. Bone marrow biopsy Shows proliferation, mainly of the megakaryocytic lineage, with an increase in enlarged mature megakaryocytes. (Option A) No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis is present, Very rarely a minor increase in reticulin fibers. (Option C) The presentation does not meet WHO criteria for BCR-ABL1 +ve CML, PCV, myelofibrosis, MDS, or other myeloid neoplasms. Presence of JAK2, CALR, or MPL mutation. (Option B) Minor criteria: Presence of a clonal marker or absence of evidence of reactive thrombocytosis. Clinical features Thrombotic or hemorrhagic symptoms such as Bleeding tendency Microvascular occlusion Thrombosis of major arteries (leading to CVA and transient ischemic attacks), and vasomotor symptoms such as headache, visual disturbances, and syncope. Mild splenomegaly and rarely hepatomegaly and lymphadenopathy

↑ *Back to this question in Part A*

@Neet_pg_bot

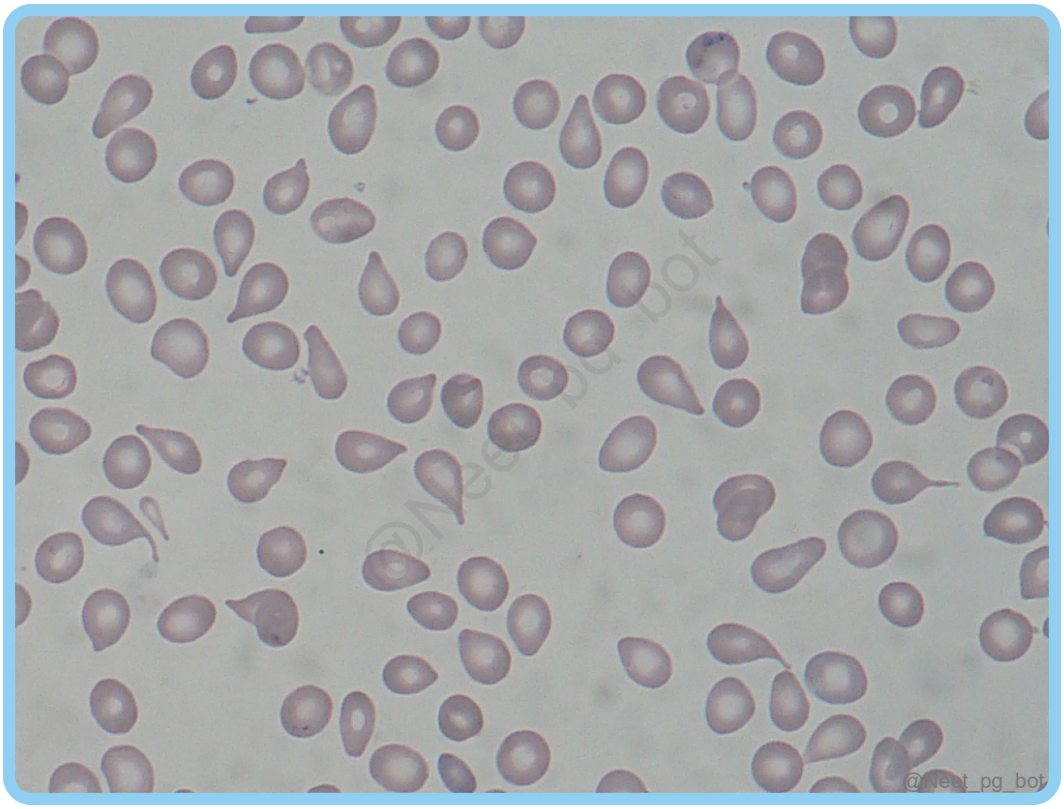
Q4: A 65-year-old man presents with progressive fatigue and significant weight loss for the past six months. Examination reveals a markedly enlarged spleen. Peripheral blood smear shows teardrop-shaped red cells. Bone marrow biopsy confirms the diagnosis of primary myelofibrosis. Which of the following statements regarding the diagnosis is true? 1) It is characterized by extensive marrow fibrosis. 2) Diagnostic criteria include the presence of JAK2, CALR, or MPL mutations. 3) Pathogenesis involves the inappropriate release of fibrogenic factors like PDGF and TGF-β. (Q845784)

A. All statements are true

B. 1,2

C. Only 3

D. 2,3



Correct Answer: A. All statements are true

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Primary myelofibrosis (PMF) is a chronic myeloproliferative neoplasm characterized by the development of extensive marrow fibrosis, which impairs normal hematopoiesis. (Statement 1) This fibrosis is

driven by the inappropriate release of fibrogenic factors, such as platelet-derived growth factor and TGF-β, from neoplastic megakaryocytes. (Statement 3) Clinically, PMF presents with progressive anemia, splenomegaly, and symptoms like fatigue and weight loss. WHO diagnostic criteria: Major criteria Megakaryocyte proliferation and atypia, usually with reticulin or collagen fibrosis. Not meeting WHO criteria for BCR-ABL1 + CML, PV, ET, MDS, or other myeloid neoplasm Presence of JAK2, CALR, or MPL mutation or in the absence of these mutations, presence of other clonal markers or absence of minor reactive BM reticulin fibrosis. (Statement 2) Minor criteria: Leukocytosis ≥ 11 × 10 9 /L. Increased Serum Lactate Dehydrogenase (LDH). Anemia not attributed to another condition. Palpable Splenomegaly.

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 626

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5807384/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 60-year-old man presents with complaints of increasing fatigue, early satiety, and unintentional weight loss over the past few months. On examination, there is palpable splenomegaly. Laboratory reports reveal pancytopenia with dacrocytes on the peripheral smear. Which of the following is not associated with Myelofibrosis? (Q845785)

A. Dry tap

B. Leukoerythroblastic blood picture

C. Dacrocytes

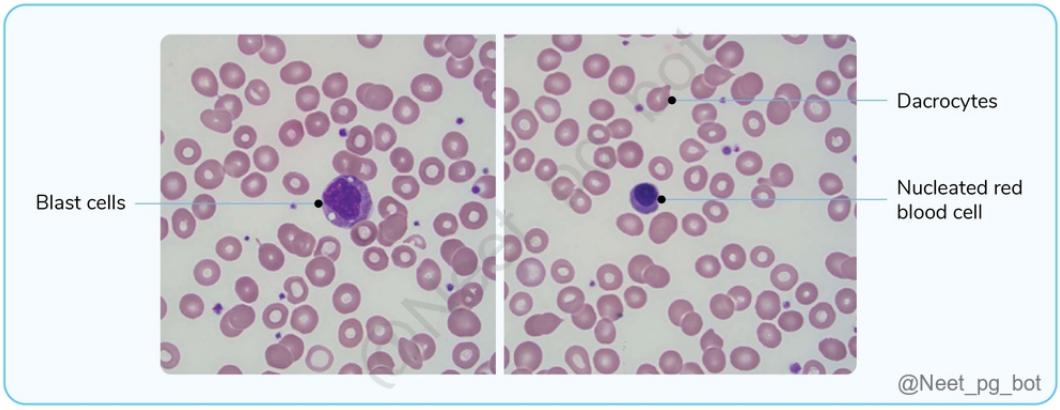
D. Myeloblasts

Correct Answer: D. Myeloblasts

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Myeloblasts are seen in AML and are not associated with myelofibrosis. Myelofibrosis is the development of obliterative marrow fibrosis. Replacement of the marrow by fibrous tissue reduces bone marrow hematopoiesis, leading to cytopenias and extensive extramedullary hematopoiesis. Investigations include CBC-pancytopenia due to obliterative bone marrow fibrosis Peripheral smear reveals a leukoerythroblastic blood picture where the distortion of the marrow leads to the premature release of immature erythroid and granulocyte (Option B) Teardrop-shaped red cells (dacrocytes) that are damaged during the birthing process in the fibrotic marrow (Option C) Bone marrow aspirate may reveal a dry tap. (Option A) May reveal thickening and distortion of bony trabeculae and deposition of reticulin and collagen fibers.



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 626

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5013940/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 75-year-old man presents with increasing fatigue, weakness, and easy bruising over the past few months. Labs show pancytopenia. Peripheral blood smear reveals dysplastic differentiation in the erythroid, granulocytic, monocytic, and megakaryocytic lineages. Which condition does this suggest? (Q845787)

A. Hyperlobated megakaryocyte

B. Leukoerythroblastic picture

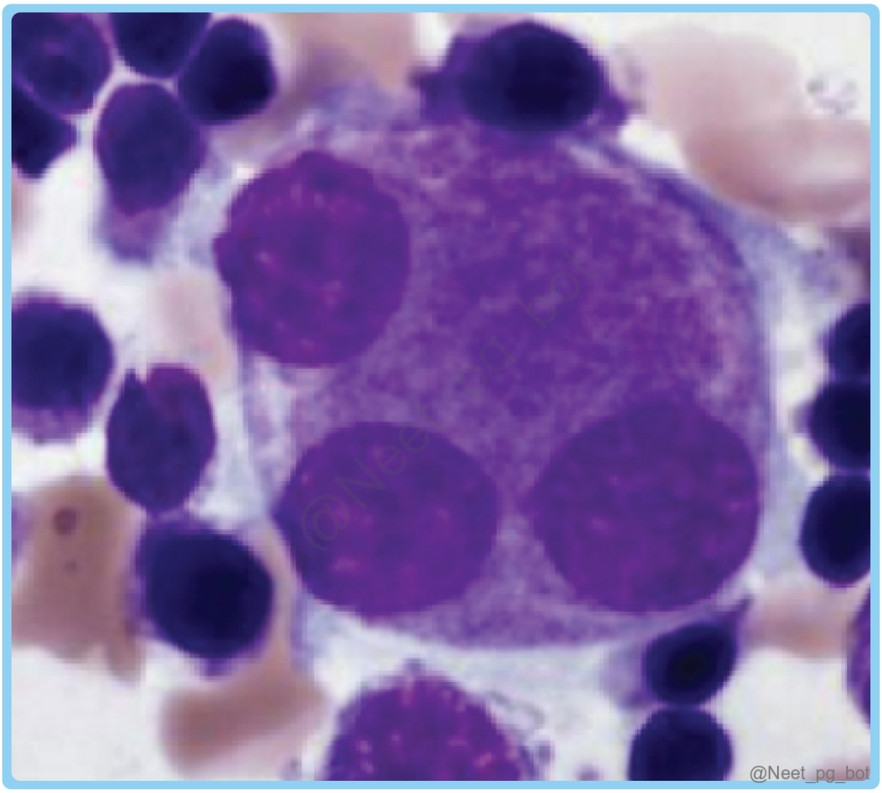
C. Increased proliferation of RBCs

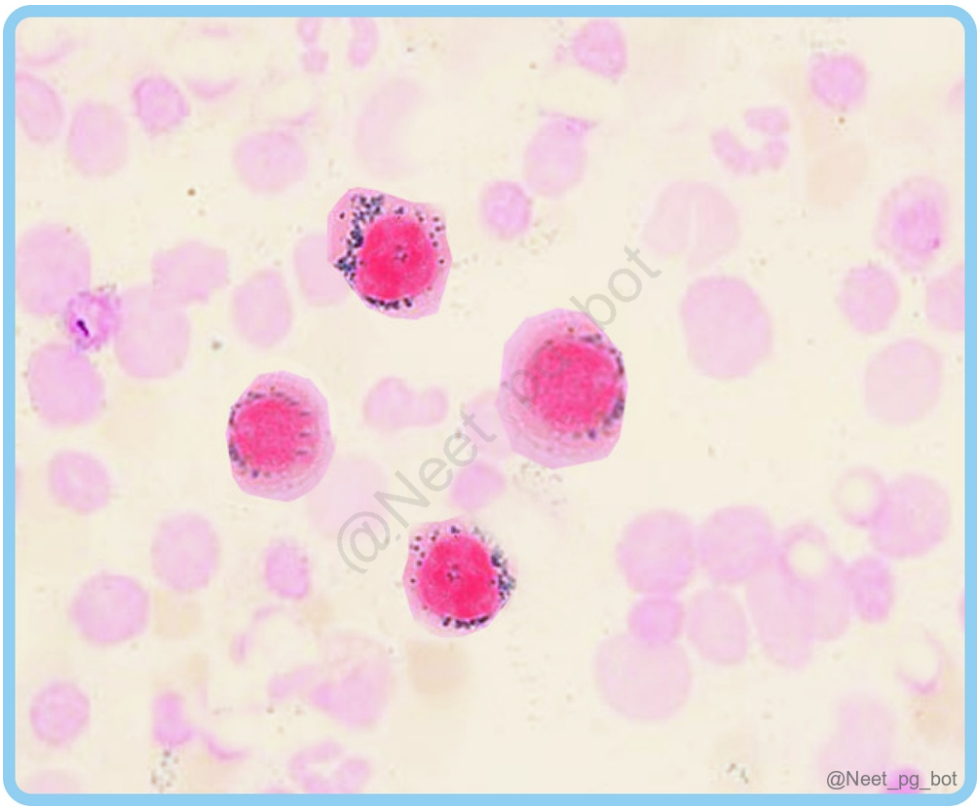
D. Pawn ball megakaryocyte

Correct Answer: D. Pawn ball megakaryocyte

Explanation: Pawn ball megakaryocytes is associated with Myelodysplastic syndrome. Myelodysplastic Syndrome (MDS) is a group of clonal stem cell disorders characterized by maturation defects and ineffective hematopoiesis with a risk transformation to AML Bone marrow replaced by clonal progeny of a neoplastic multipotent stem cell Leading to ineffective and disordered differentiation Can cause cytopenias and potential malignancy Genetic Causes Adults: Deletion of 5q chromosome Children: Monosomy 7 Types Primary (idiopathic) Secondary (due to genotoxic drugs or radiation therapy) Peripheral Smear Findings: Dysplastic differentiation of erythroid, granulocytic, monocytic, and megakaryocytic lineages Ring sideroblasts Erythroblasts with iron-laden mitochondria (visible as perinuclear granules in Prussian blue stain) Neutrophils with decreased secondary

granules Döhle bodies PseudoPelger–Hüet cells (neutrophils with two nuclear lobes) Megakaryocytes with Single nuclear lobes Multiple separate nuclei (Pawnball megakaryocytes) Ringed sideroblasts: Döhle bodies: PseudoPelger–Hüet cells: Hyperlobated megakaryocytes (Option A): These are seen in Essential thrombocytosis, where peripheral smears reveal abnormally large platelets and marked thrombocytosis. It is characterized by erythromelalgia, a throbbing and burning of hands and feet caused by the occlusion of small arterioles by platelet aggregates. Leukoerythroblastic picture (Option B): This is seen in Myelofibrosis, which causes obliterative marrow fibrosis, decreasing hematopoiesis and causing cytopenias, with extensive extramedullary hematopoiesis. Increased proliferation of RBCs (Option C): It is seen in Polycythemia Vera due to JAK2 mutation. Patients present with symptoms such as headaches, dizziness, and pruritus due to hyperviscosity. Bone marrow biopsy shows hypercellularity with increased erythropoiesis.





@Neet_pg_bot

Q7: A 5-year-old child presents with a skin rash, recurrent ear infections, bone pain, and polyuria. Imaging revealed lytic bone lesions and a biopsy of one of the lesions showed CD1a and S-100 positive Langerhans cells. Which of the following types of Langerhans cell histiocytosis (LCH) is characterized by multifocal uni system involvement? (Q845790)

A. Eosinophilic granuloma

B. Hand-Schüller-Christian disease

C. Letterer-Siwe disease

D. Both A and C

Correct Answer: B. Hand-Schüller-Christian disease

Explanation: Langerhans Cell Histiocytosis (LCH) is a rare inflammatory and neoplastic condition that involves myeloid dendritic cells Genetic Mutation: BRAF V600E mutation found in the majority of cases BRAF gene encodes B-Raf, part of the MAPK pathway Mutation establishes the neoplastic nature of LCH Categories: Unisystem: Unifocal Multifocal Multisystem Types of langerhan histiocytosis: Eosinophilic granuloma (Option A) Hand-Schuller-Christian disease (Option B) Letterer-Siwe disease (Option C) Unifocal involvement. Primarily involves lytic bone lesions. Seen in young children. Multifocal involvement. It is characterized by a triad of symptoms such as: Bony lesions in a calvarial defect. Diabetes insipidus and Exophthalmos. It is a more severe, disseminated form of LCH with multisystem involvement. It is characterized by lytic bony lesions and seborrheic

dermatitis. LCH Diagnosis: Light Microscopy Eosinophils appear as orange-looking cells Nuclei have a coffee bean appearance Immunohistochemistry (IHC): Positive markers: CD1a, CD207 (langerin), S100, HLA-DR Electron Microscopy:(Gold standard for diagnosis) Reveals tennis racket appearance of Birbeck granules

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Pseudo-Gaucher cells are commonly seen in which of the following conditions? (Q889668)

A. Gaucher disease

B. Chronic myeloid leukaemia

C. Hairy cell leukaemia

D. Multiple myeloma

Correct Answer: B. Chronic myeloid leukaemia

Explanation: Pseudo-Gaucher cells are macrophages with cytoplasm resembling true Gaucher cells , seen in conditions associated with high cell turnover , particularly chronic myeloid leukaemia (CML) . In CML, rapid myeloid proliferation leads to increased breakdown of leukocytes, resulting in the accumulation of glucocerebroside within marrow macrophages. Unlike true Gaucher cells, these cells occur without β-glucocerebrosidase deficiency . They are termed “pseudo” because they resemble Gaucher cells morphologically but do not represent a lysosomal storage disorder. Gaucher disease (Option A): Characterised by true Gaucher cells caused by β-glucocerebrosidase deficiency , leading to glucocerebroside accumulation in macrophages. Hairy cell leukaemia (Option C): Characterised by TRAP-positive B cells , marrow fibrosis, and “fried-egg” appearing cells; pseudo-Gaucher cells are not a typical feature. Multiple myeloma (Option D): Although rare pseudo-Gaucher-like cells have been reported in high cell turnover states, multiple myeloma is primarily characterised by clonal plasma cell proliferation , not by classic pseudo-Gaucher cells.

@Neet_pg_bot

Q9: Which of the following findings is least likely to be seen in polycythemia vera (PCV)? (Q889669)

A. Low serum erythropoietin

B. Basophilia

C. Budd-chiari syndrome

D. Lymphocytosis

Correct Answer: D. Lymphocytosis

Explanation: Lymphocytosis is not a feature of PCV because the disease arises from a myeloid progenitor , not the lymphoid lineage. Polycythemia Vera (PCV): Myeloproliferative neoplasm → ↑ RBCs, granulocytes, platelets

(panmyelosis) Symptoms are mainly from erythrocytosis Pathogenesis: JAK2 V617F mutation → constitutive JAK/STAT → growth factor-independent hematopoiesis Low EPO (Option A) , hyperviscosity → thrombosis & bleeding Morphology: Hypercellular marrow, ↑ erythroid/granulocyte/megakaryocyte precursors ↑ basophils (Option B) , giant/abnormal platelets Mild organomegaly; fibrosis & extramedullary hematopoiesis in spent phase Clinical features: Middle-aged adults; plethoric, cyanotic, pruritus, headache, dizziness, GI symptoms Complications: thrombosis (DVT, MI, stroke, Budd-Chiari (Option C)), bleeding, gout Management: Phlebotomy + low-dose aspirin JAK2 inhibitors Progression: 10-20% → myelofibrosis, ~2% → AML

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 568, 569

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following conditions is most likely associated with a leucoerythroblastic blood film? (Q889671)

A. Iron deficiency anaemia

B. Vitamin B12 deficiency

C. Primary myelofibrosis

D. Thalassemia

Correct Answer: C. Primary myelofibrosis

Explanation: Primary myelofibrosis disrupts normal marrow architecture due to progressive marrow fibrosis , leading to a leucoerythroblastic blood film characterised by nucleated RBCs , tear-drop cells (dacrocytes) , and early myeloid precursors in the peripheral blood. Leucoerythroblastic Blood Film / Anaemia: Presence of immature blood cells in peripheral blood - nucleated RBCs along with early myeloid precursors (myelocytes, metamyelocytes). Significance : Pathological in adults ; indicates marrow infiltration, fibrosis, or severe marrow stress . It may clinically resemble leukaemia due to circulating immature cells and splenomegaly, though marked leukocytosis is more typical of leukaemia. Common causes: Marrow infiltration: metastatic carcinoma, myelofibrosis Severe systemic stress: sepsis, severe infections (e.g., tuberculosis) Other marrow stress: acute blood loss, severe haemolysis, marrow recovery phase Iron deficiency anaemia (Option A): Causes microcytic, hypochromic RBCs but does not disrupt marrow architecture; therefore, a leucoerythroblastic blood film is uncommon. Vitamin B12 deficiency (Option B): Causes megaloblastic anaemia with hypersegmented neutrophils . Although severe cases may show occasional nucleated RBCs, a true leucoerythroblastic picture with myeloid precursors is not typical. Thalassemia (Option D): Shows microcytosis , target cells , and marked erythroid hyperplasia. Severe forms may show nucleated RBCs, but true leucoerythroblastosis with early myeloid precursors is uncommon, as the marrow is hyperactive rather than infiltrated.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following is not part of the WHO 2022 diagnostic criteria for CMML? (Q889674)

A. Persistent absolute (≥0.5 × 10■/L) and relative (≥10%) peripheral blood monocytosis

B. Blasts constitute <20% in blood and bone marrow

C. Presence of Philadelphia chromosome (BCR::ABL1 fusion)

D. Dysplasia involving ≥1 myeloid lineage

Correct Answer: C. Presence of Philadelphia chromosome (BCR::ABL1 fusion)

Explanation: The presence of the Philadelphia chromosome (BCR::ABL1 fusion) establishes a diagnosis of chronic myeloid leukaemia (CML) and therefore excludes chronic myelomonocytic leukaemia (CMML). According to WHO 2022, CMML requires exclusion of BCR::ABL1-positive CML and other defined myeloproliferative neoplasms. CMML (WHO 2022) - Diagnostic Criteria: Prerequisite Criteria (all must be present): Persistent peripheral blood monocytosis (Option A) Absolute monocyte count ≥ 0.5 × 10■/L Relative monocytes ≥ 10% of leukocytes Blasts < 20% in peripheral blood and bone marrow (Option B) Does not meet criteria for: Chronic myeloid leukaemia (BCR::ABL1-positive) Other myeloproliferative neoplasms (MPNs) Myeloid/lymphoid neoplasms with eosinophilia and defining gene rearrangements (e.g., PDGFRA, PDGFRB, FGFR1, JAK2) Supporting criteria: Dysplasia in ≥1 myeloid lineage (Option D) Acquired clonal cytogenetic or molecular abnormality Abnormal distribution of peripheral blood monocyte subsets Requirements for Diagnosis: If absolute monocytosis ≥ 1 × 10■/L: At least one supporting criterion (dysplasia, clonal abnormality, or abnormal monocyte subsets) must be present. If absolute monocytosis 0.5-<1 × 10■/L: Both dysplasia and an acquired clonal cytogenetic/molecular abnormality must be demonstrated. Subtyping Based on WBC: MD-CMML (Myelodysplastic type): WBC < 13 × 10■/L MP-CMML (Myeloproliferative type): WBC ≥ 13 × 10■/L Subgrouping Based on Blasts (including promonocytes): CMML-1: <5% blasts in peripheral blood <10% in bone marrow CMML-2: 5-19% blasts in peripheral blood 10-19% in bone marrow

References:

https://www.mll.com/en/myelodysplastic-myeloproliferative-neoplasm-mds-mpn/chronic-myelomonocytic-leukemia-cmml

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following findings is not typically present in juvenile myelomonocytic leukaemia (JMML)? (Q889678)

A. Peripheral blood monocytosis ≥1 × 10■/L

B. Blasts <20% in blood and marrow

C. BCR::ABL1 fusion gene

D. Splenomegaly

Correct Answer: C. BCR::ABL1 fusion gene

Explanation: The presence of the BCR::ABL1 fusion gene establishes a diagnosis of chronic myeloid leukaemia (CML) and excludes juvenile myelomonocytic leukaemia (JMML). JMML requires the absence of BCR::ABL1. Diagnostic Criteria for JMML: Category Requirements Key Details 1. Clinical & Laboratory All Required Peripheral blood monocyte count ≥1 × 10■/L (Option A) Blasts/promonocytes <20% (blood & bone marrow) (Option B) Evidence of organ infiltration (splenomegaly) (Option D) Absence of BCR::ABL1 fusion gene Absence of KMT2A rearrangement 2. Genetic Criteria Any 1 Sufficient Canonical RAS pathway variant: PTPN11, KRAS, or NRAS (somatic); NF1 or CBL (with loss of heterozygosity) Noncanonical RAS variant: (e.g.,

RRAS, RRAS2) or fusions activating upstream genes (ALK, PDGFRB, ROS1) 3. Other Criteria 2+ Required* Circulating myeloid and erythroid precursors Increased Haemoglobin F for age Thrombocytopenia with hypercellular bone marrow GM-CSF hypersensitivity (myeloid progenitor cells) *(If no defining genetic mutation identified - at least two required)

References:

https://www.ncbi.nlm.nih.gov/books/NBK602741/table/CDR0000810728__2008/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following numbered conditions are histiocytic and dendritic cell neoplasms? Langerhans Cell Histiocytosis (LCH) Chronic Lymphocytic Leukaemia (CLL) Rosai-Dorfman Disease (RDD) Juvenile Xanthogranuloma (JXG) Erdheim-Chester Disease (ECD) (Q889681)

A. 1, 3, 4, 5

B. 2, 3, 4

C. 1, 2, 5

D. 2, 4, 5

Correct Answer: A. 1, 3, 4, 5

Explanation: Histiocytic & Dendritic Cell Neoplasms are a group of rare neoplasms originating from cells of the mononuclear phagocyte system, including histiocytes (macrophage■like cells) and dendritic cells (antigen■presenting cells). Langerhans Cell Histiocytosis (LCH) Langerhans Cell Sarcoma Indeterminate Dendritic Cell Histiocytosis Juvenile Xanthogranuloma (JXG) Rosai-Dorfman Disease (RDD) Histiocytic Sarcoma Interdigitating Dendritic Cell Sarcoma Erdheim-Chester Disease (ECD) ALK-Positive Histiocytosis Blastic Plasmacytoid Dendritic Cell Neoplasm (BPDCN)

https://www.ncbi.nlm.nih.gov/books/NBK586208/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following conditions is typically not characterised by pancytopenia? (Q889685)

A. Vitamin B12 deficiency

B. Hairy cell leukaemia

C. Hypocellular myelodysplastic syndrome

D. Immune thrombocytopenic purpura (ITP)

Correct Answer: D. Immune thrombocytopenic purpura (ITP)

Explanation: Immune thrombocytopenic purpura (ITP) is characterised by isolated immune-mediated platelet destruction, with normal red cell and white cell counts. Therefore, pancytopenia is not typical. Pancytopenia with Hypocellular Bone Marrow: Acquired aplastic anaemia Constitutional aplastic anaemia (e.g., Fanconi anaemia, dyskeratosis congenita) Hypocellular myelodysplastic syndrome (Option C) Rare aleukemic leukaemia Some acute lymphoid leukaemias Rare lymphomas of bone marrow Copper deficiency Pancytopenia with Cellular Bone Marrow: Primary bone marrow diseases: Myelodysplastic syndromes Paroxysmal nocturnal hemoglobinuria (PNH) Myelofibrosis Aleukemic leukemia Myelophthisis Bone marrow lymphoma Hairy cell leukaemia (Option B) Secondary to systemic diseases: Systemic lupus erythematosus (SLE) Hypersplenism Vitamin B■■ or folate deficiency (Option A) Copper deficiency Alcohol HIV infection Brucellosis Sarcoidosis Tuberculosis Leishmaniasis Sepsis

Q1: A 64-year-old man presents with persistent lymphocytosis on routine blood work. Flow cytometry shows a clonal B-cell population consistent with CLL/SLL. What absolute lymphocyte count (ALC) is required to diagnose CLL rather than SLL? (Q884880)

A. >1,500/mm³

B. >3,000/mm³

C. >5,000/mm³

D. >10,000/mm³

Correct Answer: C. >5,000/mm³

Explanation: An ALC >5,000/mm³ is required to diagnose Chronic Lymphocytic Leukemia. If the count is lower with predominant nodal disease, it is classified as Small Lymphocytic Lymphoma. Chronic Lymphocytic Leukemia / Small Lymphocytic Lymphoma: Same disease entity Differ only by degree of peripheral blood lymphocytosis CLL: Absolute lymphocyte count > 5,000/mm³ SLL: Minimal/no peripheral blood lymphocytosis Epidemiology: Most common adult leukemia in Western countries Median age at diagnosis: ~60 years Male predominance: 2:1

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 543

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: Which of the following genetic alterations represents the central pathogenic event in classic Hodgkin lymphoma? (Q884843)

A. Loss-of-function mutation of IKBα (NFKBIA)

B. Activation of NF-κB

C. Loss-of-function mutation of TNFAIP3 (A20)

D. Copy number gain of the REL proto-oncogene

Correct Answer: B. Activation of NF-κB

Explanation: In classic Hodgkin lymphoma, multiple genetic alterations converge to cause constitutive activation of NF-κB , the central pathogenic driver of Reed-Sternberg cell survival. NF-κB Activation (Central Event): Promotes RS cell growth & survival. Mechanisms: EBV (LMP-1) - mediated activation Loss-of-function mutations in: IκB TNFAIP3 (A20) REL proto-oncogene (2p) copy gain Loss-of-function mutation of IKBα (NFKBIA) (Option A) : IKBα is a negative regulator of NF-κB. Its loss leads to NF-κB activation, but this is a mechanism causing the central event, not the event itself. Loss-of-function mutation of TNFAIP3 (A20) (Option C) : TNFAIP3 is another negative regulator of NF-κB. Mutation results in increased NF-κB signalling, but it is one of several contributing genetic alterations. Copy number gain of the REL proto-oncogene (Option D) : REL enhances NF-κB activity. Its amplification contributes to pathway activation but is not the defining central event.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 557

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A patient with classic Hodgkin lymphoma undergoes cytogenetic analysis. The Reed-Sternberg cells show a recurrent copy number gain on chromosome 2p, contributing to increased NF-κB activity. Which gene is most likely amplified? (Q884845)

A. TNFAIP3

B. NFKBIA

C. REL

D. PD-L1

Correct Answer: C. REL

Explanation: Copy number gain on chromosome 2p in classic Hodgkin lymphoma commonly involves the REL proto-oncogene , enhancing NF-κB signalling. TNFAIP3 (Option A) : Located on chromosome 6; loss-of-function mutation (not amplification) increases NF-κB activity. NFKBIA (Option B) : Encodes IκBα, a negative regulator of NF-κB; typically inactivated, not amplified. PD-L1 (Option D) : Located on chromosome 9p; copy number gain causes immune evasion, not direct NF-κB activation.

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 557

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Reed-Sternberg-like cells (RSLC) are seen in which of the following conditions? Infectious mononucleosis Non-Hodgkin lymphoma Solid tumors Classic Hodgkin lymphoma (Q884847)

A. 1, 2 only

B. 1, 2, 3 only

C. 4 only

D. 1, 2, 3, 4

Correct Answer: B. 1, 2, 3 only

Explanation: Classic Hodgkin lymphoma (cHL) is characterised by true Reed-Sternberg (RS) cells , not Reed-Sternberg-like cells. Correct Answer: B) 1, 2, 3 only

References:

https://pmc.ncbi.nlm.nih.gov/articles/PMC9754675/

https://www.nature.com/articles/modpathol201270

↑ *Back to this question in Part A*

@Neet_pg_bot

Q5: A 28-year-old man presents with a 3-month history of painless cervical lymphadenopathy. He reports sharp pain in the neck nodes within minutes of drinking small amounts of alcohol, which resolves spontaneously. He also has intermittent low-grade fever and night sweats. Which of the following is the most likely diagnosis? (Q884849)

A. Non-Hodgkin lymphoma

B. Metastatic squamous cell carcinoma

C. Hodgkin lymphoma

D. Tuberculous lymphadenitis

Correct Answer: C. Hodgkin lymphoma

Explanation: Hodgkin lymphoma is classically associated with alcohol-induced pain in involved lymph nodes , a rare but highly suggestive symptom. The presence of painless lymphadenopathy, B symptoms (fever, night sweats), and alcohol-triggered nodal pain strongly supports this diagnosis. The pathogenesis is thought to involve alcohol-induced vasodilation and inflammatory mediator release within diseased lymph nodes.

References:

https://pmc.ncbi.nlm.nih.gov/articles/PMC3652965/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which subtype of Hodgkin lymphoma is associated with biphasic incidence? (Q884854)

A. Nodular sclerosis

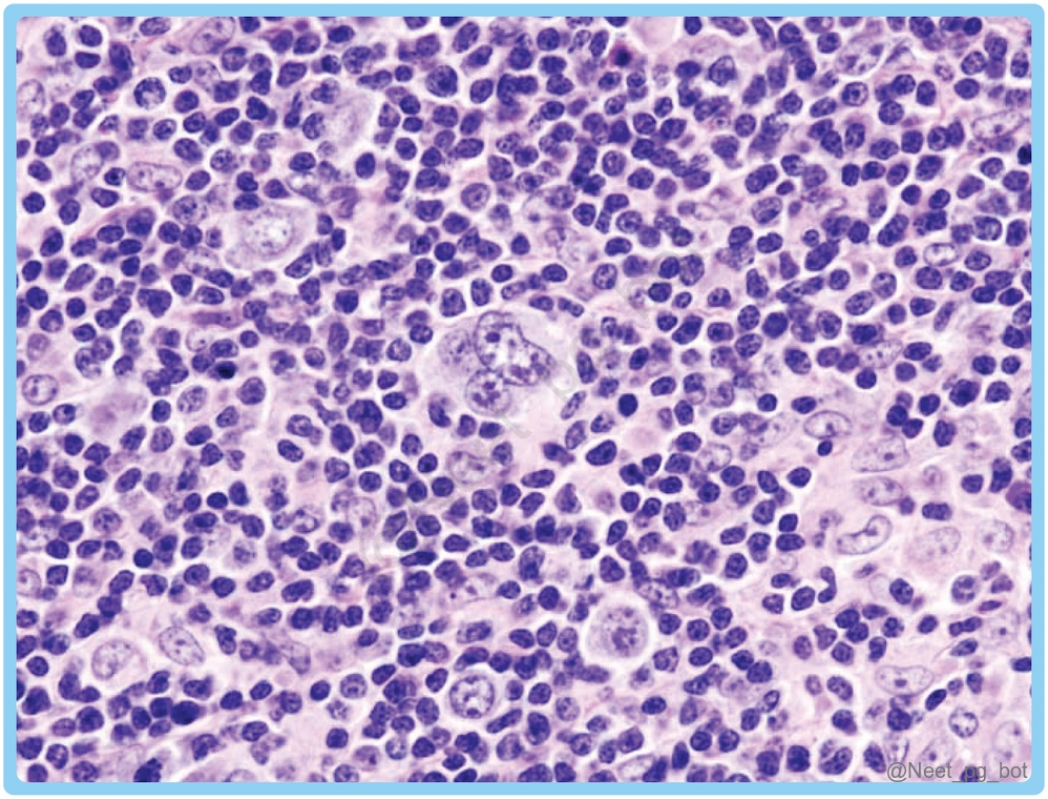
B. Mixed cellularity

C. Lymphocyte-rich

D. Nodular lymphocyte predominant

Correct Answer: B. Mixed cellularity

Explanation: Mixed cellularity Hodgkin lymphoma shows a biphasic age distribution and is often EBV-associated. Mixed Cellularity Hodgkin Lymphoma: Biphasic incidence (young adults & >55 years) More common in males ~70% EBV associated Morphology: Numerous classic Reed–Sternberg cells Mixed inflammatory background (T lymphocytes, eosinophils, plasma cells, macrophages) ■ Immunophenotype: CD15+, CD30+



References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 558

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 65-year-old man presents with fever, weight loss, and generalized lymphadenopathy (Stage III). Lymph node biopsy shows numerous classic Reed–Sternberg cells in a mixed inflammatory background. Which of the following statements regarding this subtype of hodgkin lymphoma is incorrect? (Q884858)

A. It often presents at advanced stage.

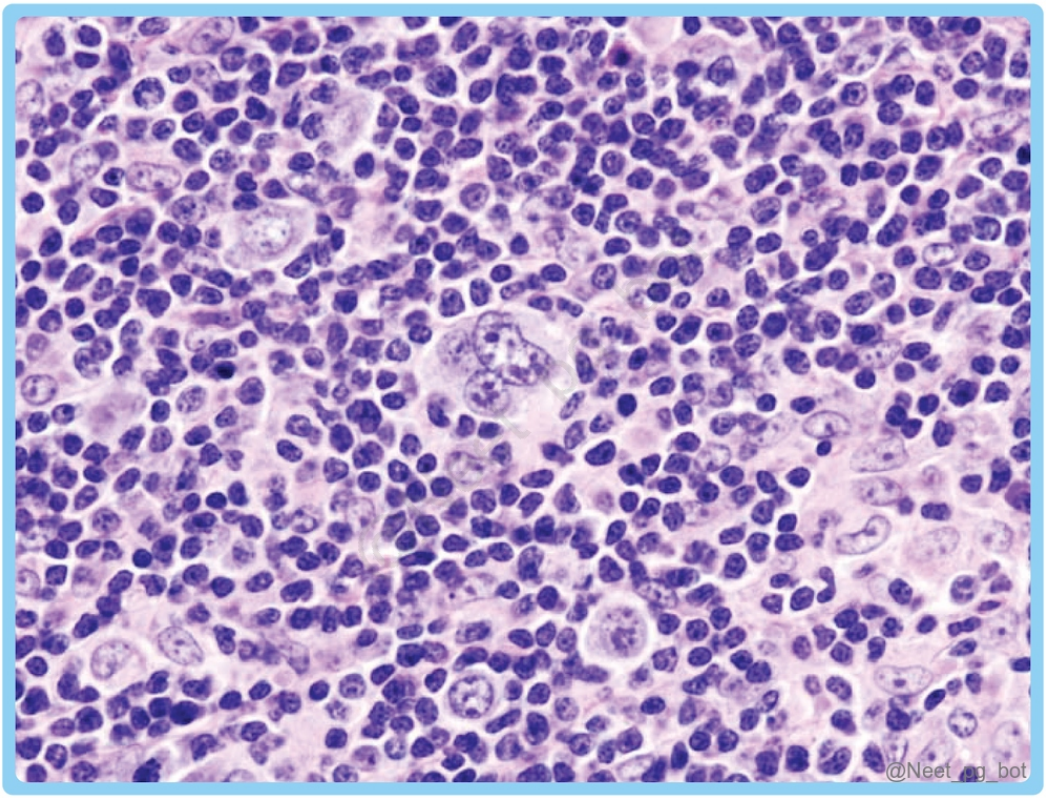
B. EBV positivity is seen in approximately 70% of cases.

C. It accounts for about 20–25% of Hodgkin lymphoma cases.

D. It most commonly presents as a mediastinal mass in young females.

Correct Answer: D. It most commonly presents as a mediastinal mass in young females.

Explanation: The clinical description provided—a 65-year-old man with fever, weight loss, and a biopsy showing Reed–Sternberg cells in a "mixed inflammatory background"—identifies this subtype as Mixed Cellularity Hodgkin Lymphoma (MCHL) . Presenting as a mediastinal mass in young females is the classic clinical hallmark of Nodular Sclerosis Hodgkin Lymphoma (NSHL) , not the Mixed Cellularity subtype. Mixed Cellularity Hodgkin Lymphoma: ~20–25% of Hodgkin lymphoma cases (Option C) Morphology: Diffuse effacement of lymph node Mixed inflammatory "list-style-type:square" aria-level="3">T cells, eosinophils, plasma cells, macrophages Numerous classic Reed–Sternberg cells and mononuclear variants ~70% EBV positive (Option B) Clinical features: More common in males Often older patients Frequently presents with B symptoms (fever, night sweats, weight loss) More likely advanced stage at diagnosis (Option A) Overall prognosis remains very good.



References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 557

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A lymph node biopsy shows a ring of tightly packed small B lymphocytes surrounding a germinal center and displaced outward by it. Which zone is being described? (Q884865)

A. Germinal center

B. Mantle zone

C. Marginal zone

D. Paracortex

Correct Answer: B. Mantle zone

Explanation: The mantle zone consists of tightly packed small naïve B lymphocytes that form a ring around the germinal center and are pushed outward by it. Germinal Centre: (Option A) Round/oval zone containing pale-staining cells surrounded by darker cells Predominantly B lymphocytes Centroblasts (dark zone) Centrocytes (light zone) Scattered follicular T helper (Tfh) cells and T regulatory cells Tingible body macrophages Follicular dendritic cells (FDCs) Mantle zone: Tightly packed small naïve B lymphocytes Surrounds and is pushed outward by the germinal centre Marginal zone: (Option C) Loosely arranged small B lymphocytes with more cytoplasm Located at the outer rim of the mantle zone Contains: Post-follicular memory B cells (T-cell dependent responses) Naïve B cells Often poorly developed in the lymph nodes Paracortex (Option D) : The region between the follicles and the medulla, primarily populated by T lymphocytes and high endothelial venules.

@Neet_pg_bot

Q9: Which of the following is a T-cell neoplasm? (Q884874)

A. Follicular lymphoma

B. Mantle cell lymphoma

C. Anaplastic large-cell lymphoma

D. Burkitt lymphoma

Correct Answer: C. Anaplastic large-cell lymphoma

Explanation: Anaplastic large-cell lymphoma is a T-cell lymphoma (often CD30+). WHO classification of lymphoid neoplasms: Precursor B-cell neoplasm: B-cell acute lymphoblastic leukaemia/lymphoma (B-ALL) Peripheral B-cell neoplasm: Chronic lymphocytic leukaemia/small lymphocytic lymphoma B-cell prolymphocytic leukaemia Lymphoplasmacytic lymphoma Splenic and nodal marginal zone lymphomas Extranodal marginal zone lymphoma Mantle cell lymphoma (Option B) Follicular lymphoma (Option A) Marginal zone lymphoma Hairy cell leukaemia Plasmacytoma/plasma cell myeloma Diffuse large B-cell lymphoma Burkitt lymphoma (Option D) Precursor T-cell neoplasm T-cell acute lymphoblastic leukaemia/lymphoma (T-ALL) Peripheral T-cell and

NK-cell neoplasms T-cell prolymphocytic leukaemia Large granular lymphocytic leukaemia Mycosis fungoides/Sézary syndrome Peripheral T-cell lymphoma, unspecified Anaplastic large-cell lymphoma Angioimmunoblastic T-cell lymphoma Enteropathy-associated T-cell lymphoma Panniculitis-like T-cell lymphoma Hepatosplenic γδ T-cell lymphoma Adult T-cell leukaemia/lymphoma Extranodal NK/T-cell lymphoma NK-cell leukaemia Hodgkin's lymphoma: Classic subtypes Nodular sclerosis Mixed cellularity Lymphocyte-rich Lymphocyte depletion Nodular lymphocyte predominant

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following is the most common site of primary extranodal non-Hodgkin lymphoma? (Q884877)

A. Skin

B. Gastrointestinal tract

C. Central nervous system

D. Bone marrow

Correct Answer: B. Gastrointestinal tract

Explanation: The gastrointestinal tract is the most common site of primary extranodal non-Hodgkin lymphoma. Primary Extranodal Lymphoma (pENL): Lymphoma arising in tissues other than lymph nodes. Most common site: Gastrointestinal Tract - specifically the stomach, followed by the small and large bowel. Other sites: Head/Neck (nasopharynx), Testis, Uterus/Ovary, Thyroid, and CNS. Most common subtype: Diffuse Large B-cell Lymphoma (DLBCL) .

References:

https://pmc.ncbi.nlm.nih.gov/articles/PMC5686961/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 65-year-old man presents with lymphadenopathy and lymphocytosis. Lymph node biopsy & peripheral smear findings are as shown. Which feature is

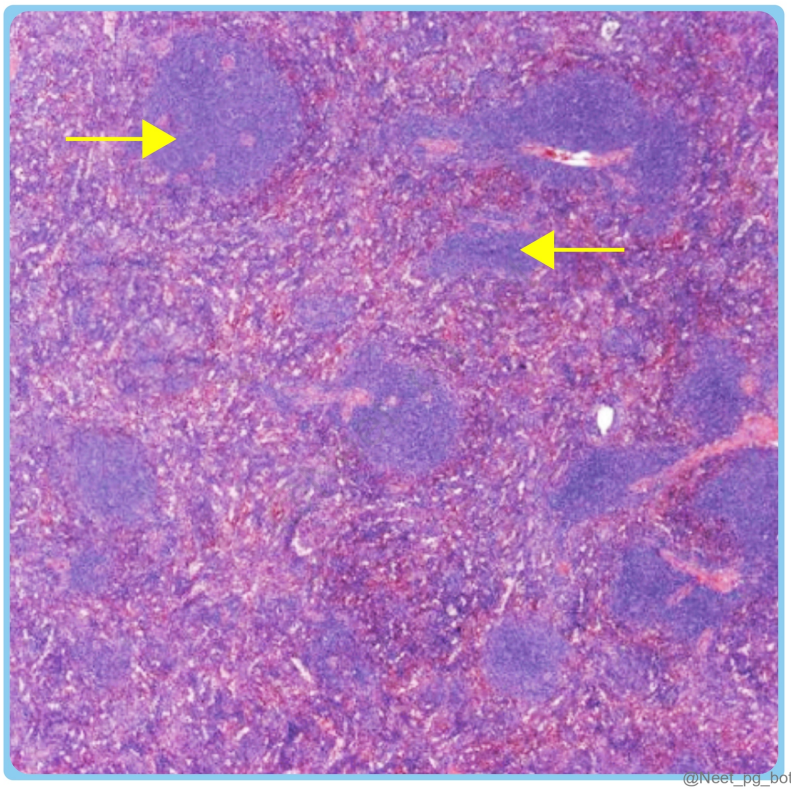
pathognomonic for this condition? (Q884878)

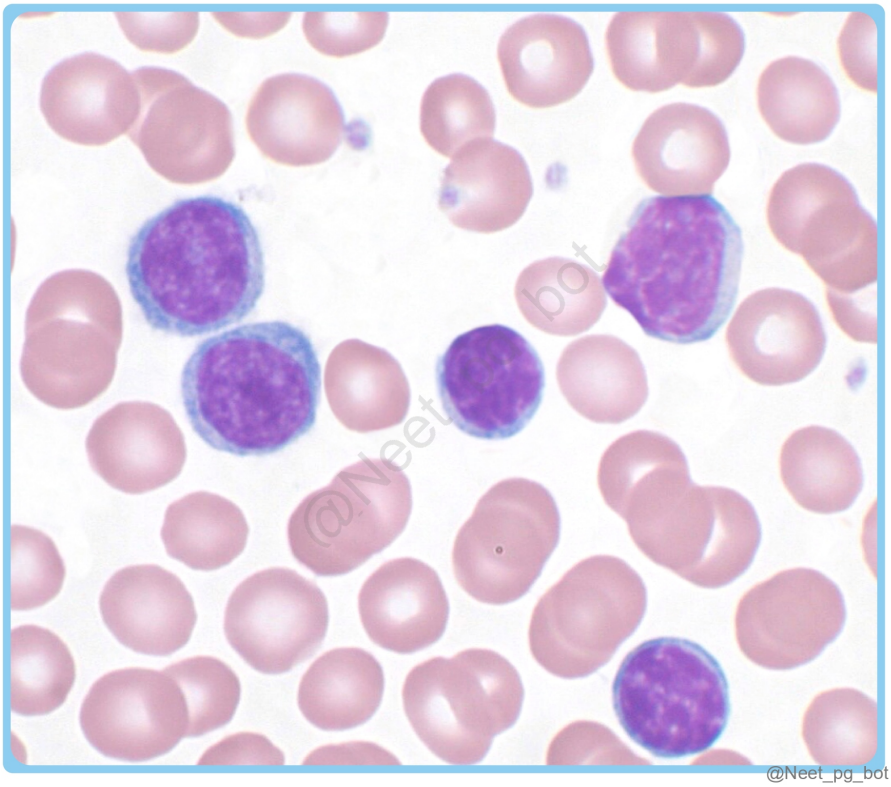
A. Smudge cells

B. Diffuse lymph node effacement

C. Proliferation centres

D. Bone marrow involvement





Correct Answer: C. Proliferation centres

Explanation: Lymph node biopsy shows diffuse sheets of small lymphocytes with scattered pale nodular aggregates of larger activated cells, and the Peripheral smear shows smudge cells. The clinical presentation described (65-year-old male, lymphadenopathy, lymphocytosis, and smudge cells) is classic for Chronic Lymphocytic Leukaemia (CLL) / Small Lymphocytic Lymphoma (SLL) . Proliferation centres are pathognomonic for Chronic Lymphocytic Leukaemia / Small Lymphocytic Lymphoma. Chronic Lymphocytic Leukaemia / Small Lymphocytic Lymphoma (CLL/SLL): Lymph node findings: Diffuse effacement of lymph node architecture Predominantly small lymphocytes (6-12 µm) Round to slightly irregular nuclei Condensed (clumped) chromatin Scant cytoplasm Proliferation centres (pseudofollicles) present: Aggregates of larger activated lymphocytes Contain mitotically active cells Pathognomonic for CLL/SLL Smudge cells (Option A): These are fragile lymphocytes seen on peripheral smear in CLL, but they are not specific and therefore not pathognomonic . Diffuse lymph node effacement (Option B): Although seen in CLL/SLL, diffuse effacement can occur in many other lymphomas , so it is not diagnostic . Bone marrow involvement (Option D): Bone marrow infiltration is common in CLL/SLL, but it is not unique to this disease and therefore not pathognomonic .

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 543

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: What is the most common subtype of Hodgkin lymphoma? (Q884841)

A. Lymphocyte-rich

B. Mixed cellularity

C. Nodular sclerosis

D. Lymphocyte-depleted

Correct Answer: C. Nodular sclerosis

Explanation: The most common subtype of Hodgkin lymphoma is Nodular sclerosis . Nodular Sclerosis Hodgkin Lymphoma (NSHL): Most common subtype (65–70%) Histology: ■■ Lacunar Reed–Sternberg cells Collagen bands → nodular appearance Mixed inflammatory background Immunophenotype markers: Positive: PAX5, CD15, CD30 Negative: CD45, other B/T markers Clinical: Adolescents & young adults Equal M:F Cervical,

supraclavicular, mediastinal nodes EBV: Uncommon association Prognosis: Excellent Lymphocyte-rich (Option A) : Uncommon subtype; characterised by predominance of reactive lymphocytes with few classic Reed–Sternberg cells; very good prognosis. Mixed cellularity (Option B) : Second most common (20–25%); diffuse pattern with numerous RS cells; frequently EBV-associated; more common in older males. Lymphocyte-depleted (Option D) : Least common (<5%); numerous pleomorphic RS cells with paucity of lymphocytes; associated with HIV, elderly patients, advanced stage; poorer prognosis.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 557

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: Which of the following statements about extranodal marginal zone (MALT) lymphoma is correct? (Q884881)

A. t(11;18) translocation makes it antigen-dependent

B. Spreads systemically early

C. May regress if inciting agent is removed

D. Not associated with chronic inflammation

Correct Answer: C. May regress if inciting agent is removed

Explanation: Extranodal MALT lymphoma often develops in chronically inflamed tissues (e.g., H. pylori gastritis) and can regress if the triggering antigen is eliminated. Extranodal MZL (MALToma): Triggers: Chronic inflammation (autoimmune or infection) Salivary gland – Sjögren syndrome Thyroid – Hashimoto thyroiditis Stomach – H. pylori gastritis Features: Localized disease for long periods (Option B) May regress if trigger removed Pathogenesis: Reactive Phase: Begins as polyclonal lymphoid hyperplasia due to chronic antigenic stimulation. Early Neoplastic Phase: Emergence of a monoclonal B-cell population Still antigen-dependent Tumor may regress if antigen is removed Antigen-Independent Phase: (Option A) Chromosomal translocations (t(11;18), t(14;18), t(1;14)) These upregulate BCL10 or MALT1 Activation of NF-κB pathway → promotes B-cell survival and proliferation Advanced Disease: Systemic spread Possible transformation to Diffuse Large B-Cell Lymphoma (DLBCL)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 548, 549

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Marginal zone lymphoma primarily arises from which type of B cell? (Q884882)

A. Naïve B cells

B. Memory B cells

C. Plasma cells

D. Pre-B cells

Correct Answer: B. Memory B cells

Explanation: Marginal zone lymphomas originate from memory B cells , often showing somatic hypermutation. Sites: Lymph nodes, spleen, extranodal (MALT)

References:

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 548

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Extranodal marginal zone (MALT) lymphoma is commonly associated with which of the following conditions? Sjögren syndrome Hashimoto thyroiditis Helicobacter pylori gastritis (Q884884)

A. 1 and 2 only

B. 2 and 3 only

C. 1 and 3 only

D. 1, 2, and 3

Correct Answer: D. 1, 2, and 3

Explanation: Extranodal Marginal Zone (MALT) Lymphoma is fundamentally a malignancy that arises in the context of chronic persistent inflammation . This inflammation can be triggered by either autoimmune disorders or chronic infections, which provide the stimulus for B-cell proliferation. Extranodal MZL (MALToma): Triggers: Chronic inflammation (autoimmune or infection) Salivary gland - Sjögren syndrome Thyroid - Hashimoto thyroiditis Stomach - H. pylori gastritis Features: Localized disease for long periods May regress if trigger removed

@Neet_pg_bot

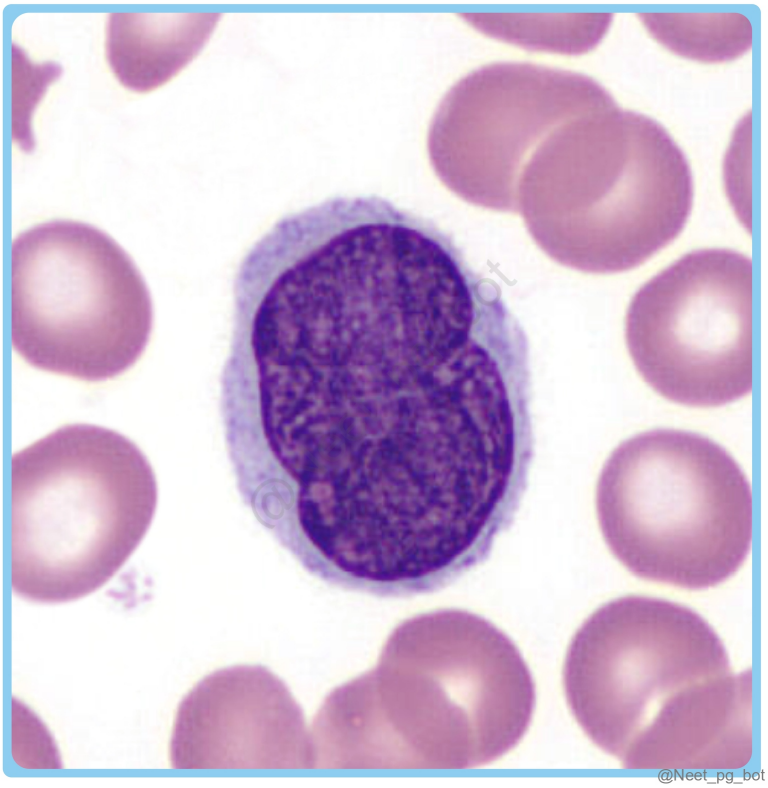
Q16: A 62-year-old man presents with generalized exfoliative erythroderma and intense pruritus. Examination reveals diffuse lymphadenopathy. Peripheral blood smear shows findings as shown. Skin biopsy demonstrates dermal infiltration by atypical CD4■ T cells. What is the most likely diagnosis? (Q884885)

A. Sézary syndrome

B. Mycosis fungoides

C. Peripheral T-cell lymphoma

D. Adult T-cell leukemia/lymphoma



Correct Answer: A. Sézary syndrome

Explanation: The most likely diagnosis is B. Sézary syndrome. It presents with the triad of generalized erythroderma, lymphadenopathy, and circulating malignant T cells (Sézary cells) with cerebriform nuclei in peripheral blood (leukemic phase). Sezary syndrome: Generalized exfoliative erythroderma Leukemia of Sézary cells (cerebriform nuclei) Generalized lymphadenopathy Skin lesions rarely form tumors Prognosis: More aggressive than MF Poorer survival (minority alive at 5 years) Mycosis fungoides (Option A) : Typically presents with patch/plaque/tumor stages confined mainly to skin early; leukemic involvement is not a defining early feature. Peripheral T-cell lymphoma (Option C) : Usually presents with nodal/systemic disease without characteristic erythroderma and circulating Sézary cells. Adult T-cell leukemia/lymphoma (Option D) : Associated with HTLV-1 infection and commonly presents with hypercalcemia and systemic disease rather than classic erythroderma with Sézary cells.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Pages 551, 552

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: A 60-year-old woman with rheumatoid arthritis presents with recurrent infections. She has splenomegaly and neutropenia. Peripheral smear shows large lymphocytes with azurophilic granules. Cells are CD3■. What is the most likely diagnosis? (Q884888)

A. Chronic lymphocytic leukemia

B. Hairy cell leukemia

C. Large granular lymphocytic leukemia

D. Sézary syndrome

Correct Answer: C. Large granular lymphocytic leukemia

Explanation: The most likely diagnosis is Large granular lymphocytic (LGL) leukemia . It classically presents in adults with rheumatoid arthritis (Felty-like association), neutropenia, splenomegaly, and large granular CD3■ T lymphocytes with azurophilic granules on peripheral smear. Large Granular Lymphocytic (LGL) Leukemia: Types: T-cell (CD3■) - more common, indolent NK-cell (CD3■, CD56■) - more aggressive Age: Adults Key Mutation: STAT3 mutation (30–40%) → cytokine-independent activation Morphology: Large lymphocytes Pale cytoplasm with azurophilic granules Clinical features: Neutropenia (common) Anemia ± pure red cell aplasia Splenomegaly Strong association with autoimmune disorders (e.g., Felty syndrome) Clonal cytotoxic T/NK-cell proliferation → prominent cytopenias + autoimmunity. Chronic lymphocytic leukemia (Option A) : Characterized

by small mature lymphocytes with smudge cells, not large granular cells. Hairy cell leukemia (Option B) : Shows cells with cytoplasmic “hairy” projections and marked pancytopenia with massive splenomegaly. Sézary syndrome (Option D) : Presents with erythroderma and circulating cerebriform T cells, not granular cytotoxic lymphocytes.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 552

↑ *Back to this question in Part A*

@Neet_pg_bot

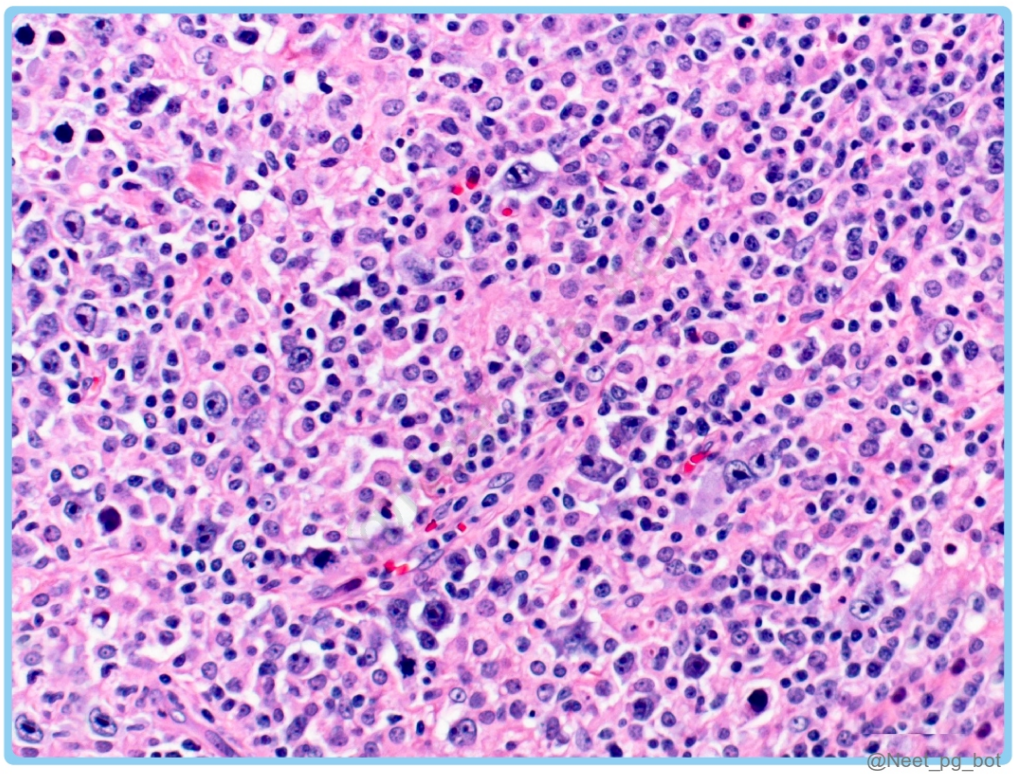
Q18: A 70-year-old man presents with fever, weight loss, and rapidly enlarging lymph nodes. Biopsy shows diffuse sheets of large CD20+ B cells. EBER in situ hybridisation is positive in tumour cells. What is the most likely diagnosis? (Q884909)

A. Epstein-Barr virus-positive diffuse large B-cell lymphoma

B. Classic Hodgkin lymphoma

C. Burkitt lymphoma

D. Angioimmunoblastic T-cell lymphoma



Correct Answer: A. Epstein-Barr virus-positive diffuse large B-cell lymphoma

Explanation: The most likely diagnosis is Epstein-Barr virus-positive diffuse large B-cell lymphoma (EBV+ DLBCL) . The patient has an aggressive large B-cell lymphoma (CD20 positive) with strong EBER positivity, indicating EBV-driven disease. The activated B-cell phenotype and presentation in an older adult with B symptoms are characteristic. Epstein-Barr virus-positive diffuse large B-cell lymphoma (EBV+ DLBCL) : A subtype of Diffuse Large B-Cell Lymphoma associated with Epstein–Barr virus (EBV). Occurs in both elderly and younger patients ~2–14% of DLBCL cases. More common in older adults. Slight male predominance. Pathogenesis: EBV infects B cells → viral proteins (e.g., LMP1) activate the NF-κB pathway. Usually shows an activated B-cell (ABC) phenotype. Most cases exhibit the EBV latency II pattern. Clinical features: Rapid lymphadenopathy. B symptoms (fever, weight loss, night sweats). Often advanced stage with extranodal involvement. Diagnosis: Lymph node biopsy. EBV detection by EBER in situ hybridisation. Treatment: Treated with standard R-CHOP–based chemotherapy. Response may be inferior to EBV-negative DLBCL. Prognosis: Generally poorer than EBV-negative DLBCL. High EBV load may indicate a worse outcome. Classic Hodgkin lymphoma (Option B) : Reed–Sternberg cells (CD15+, CD30+), not diffuse CD20+ sheets. Burkitt lymphoma (Option C) : MYC translocation, starry-sky pattern, very high Ki-67. Angioimmunoblastic T-cell lymphoma (Option D) : T-cell (CD3+) neoplasm, not B-cell.

https://www.ncbi.nlm.nih.gov/books/NBK578250/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 62-year-old man is newly diagnosed with diffuse large B-cell lymphoma. The clinician plans to calculate the International Prognostic Index (IPI) score to assess prognosis. Which of the following are included in the IPI score? Age >60 years Elevated serum lactate dehydrogenase (LDH) Presence of B symptoms ECOG performance status ≥2 More than one extranodal site (Q884910)

A. 1, 2, 3

B. 1, 2, 4, 5

C. 2, 3, 4

D. 1, 3, 5

Correct Answer: B. 1, 2, 4, 5

Explanation: The International Prognostic Index (IPI) includes five clinical variables: Age > 60 years Ann Arbor Stage III or IV disease Serum LDH above the upper limit of normal ECOG Performance Status ≥ 2 >1 extranodal site of involvement

References:

https://pmc.ncbi.nlm.nih.gov/articles/PMC10620582/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 70-year-old man with a 5-year history of chronic lymphocytic leukaemia develops rapidly enlarging lymph nodes, fever, weight loss, and elevated LDH. Lymph node biopsy shows diffuse large B-cell lymphoma. What is the most likely diagnosis? (Q884911)

A. Progressive CLL

B. Richter syndrome

C. Prolymphocytic transformation

D. Hodgkin lymphoma

Correct Answer: B. Richter syndrome

Explanation: The most likely diagnosis is Richter syndrome (also known as Richter transformation). An important factor affecting survival in chronic lymphocytic leukaemia / small lymphocytic lymphoma (CLL/SLL) is its ability to transform into a more aggressive malignancy. Most common transformation: Transformation to Diffuse Large B-Cell Lymphoma (DLBCL) Known as Richter syndrome Occurs in approximately 5–10% of patients with CLL/SLL Associated with rapid clinical deterioration (Most survive < 2 years) Markedly worse prognosis compared to typical CLL Progressive CLL (Option A) : Shows gradual progression, not transformation to DLBCL. Prolymphocytic transformation (Option C) : Characterised by increased circulating prolymphocytes, not DLBCL. Hodgkin lymphoma (Option D) : Rare transformation variant; biopsy would show Reed-Sternberg cells.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 544

↑ *Back to this question in Part A*

@Neet_pg_bot

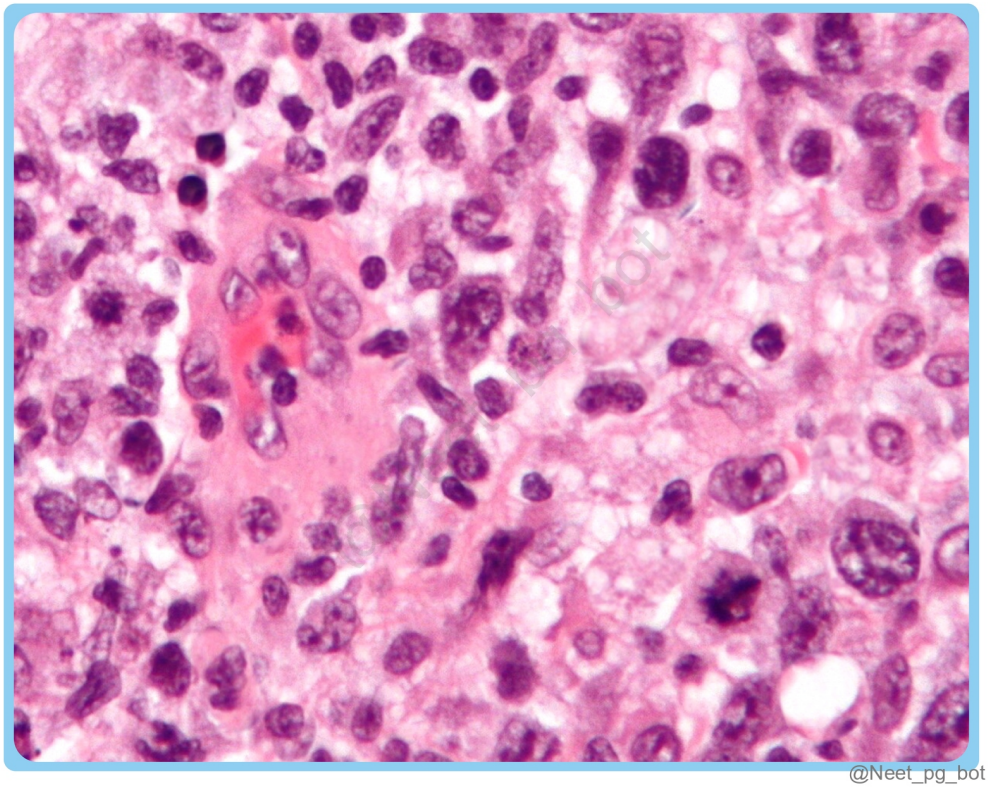
Q21: A 15-year-old boy presents with painless lymphadenopathy. Biopsy shows findings as shown. Tumour cells are CD30 positive and ALK positive. What is the most likely diagnosis? (Q884912)

A. Diffuse large B-cell lymphoma

B. Classical Hodgkin lymphoma

C. Anaplastic large-cell lymphoma

D. Adult T-cell leukaemia/lymphoma



Correct Answer: C. Anaplastic large-cell lymphoma

Explanation: The most likely diagnosis is Anaplastic large-cell lymphoma (ALCL) . The image showing large cells with horseshoe-shaped or kidney-shaped nuclei is the definitive morphological feature of ALCL. Anaplastic large cell lymphoma: Caused by ALK gene rearrangement (2p23) → ALK fusion protein Constitutive tyrosine kinase activation → RAS & JAK/STAT signalling IHC: ALK positive, CD30 positive Morphology: Large anaplastic cells Characteristic “hallmark cells” : Horseshoe / embryoid nuclei Abundant cytoplasm Tumour cells may cluster around venules Can mimic metastatic carcinoma Common in children & young adults Often involves lymph nodes and soft tissues Prognosis: Good prognosis Cure rate with chemotherapy: 75-80% ALK inhibitors are effective in refractory cases ALK-negative type: Occurs in older adults Worse prognosis Also CD30 positive Lacks ALK rearrangement Diffuse large B-cell lymphoma (Option A) : Typically CD20 positive (B-cell markers) and ALK negative; lacks hallmark cells. Classical Hodgkin lymphoma (Option B) : CD30 positive but ALK negative; shows Reed-Sternberg cells. Adult T-cell leukaemia/lymphoma (Option D) : Associated with HTLV-1 infection and does not show ALK positivity or hallmark cells.

Robbins, Cotran & Kumar, Pathologic Basis of Disease, 11th Edition, Page 551

↑ *Back to this question in Part A*

@Neet_pg_bot

Q22: Match the following lymphomas with their cell of origin. Lymphoma/leukaemia Cell of origin 1. Diffuse large B-cell lymphoma a. Memory B-cell 2. Mantle cell lymphoma b. Germinal/post germinal center B cell 3. Hairy cell lymphoma c. Helper T-cell 4. Mycosis fungoides d. Naive B cell (Q845823)

A. 1-b, 2-a, 3-c, 4-d

B. 1-a, 2-b, 3-d, 4-c

C. 1-d, 2-a, 3-d, 4-c

D. 1-b, 2-d, 3-a, 4-c

Correct Answer: D. 1-b, 2-d, 3-a, 4-c

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Neoplasm Cell of origin Description Diffuse large B-cell lymphoma (Statement 1) Germinal/post-germinal center B cells Most common NHL. Associated with BCL6 gene rearrangement If CLL transforms into DLBCL, it is called Richter's Syndrome. Hairy cell leukemia (Statement 3) Memory B cells More common in boys. BRAF V600E Mutation + It presents with massive splenomegaly affecting the red pulp of the spleen. Mantle cell lymphoma (Statement 2) Naive B cell Translocation t(11:14). Associated with GIT polyps. Cyclin D1 and SOX11 +ve, Mycosis Fungoides (Statement 4) Helper T cells Cutaneous T-cell NHL. presents with erythema and pruritus. If it affects the blood vessels, it is known as Sezary syndrome.

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Pages 594-595

↑ *Back to this question in Part A*

@Neet_pg_bot

Q23: In the WHO classification of Hodgkin lymphoma, which marker is typically expressed in classical Hodgkin lymphoma? (Q845792)

A. CD20

B. CD15

C. CD45

D. BCL-6

Correct Answer: B. CD15

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The CD15 marker is typically expressed by Reed-Sternberg cells in classical Hodgkin lymphoma, aiding in its identification and diagnosis. WHO Classification of Hodgkin lymphoma: 1. Classical Hodgkin Lymphoma (CHL) Nodular Sclerosis Hodgkin Lymphoma Mixed Cellularity Hodgkin Lymphoma Lymphocyte-Rich Hodgkin Lymphoma Lymphocyte-Depleted Hodgkin Lymphoma 2. Non-classical lymphoma: Nodular Lymphocyte-Predominant Hodgkin Lymphoma (NLPHL) CD20, CD45, and BCL-6 are expressed in Non-classical Nodular Lymphocyte-Predominant Hodgkin Lymphoma. (Option A,C,D)

References:

Robbin's and Cotran, Pathological Basis of Disease,10th Edition, Page 611

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: Match the following characteristic cells with their corresponding histopathological variant of Hodgkin lymphoma: Cells A) Popcorn cells B) Lacunar cells C) Mononuclear cells D) Reed-Sternberg cells Histopathology 1. Classical Hodgkin Lymphoma (general type) 2.Mixed Cellularity Classical Hodgkin Lymphoma 3. Nodular Sclerosis Classical Hodgkin Lymphoma 4. Nodular Lymphocyte Predominant Hodgkin Lymphoma (Q845796)

A. A-4, B-3, C-2, D-1

B. A-1, B-4, C-3, D-2

C. A-3, B-2, C-1, D-4

D. A-4, B-1, C-2, D-3

Correct Answer: A. A-4, B-3, C-2, D-1

Explanation: Cells Histopathological variants of Hodgkin's Lymphoma Mononuclear cells (Option C) Single nucleus with a large, inclusion-like nucleolus with abundant cytoplasm. Seen in Mixed Cellularity Hodgkin Lymphoma Popcorn cells (Option A) Cells with multiple infolded nuclear membranes, small nucleoli, fine

chromatin, and abundant pale cytoplasm. Seen in Nodular lymphocyte - Predominant Hodgkin lymphoma. Reed-sternberg cell (Option D) It is characterised by two nuclear lobes, large inclusion-like nucleoli, and abundant cytoplasm and is typically surrounded by lymphocytes, macrophages, and an eosinophil. Classic Hodgkin Lymphoma (general type) Lacunar cells (Option B) Typically found in the nodular sclerosis subtype. Nuclei are more delicate, folded, or multilobate. Abundant pale cytoplasm often gets disrupted during sectioning, creating an appearance where the nucleus sits in an empty space (lacuna).

Robbin’s and Cotran Pathological Basis of Disease, 10th Edition, Page 612

↑ *Back to this question in Part A*

@Neet_pg_bot

Q25: A 28-year-old female presents with painless swelling in her neck and shortness of breath. Imaging studies reveal a large mediastinal mass. A biopsy of the lymph node shows frequent lacunar cells and Reed-Sternberg cells. The RS cells are positive for CD15 and CD30 and usually negative for EBV. Which subtype of Hodgkin's lymphoma is most likely? (Q845799)

A. Nodular Sclerosis Classical Hodgkin Lymphoma

B. Nodular Lymphocyte-Predominant Hodgkin Lymphoma

C. Lymphocyte-Rich Classical Hodgkin Lymphoma

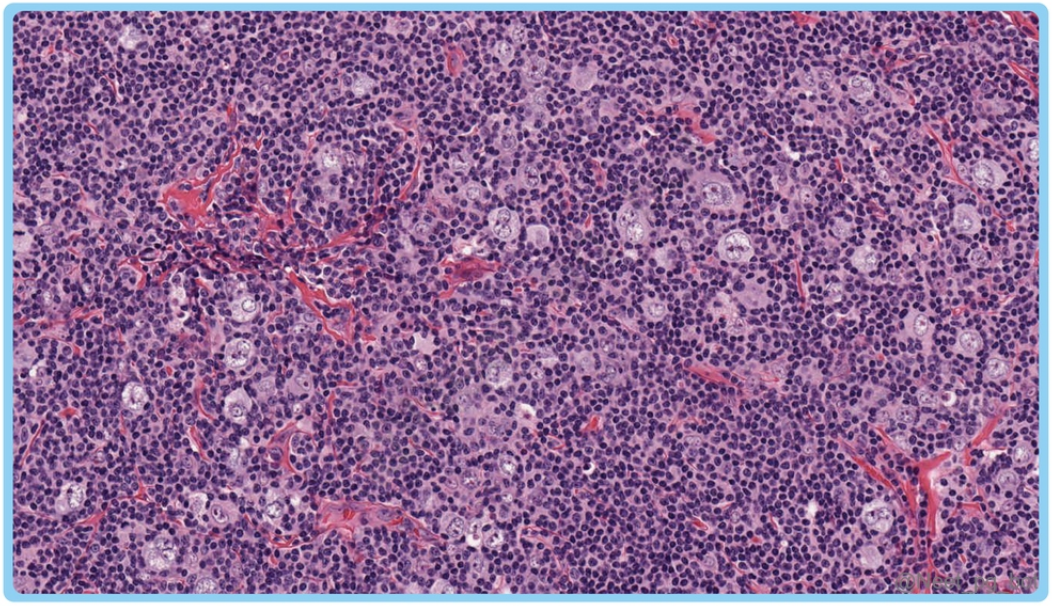
D. Lymphocyte-depleted classical Hodgkin Lymphoma

Correct Answer: A. Nodular Sclerosis Classical Hodgkin Lymphoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical scenario points towards diagnosing Nodular Sclerosis type of Classical Hodgkin Lymphoma which features characteristic Lacunar variant Reed-Sternberg cells and collagen deposition in lymph nodes. Its background includes T cells, eosinophils, plasma cells, and macrophages, with occasional diagnostic Reed-Sternberg cells, which express PAX5, CD15, and CD30. Spread may involve spleen, liver, and bone marrow, infrequently associated with Epstein-Barr virus. Occurring equally in males and females, it commonly affects lower cervical, supraclavicular, and mediastinal lymph nodes in adolescents or young adults and has an excellent prognosis. Nodular Lymphocyte-Predominant Hodgkin Lymphoma (Option B) is characterised by a background of follicular dendritic cells and reactive B cells, with frequent lymphocyte-rich (Popcorn cell) variants, typically does not express CD15 or CD30 and is usually EBV-negative. Lymphocyte-Rich Classical Hodgkin Lymphoma (Option C) is characterised by a background infiltrate rich in T lymphocytes, with frequent mononuclear and diagnostic RS cells. RS cells of this type typically express CD15 and CD30 and are usually EBV-negative. Lymphocyte-Depleted Classical Hodgkin Lymphoma (Option D) has a paucity of background reactive cells and frequent diagnostic RS cells. RS cells in lymphocyte-depleted classical Hodgkin lymphoma typically express CD15 and CD30 and are usually EBV-positive. It often presents with advanced disease.



References:

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 612

↑ *Back to this question in Part A*

@Neet_pg_bot

Q26: A 35-year-old male presents with painless swelling of multiple lymph nodes, fever, night sweats, and weight loss. A biopsy of the affected lymph node reveals the presence of Reed-Sternberg cells. Which of the following options regarding Mixed cellularity type Hodgkin’s Lymphoma is not true? (Q845800)

A. It is characterised by frequent mononuclear and diagnostic Reed-Sternberg (RS) cells.

B. RS cells in this subtype typically express CD15 and CD30.

C. More than 70% of cases are Epstein-Barr virus (EBV) positive.

D. It is usually associated with a better prognosis than other subtypes of Hodgkin’s lymphoma.

Correct Answer: D. It is usually associated with a better prognosis than other subtypes of Hodgkin’s lymphoma.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Mixed Cellularity Hodgkin's Lymphoma often presents at an advanced stage (III or IV), which is generally associated with a worse prognosis compared to the Nodular Sclerosis subtype, which typically presents at an earlier stage (I or II) and has a relatively better prognosis. Mixed-Cellularity Hodgkin Lymphoma (MCHL) accounts for 20% to 25% of cases and features lymph nodes diffusely effaced by a heterogeneous cellular infiltrate, including T cells, eosinophils, plasma cells, and macrophages, along with abundant Reed-Sternberg and mononuclear variants. (Option A) Approximately 70% of Reed-Sternberg cells are EBV-positive. (Option B) RS cells are CD15+, CD30+ (Option C) MCHL is more prevalent in males and is more likely to be associated with systemic symptoms such as night sweats and weight loss.

References:

Robbin's and Cotran, Pathological Basis of Disease, 10th Edition, Page 612

↑ *Back to this question in Part A*

@Neet_pg_bot

Q27: A 32-year-old male presents with painless lymphadenopathy in the cervical region. A biopsy reveals the presence of numerous small lymphocytes with scattered large mononuclear Hodgkin and Reed-Sternberg cells, which are CD20 positive and CD15/CD30 negative. Which subtype of Hodgkin's lymphoma is most consistent with these findings? (Q845805)

A. Nodular sclerosis Hodgkin lymphoma

B. Mixed cellularity Hodgkin lymphoma

C. Nodular Lymphocyte-predominant Hodgkin lymphoma

D. Lymphocyte-depleted Hodgkin lymphoma

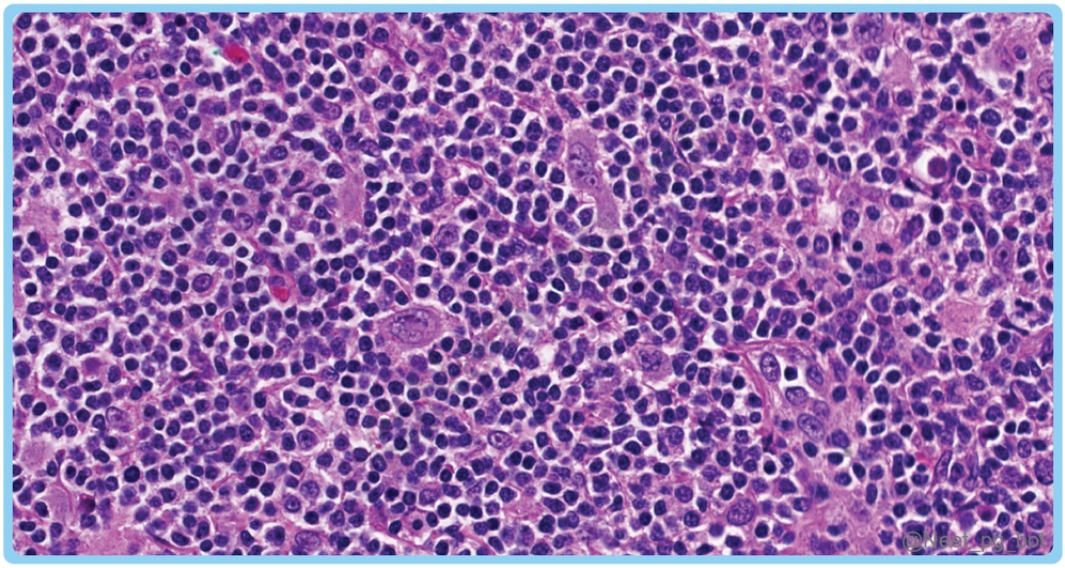
Correct Answer: C. Nodular Lymphocyte-predominant Hodgkin lymphoma

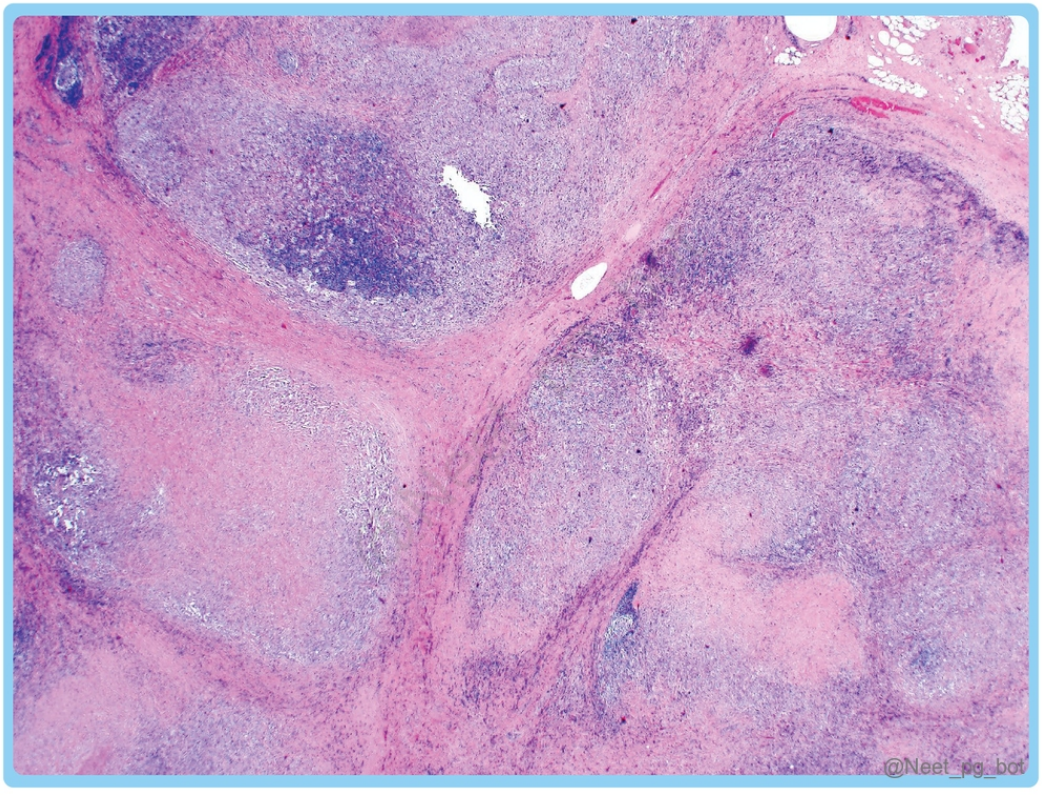
■ *Listen (English)*

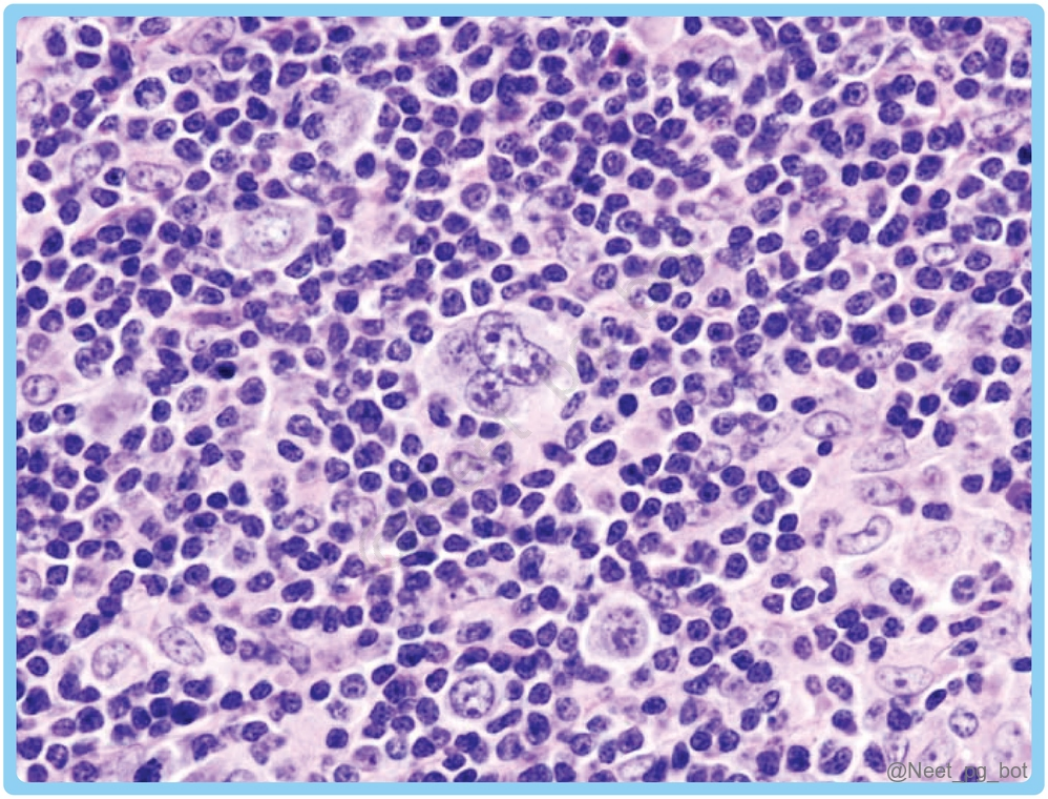
■ *Listen (Hindi)*

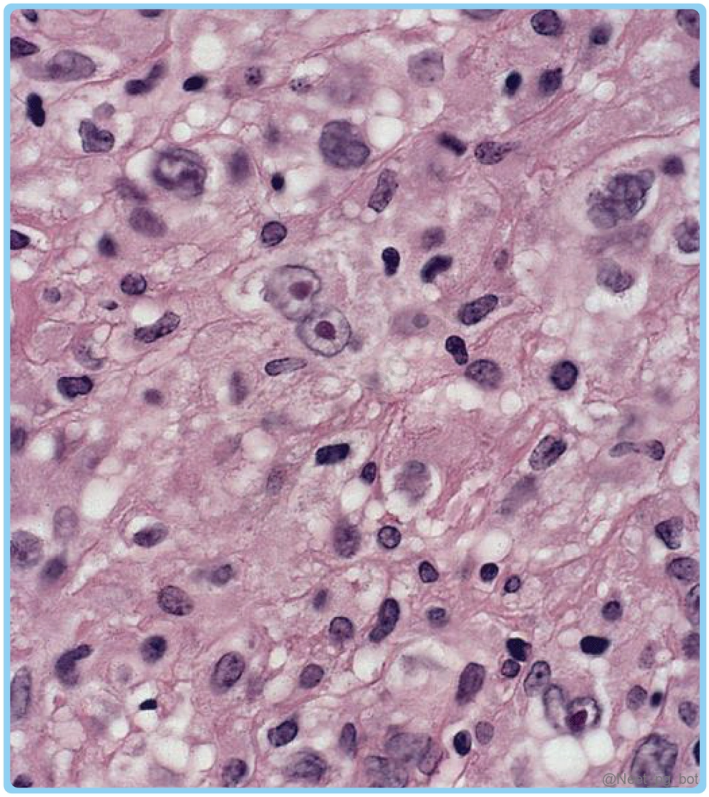
Explanation: ■■■■■■■ Histological Features: Nodular Lymphocyte-predominant Hodgkin lymphoma is characterised by a predominance of reactive lymphocytes with relatively few Reed-Sternberg (RS) cells. Immunophenotype: The RS cells are typically positive for CD20 and negative for CD15 and CD30 , distinguishing it from other subtypes of Hodgkin lymphoma. Clinical Presentation: Patients often present with painless lymphadenopathy, commonly in peripheral lymph nodes rather than mediastinal involvement. Prognosis: This subtype generally has a favourable prognosis compared to other types of Hodgkin lymphoma due to its lower aggressiveness and higher responsiveness to treatment. Nodular sclerosis Hodgkin lymphoma (Option A) is the most common subtype, characterised by the presence of lacunar Reed-Sternberg cells and fibrous bands that divide the lymphoid tissue into nodules. These cells are usually positive for CD15 and CD30 but negative for CD20. Mixed cellularity Hodgkin lymphoma (Option B) features a heterogeneous mixture of cells, including

Reed-Sternberg cells, lymphocytes, eosinophils, neutrophils, and plasma cells. These cells are typically CD15 and CD30 positive but negative for CD20. Lymphocyte-depleted Hodgkin lymphoma (Option D) is the least common subtype and is characterised by a paucity of lymphocytes and a high number of pleomorphic, often bizarre Reed-Sternberg cells. These cells are usually CD15 and CD30 positive but negative for CD20 and associated with a poorer prognosis









References:

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 613

↑ *Back to this question in Part A*

@Neet_pg_bot

Q28: A 65-year-old male with a history of HIV presents with fever, night sweats, and weight loss. A lymph node biopsy was done. Immunohistochemical staining shows these cells are CD15 and CD30 positive but CD20 negative. He was diagnosed with Lymphocyte-depleted Hodgkin's lymphoma. Which of the following features is characteristic of lymphocyte-depleted Hodgkin's lymphoma? (Q845806)

A. Presence of fibrous bands

B. Abundance of reactive lymphocytes

C. High number of Reed-Sternberg cells

D. Predominance of nodular growth pattern

Correct Answer: C. High number of Reed-Sternberg cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Lymphocyte-depleted Hodgkin's lymphoma Histological Features: LDHL is characterised by a scarcity of lymphocytes and many pleomorphic, often bizarre Reed-Sternberg (RS) cells. The cellular environment is typically rich in fibrosis or necrosis. Presence of fibrous bands (Option A) it is characteristic of nodular sclerosis Hodgkin's lymphoma, not LDHL. Nodular sclerosis is marked by the presence of fibrous bands that divide the lymph node into nodules. Abundance of reactive lymphocytes (Option B) it is typical of lymphocyte-rich Hodgkin's lymphoma, a subtype characterised by an abundance of small, reactive lymphocytes and relatively few Reed-Sternberg cells. Predominance of nodular growth pattern (Option D) it is associated with nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL), not LDHL. It is characterised by a nodular growth pattern and the presence of "popcorn" or lymphocyte-predominant cells,

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 614

↑ *Back to this question in Part A*

@Neet_pg_bot

Q29: A 35-year-old male presents with painless enlargement of cervical lymph nodes, accompanied by fever, night sweats, and weight loss. Biopsy reveals large, atypical cells with prominent nucleoli and a mixed inflammatory background. Immunohistochemical staining shows these cells are negative for CD15 and CD30. Which marker is most likely to be positive in these cells? (Q845807)

A. CD20

B. CD3

C. CD15

D. CD30

Correct Answer: A. CD20

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Predominant (Non-Classical) Hodgkin Lymphoma: Histological Features: Predominant (Non-Classical) Hodgkin Lymphoma is characterised by large, atypical cells with prominent nucleoli and a mixed inflammatory background. Immunophenotype: The atypical cells in this subtype typically lack expression of CD15 and CD30 but are positive for CD20 and CD45 markers, distinct from classical Hodgkin lymphoma. Clinical Presentation: painless lymphadenopathy, fever, night sweats, and weight loss, similar to classical Hodgkin lymphoma Prognosis: overall survival rates may be lower compared to classical Hodgkin lymphoma. Epidemiology: Less common than classical Hodgkin lymphoma and may occur in younger and older adults. CD3 (Option B) is a marker of mature T lymphocytes and is not typically expressed by the large, atypical cells seen in Predominant (Non-Classical) Hodgkin's lymphoma CD15 and CD 30 (Option C) and (Option D) are markers commonly expressed on Reed-Sternberg cells in classical Hodgkin's lymphoma but is typically negative in predominantly (Non-Classical) Hodgkin's lymphoma

References:

Robbin's and Cotran, Pathological Basis of Disease, 10th Edition, Page 611

↑ *Back to this question in Part A*

@Neet_pg_bot

Q30: A 45-year-old male presents with painless swelling of multiple lymph nodes in his neck and groin. He denies experiencing fever, night sweats, or weight loss. Physical examination reveals bilateral cervical and inguinal lymphadenopathy. Based on the Ann Arbor classification, what is this patient's most likely stage of disease? (Q845808)

A. Stage I

B. Stage II

C. Stage III

D. Stage IV

Correct Answer: C. Stage III

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Based on the Ann Arbor classification, Stage III involves lymph node regions on both sides of the diaphragm , corresponding to the presentation of bilateral cervical and inguinal lymphadenopathy in this patient. Clinical Staging of Hodgkins Lymphoma (Ann Arbor Classification) STAGE DISTRIBUTION OF DISEASE I Involvement of a single lymph node region (I) or a single extra lymphatic organ or site (IE). II Involvement of two

or more lymph node regions on the same side of the diaphragm alone (II) or localised involvement of an extra lymphatic organ or site (IIE). III Involvement of lymph node regions on both sides of the diaphragm without (III) or with (IIIE) localised involvement of an extra lymphatic organ or site. IV Diffuse involvement of one or more extra lymphatic organs or sites with or without lymphatic involvement. All stages are further divided based on the absence (A) or presence (B) of the following symptoms: unexplained fever, drenching night sweats, and/or unexplained weight loss of greater than 10% of normal body weight. Lugano Classification for Non-Hodgkins Lymphoma: Ann Arbor applies to both Hodgkin and non-Hodgkin lymphomas, but Lugano (2014 update) refines it with PET-CT emphasis and similar stage definitions. Lugano stage III: Nodes or spleen on both diaphragm sides. Key similarity: Diaphragm divides stages II/III; Lugano adds "bulky" for large masses >10 cm. Stage Description I One node or group of adjacent nodes (single site). IE Single extranodal lesion without nodal involvement. II ≥2 nodal groups, same side of diaphragm; may include limited contiguous extranodal (IIE). II bulky Stage II with mass ≥10 cm (or mediastinal >1/3 thoracic diameter). III Nodes/spleen on both sides of diaphragm. IV Noncontiguous extranodal sites (e.g., liver, bone marrow).

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 615

↑ *Back to this question in Part A*

@Neet_pg_bot

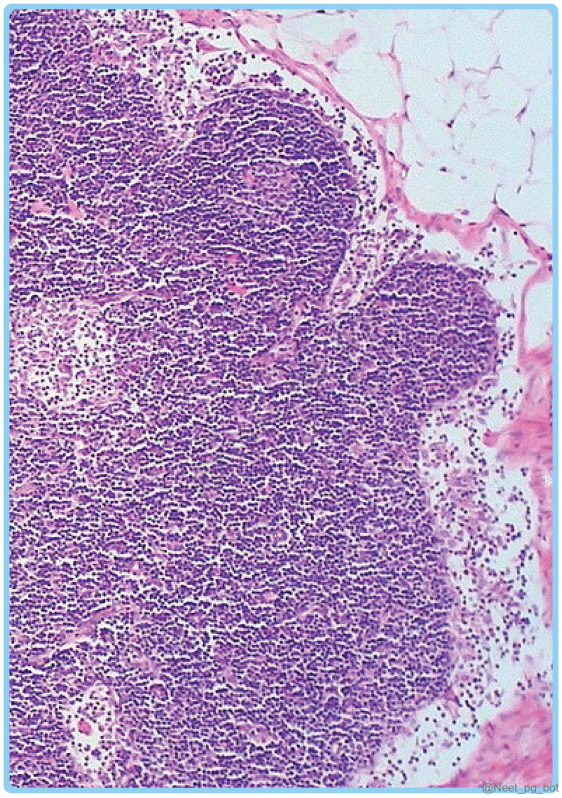
Q31: A 40-year-old male presents with a palpable lump in his right axilla. Physical examination reveals a mobile, non-tender, and rubbery lymph node. FNAC is performed, and the sample is examined under the microscope. Which of the following histological features is characteristic of a normal lymph node? (Q845821)

A. Presence of large pleomorphic cells

B. Disorganized architecture with fibrosis

C. Distorted germinal centres and absence of sinuses

D. Distinct cortex and medulla with germinal centres and sinuses



Correct Answer: D. Distinct cortex and medulla with germinal centres and sinuses

Explanation: Normal Lymph Node Histology: A normal lymph node is divided into distinct regions known as the cortex and medulla. Cortical Region: The cortex contains lymphoid follicles, which consist of densely packed B lymphocytes surrounding germinal centres. These germinal centres are sites of B cell proliferation and differentiation. Paracortex: Located between the cortex and medulla, the paracortex contains high concentrations of T lymphocytes and is involved in initiating cellular immune responses. Medullary Sinuses: The medulla contains medullary sinuses, which are spaces lined by endothelial cells and filled with lymph, serve as conduits for lymph drainage from the cortex to efferent lymphatic vessels. Medullary Cords: Interspersed between the medullary sinuses are medullary cords, which contain plasma cells, macrophages, and lymphocytes. These structures filter lymph and remove foreign particles and antigens. Afferent and Efferent Lymphatic Vessels: Lymph enters the lymph node through afferent lymphatic vessels and exits through efferent lymphatic vessels, allowing lymphocytes and antigen-presenting cells to interact with antigens and participate in immune responses. Presence of large pleomorphic cells (Option A) : These cells often indicate malignancy or infection rather than normal lymph node architecture. Disorganised architecture with fibrosis (Option B): Disorganised architecture with fibrosis is typically associated with pathological conditions, such as chronic inflammation or lymphoproliferative disorders. Distorted germinal centres and absence of sinuses (Option D): Distorted germinal centres and absence of sinuses may suggest pathological changes, such as lymphadenitis or lymphoma, rather than

normal histology.

↑ *Back to this question in Part A*

@Neet_pg_bot

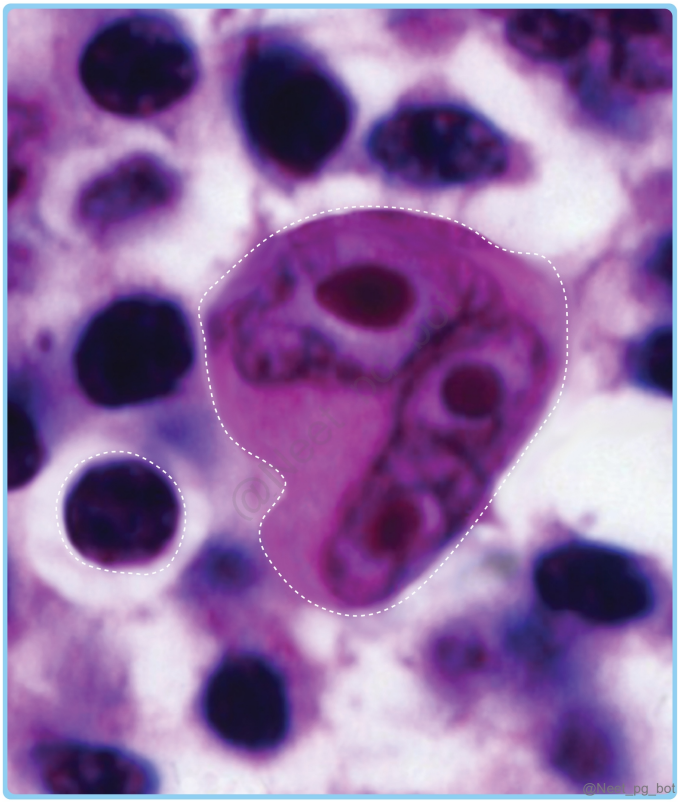
Q33: A 30-year-old female presents with painless swelling of the neck, intermittent fever, night sweats and significant weight loss over the past three months. On examination, enlarged cervical and mediastinal lymph nodes are noted. A biopsy reveals the presence of characteristic cells, as shown in the image below. Which of the following about the described condition is NOT true? (Q845791)

A. More often localised to a single axial group of nodes

B. Typically, it spreads in a contiguous manner.

C. Mesenteric nodes and Waldeyer ring involvement are rare.

D. Extranodal presentation is common.



Correct Answer: D. Extranodal presentation is common.

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The given clinical scenario and histopathological findings suggest a diagnosis of Hodgkin lymphoma, and the HPE reveals the presence of characteristic Reed-Sternberg cells. Hodgkin lymphoma typically spreads in an orderly, contiguous manner from one lymph node group to the next adjacent group without skipping areas. Feature Hodgkin Lymphoma (HL) Non-Hodgkin Lymphoma (NHL) Age of presentation Bimodal distribution peaks in young adults (15-35 years) and older adults (over 55). More common in older adults but can occur at any age. Localisation More often localised to a single axial group of nodes (cervical, mediastinal, para-aortic) (Option A) More frequent involvement of multiple peripheral nodes Pattern of Spread Orderly spread by contiguity Non Contiguous spread (Option B) Involvement of Mesenteric Nodes and Waldeyer Ring Mesenteric nodes and Waldeyer ring are rarely involved. (Option C) Waldeyer ring and mesenteric nodes are commonly involved. Extranodal Presentation Extranodal presentation is rare. Extranodal presentation is common. (Option D)

Robbin's and Cotran, Pathological Basis of Disease,10th Edition, Page 611

↑ *Back to this question in Part A*

@Neet_pg_bot

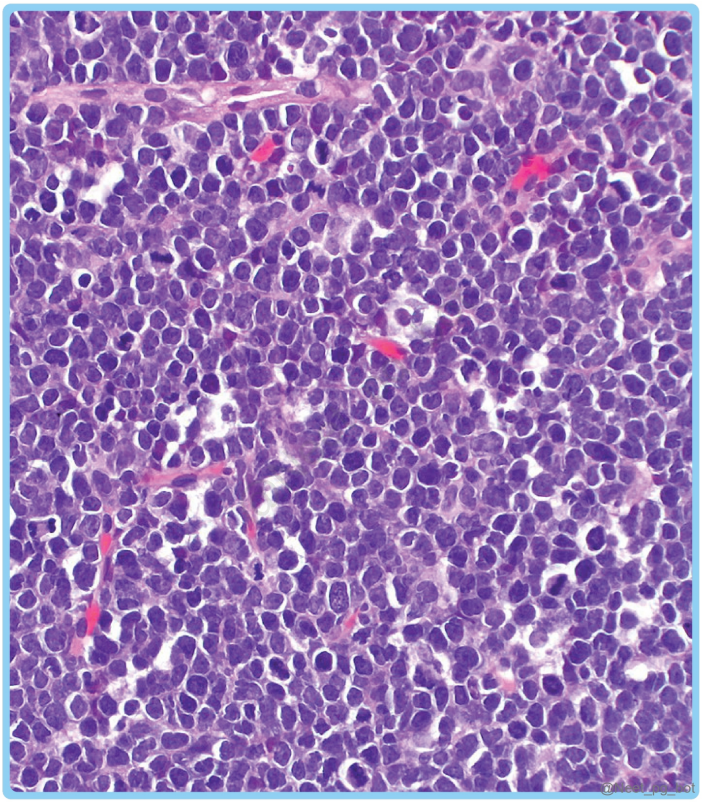
Q34: An 8-year-old boy presents with a large mass over the mandible. On the HPE of the lesion, a 'starry sky pattern' is seen, similar to the image below. This condition is associated with which of the following genetic abnormalities? (Q845824)

A. MYC gene

B. BCL2 gene

C. Cyclin-D1

D. BCL6 gene



Correct Answer: A. MYC gene

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical presentation with mandibular mass and a starry sky appearance on HPE are characteristic of Burkitt’s lymphoma, which is associated with the translocation of the MYC gene on chromosome 8, thus leading to overexpression of the MYC protein. All forms of Burkitt’s lymphoma (Endemic, Sporadic and HIV associated) are associated with such translocations. The most common translocations are t (8:2), t(8:14), and t(8:22). Endemic Burkitt's lymphoma: Strong association with Epstein-Barr Virus Infection (~95%) Common in African children Jaw/facial bone involvement (very characteristic) Often involves kidneys, ovaries, and CNS Rx: Intensive short-course combination chemotherapy (e.g., CODOX-M/IVAC) Sporadic Burkitt's lym phoma: Seen worldwide (children & young adults) EBV association less common (~20–30%) Predominantly involves abdomen (ileocecal region) Presents with abdominal mass ± intussusception Rx: Aggressive multi-agent chemotherapy Immunodeficiency-associated Burkitt's lymphoma : Occurs in HIV Infection or post-transplant patients Intermediate EBV association (~30–40%) Commonly involves lymph nodes and bone marrow More aggressive; may present with systemic (B) symptoms Rx: Combination chemotherapy (dose-adjusted regimens), add Rituximab (anti-CD20) Ki-67 Index: Near 100% (indicates the fastest-growing human tumor). BCL2 gene (Option B) translocation is associated with follicular lymphoma. The most common is t(14;18), leading to the juxtaposition of the IGH locus (Ch 14) with the BCL2 locus(Ch 18), leading to overexpression of BCL2. Cyclin-D1 (Option C) gene translocation is associated with all mantle cell lymphoma. There is a translocation of the cyclin D1 locus on chromosome 11 and IGH locus on chromosome 14; t(11;14), which results in overexpression of cyclin D1, thus promoting G1 to S-phase progression in the cell cycle. BCL6 gene (Option D) dysregulation is associated with Diffuse large B cell lymphoma. It can occur due to translocations or promoter sequence mutations of the BCL6 gene on Chr. 3q27.

↑ *Back to this question in Part A*

@Neet_pg_bot

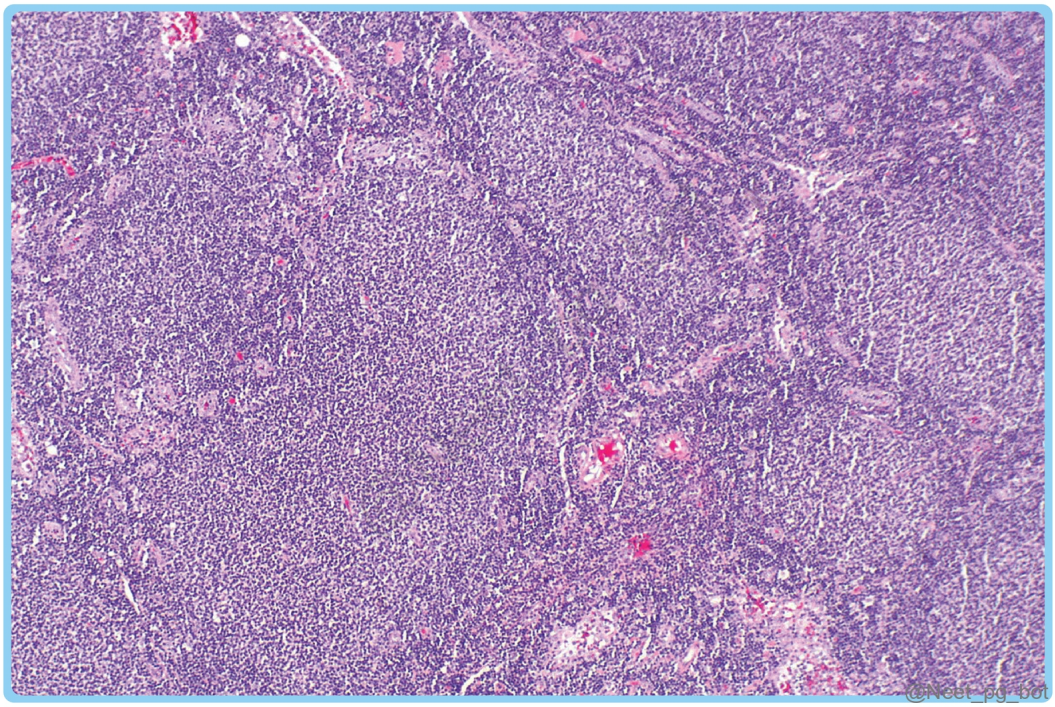
Q35: A 30-year-old man presents to the outpatient department with an axillary mass and complaints of low-grade fever, weight loss, and night sweats for the past 6 months. Histopathological examination (HPE) of a biopsy sample from the mass reveals diffuse follicular growth with centrocytes with cleaved nuclei and centroblasts. Immunohistochemistry shows BCL2 stain positive, CD19, CD20, and CD10 positive, and CD5 negative. What is the most likely diagnosis? (Q845827)

A. Follicular hyperplasia

B. Mantle cell lymphoma

C. Follicular lymphoma

D. Burkitt's lymphoma



Correct Answer: C. Follicular lymphoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The given scenario, along with HPE and IHC, is consistent with Follicular lymphoma, which is associated with BCL2- gene translocation; t(14:18) Follicular lymphoma (FL) is a malignant neoplasm originating from germinal center B-cells, characterized by the t(14;18) translocation leading to overexpression of BCL2. Clinically, it presents with painless lymphadenopathy and may include systemic symptoms. Histopathologically, FL exhibits a nodular growth pattern with centrocytes (Small cells with cleaved nuclei and scanty cytosol) and centroblasts(Larger cells with open nuclear chromatin, several nucleoli) Immunohistochemistry shows positivity for CD10/19/20, BCL2, and BCL6, and negativity for CD5. Management focuses on palliative approaches due to its indolent but incurable nature. Follicular hyperplasia (Option A) is benign, featuring reactive B cell proliferation in lymph nodes with preserved architecture, characterized by CD10/20 positivity and absence of BCL2 expression. Mantle cell lymphoma (Option B) Immunohistochemistry shows positivity for Cyclin D1, CD19, CD20, surface immunoglobulins (usually IgM and IgD), and CD5, but CD23 is negative and HPE shows small lymphoid cells with irregular nuclear outlines, condensed chromatin, and scanty cytoplasm Burkitt’s lymphoma (Option D) Histopathological examination reveals numerous mitotic and apoptotic cells, nuclear remnants phagocytosed by benign macrophages with abundant clear cytoplasm, creating a characteristic "starry sky" pattern. Immunohistochemistry shows positivity for IgM, CD19, CD20, CD10, and BCL6, but negativity for BCL2.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q36: Match the following neoplasm with its appropriate genetic mutation. Neoplasia Genetic mutation 1. Mantle cell lymphoma A. BCL6 gene 2. Burkitt’s lymphoma B. Cyclin D1 gene 3. Diffuse large B cell lymphoma C. BCL10 / MALT1 4. Marginal zone lymphoma D. MYC gene (Q845828)

A. 1-B, 2-D, 3-A, 4-C

B. 1-B, 2-A ,3-C ,4-D

C. 1-A ,2-C ,3-D,4- B

D. 1-C ,2-D ,3-A ,4- B

Correct Answer: A. 1-B, 2-D, 3-A, 4-C

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: NEOPLASIA GENETIC MUTATION Other points Burkitt’s lymphoma (Statement 2) t(8:14) c-MYC gene Associated with EBV and HIV. 3 types: Endemic, Sporadic and HIV associated. HPE shows ‘starry sky’ appearance DLBCL (Statement 3) BCL6 rearrangement Most common NHL If CLL transforms into DLBCL, it is called Richter's Syndrome. Extranodal marginal zone lymphoma (Statement 4) t(11:18) - API2-MLT fusion t(1:14) - BCL10 - IGH fusion t(14:18) - MALT1-IGH fusion Associated with H.pylori infection Sjogran's Syndrome Hashimoto's Disease. Mantle cell lymphoma (Statement 1) t(11:14) - Cyclin-D1 IGH fusion Associated with GIT polyps

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 595

↑ *Back to this question in Part A*

@Neet_pg_bot

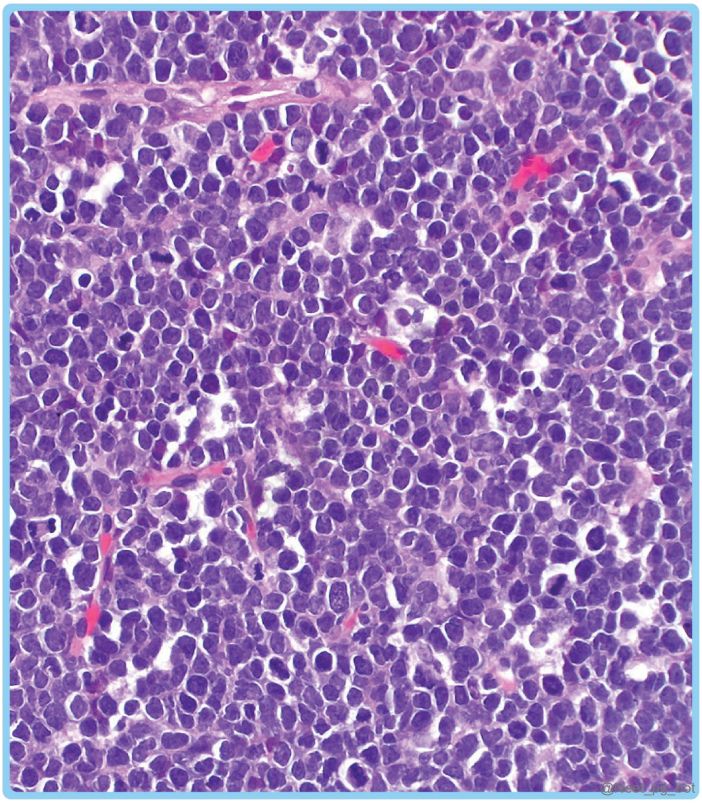
Q37: A 14-year-old boy from Bihar presents with a low-grade fever, weight loss, and abdominal pain for the past 2 months. Investigation reveals a mass involving the ileocecal region, with histopathological examination showing a 'starry sky' appearance, immunohistochemistry positive for CD10, CD19, CD20, and BCL6, and FISH indicating a (8:14) translocation involving the MYC gene. This type of presentation is common in which condition? (Q845829)

A. Endemic Burkitt’s lymphoma

B. Sporadic Burkitt’s lymphoma

C. HIV-associated Burkitt’s lymphoma

D. All of the above



Correct Answer: B. Sporadic Burkitt’s lymphoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: In the above case, the patient is from a non-endemic region, and the lesion mainly affects the abdomen. Based on the HPE and IHC findings, it is suggestive of sporadic Burkitt’s lymphoma. Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma associated with the translocations of the c-MYC gene on chromosome 8, t(8:14). It has three primary subtypes: Endemic Burkitt's lymphoma (Option A): Strong association with Epstein-Barr Virus Infection (~95%) Common in African children Jaw/facial bone involvement (very characteristic) Often involves kidneys, ovaries, and CNS Sporadic Burkitt's lym phoma (Option B): Seen worldwide (children & young adults) EBV association less common (~20–30%) Predominantly involves abdomen (ileocecal region) Presents with abdominal mass ± intussusception Immunodeficiency-associated Burkitt's lymphoma (Option C): Occurs in HIV Infection or post-transplant patients Intermediate EBV association (~30–40%) Commonly involves lymph nodes and bone marrow More aggressive; may present with systemic (B) symptoms

@Neet_pg_bot

Q38: Which of the following statements correctly differentiates between Primary Effusion Lymphoma (PEL) and Immunodeficiency-associated Large B-cell Lymphoma? (Q845830)

A. PEL presents with lymphomatous masses in solid organs, while Immunodeficiency-associated Large B-cell Lymphoma presents as effusions.

B. PEL is associated with EBV , whereas Immunodeficiency-associated Large B-cell Lymphoma is linked to HHV-8.

C. PEL presents as Effusions and is associated with HHV-8, whereas Immunodeficiency-associated Large B-cell Lymphoma is linked to EBV.

D. Both are predominantly found in immunocompetent individuals without any viral association.

Correct Answer: C. PEL presents as Effusions and is associated with HHV-8, whereas Immunodeficiency-associated Large B-cell Lymphoma is linked to EBV.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Subtypes of DLBCL: Characteristic Primary Effusion Lymphoma (PEL) Immunodeficiency-associated Large B-cell Lymphoma Presentation Malignant pleural or ascitic effusion Solid or nodal tumours , or extranodal involvement, often in immunocompromised individuals. Patient Demographics Mostly in patients with advanced HIV infection or in older adults Seen in patients with advanced HIV infection and recipients of organ or HSC transplants. Appearance of Tumor Cells Anaplastic in appearance, Typically, do not express surface B- or T-cell markers Neoplastic B cells Viral Association With Pathogenesis HHV-8 infection appears to have a causal role HIV EBV infection plays a critical pathogenic role

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Page 601.

Primary effusion lymphoma

↑ *Back to this question in Part A*

@Neet_pg_bot

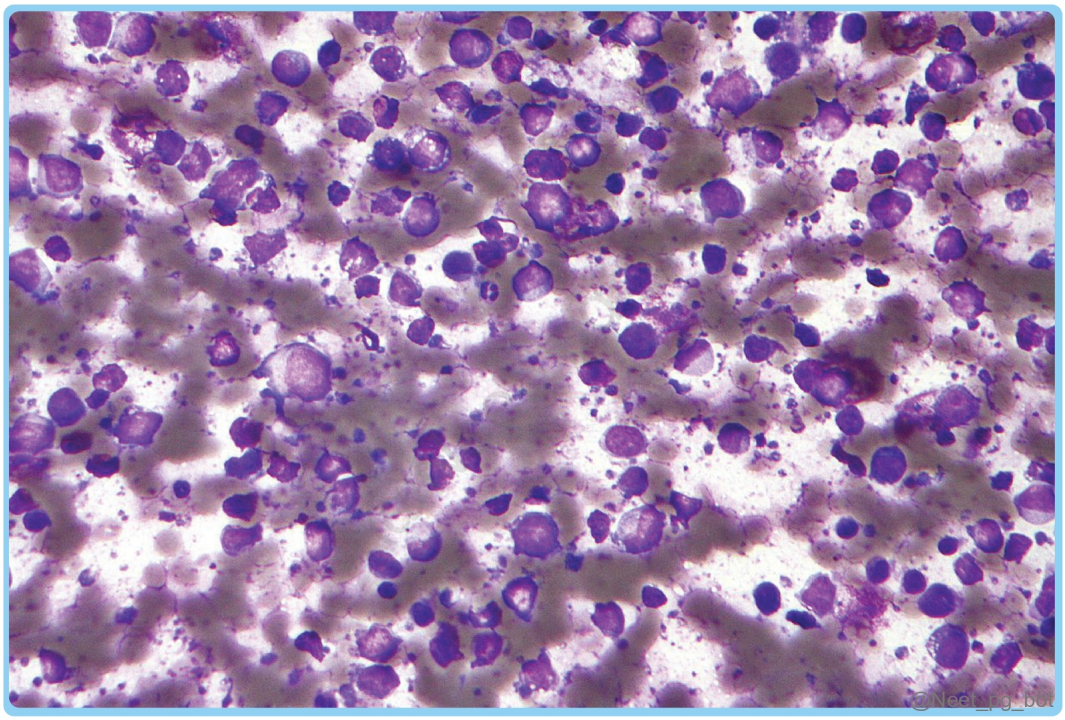
Q39: Match each lymphoma or leukaemia type with its corresponding histopathological finding. Lymphoma/Leukemia Type Histopathological Finding 1.Follicular Lymphoma A) 2. Burkitt's Lymphoma B) 3. Diffuse Large B-Cell Lymphoma (DLBCL) C) 4. Hairy Cell Leukemia D) (Q845833)

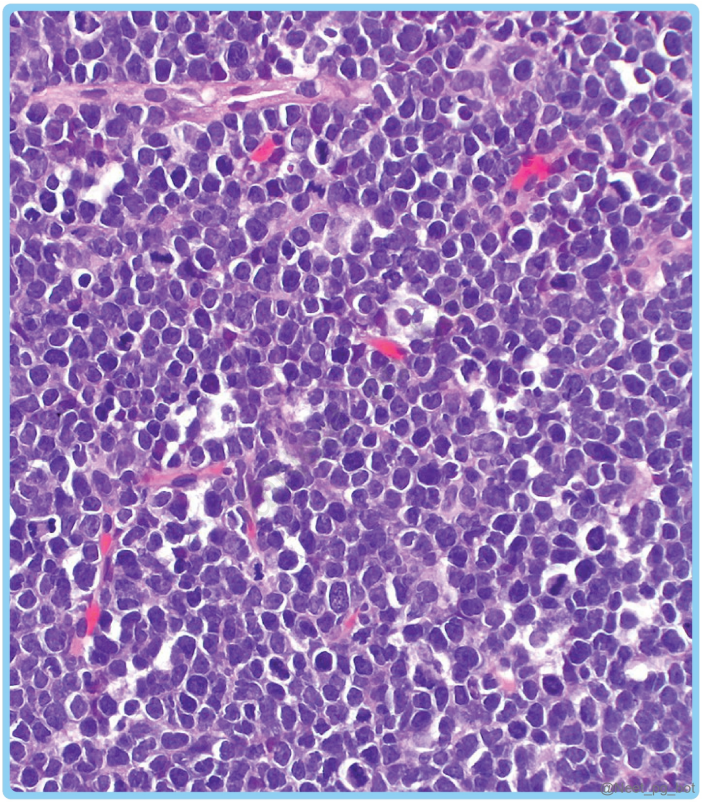
A. 1-C, 2-B, 3-A, 4-D

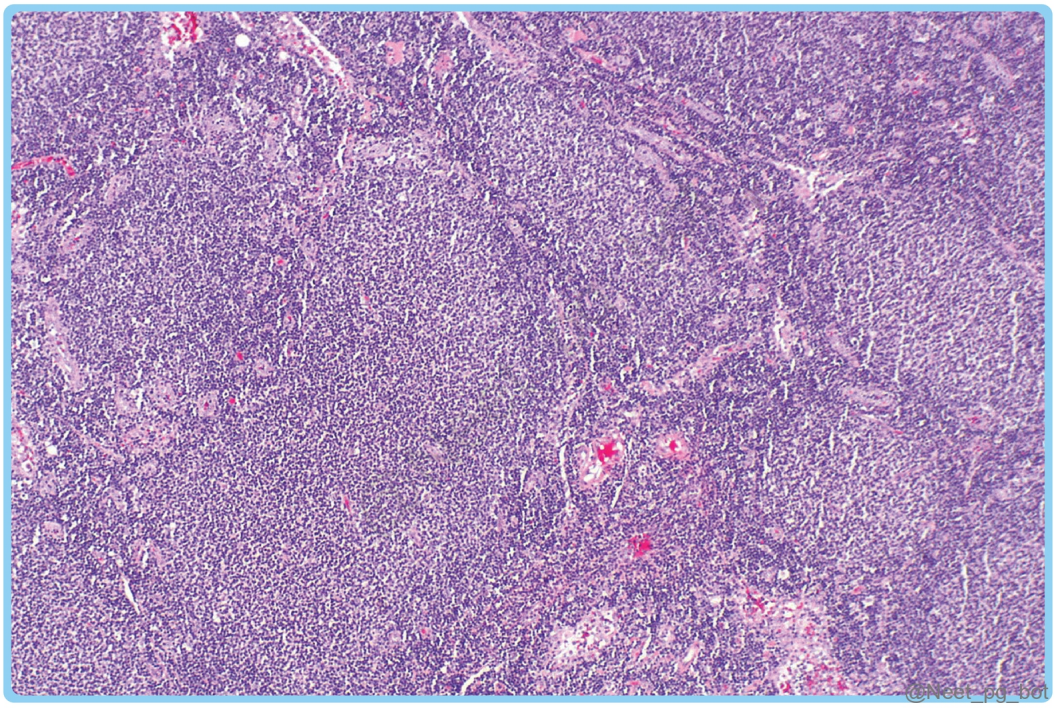
B. 1-B, 2-A, 3-D, 4-C

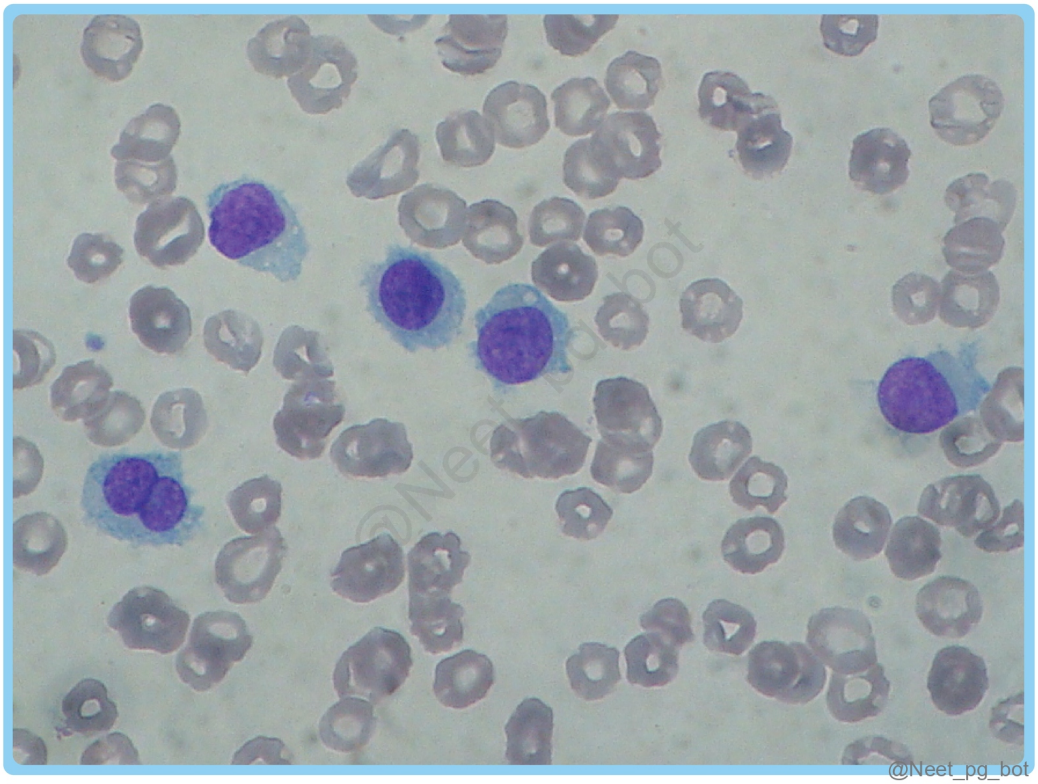
C. 1-D, 2-C, 3-B, 4-A

D. 1-A, 2-D, 3-C, 4-B







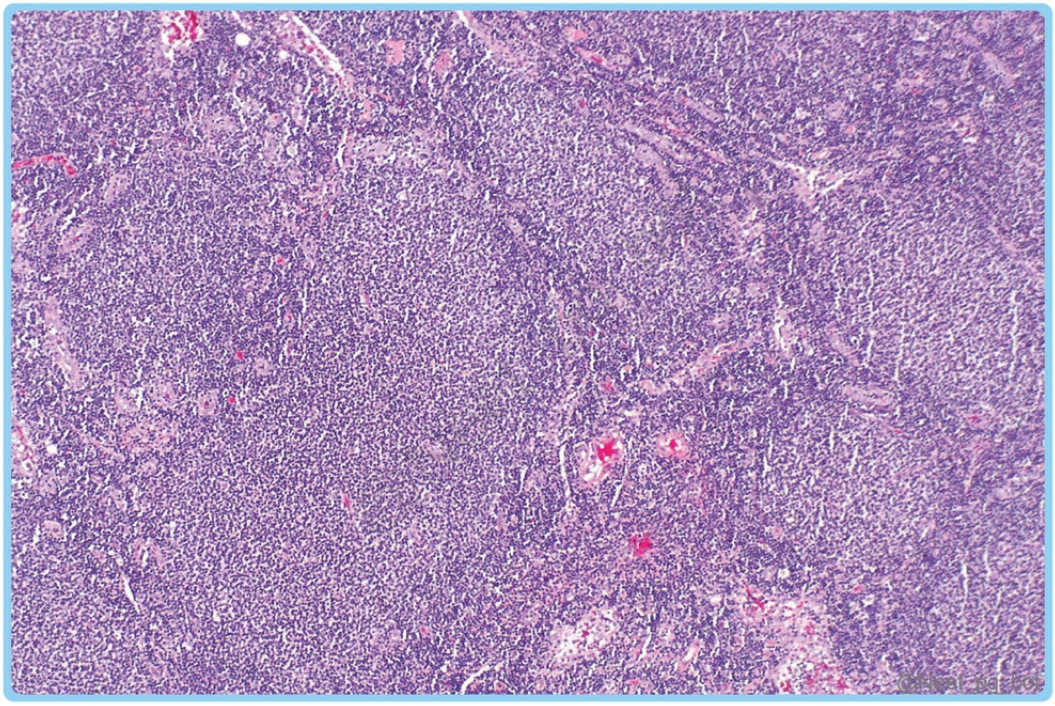


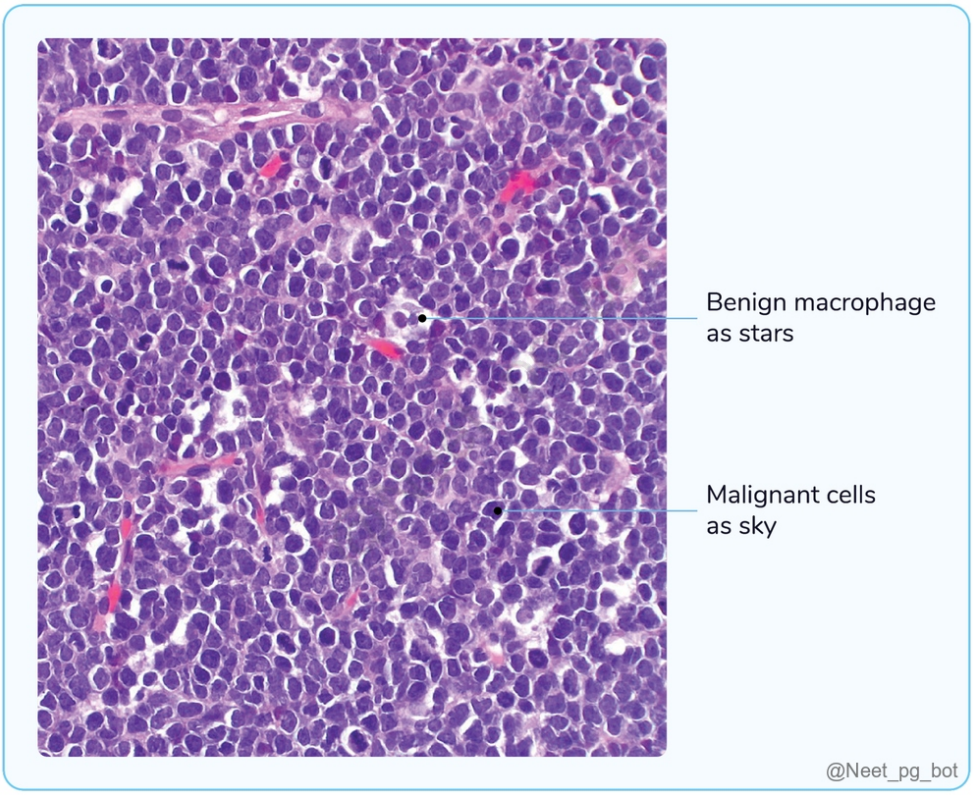
Correct Answer: A. 1-C, 2-B, 3-A, 4-D

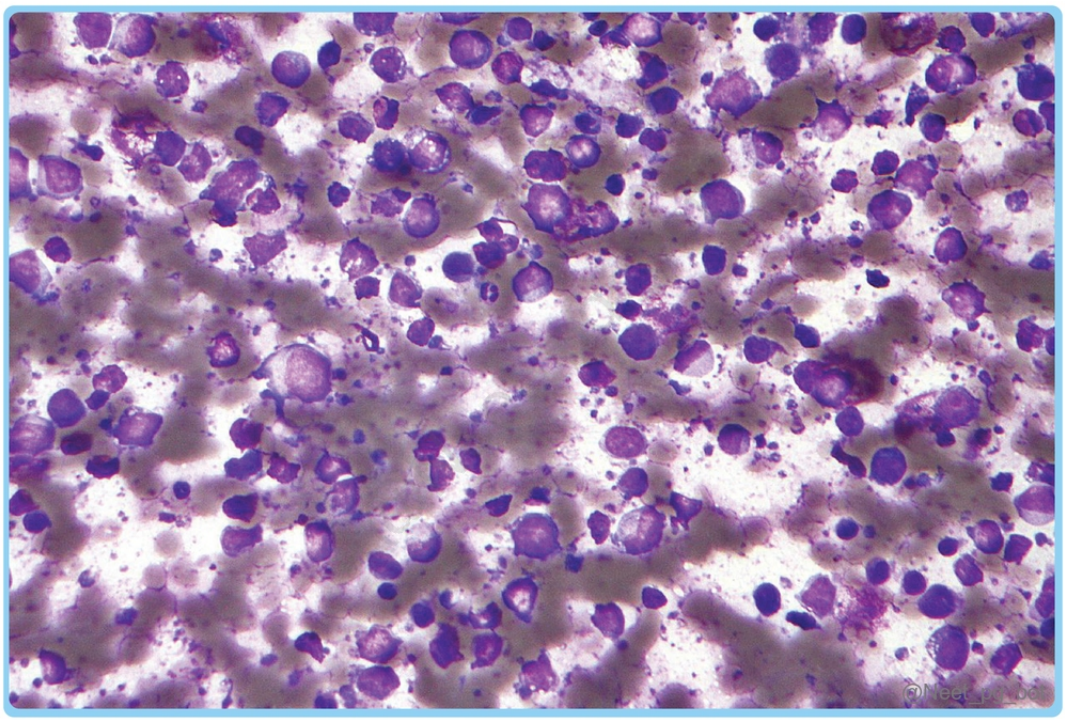
■ *Listen (English)*

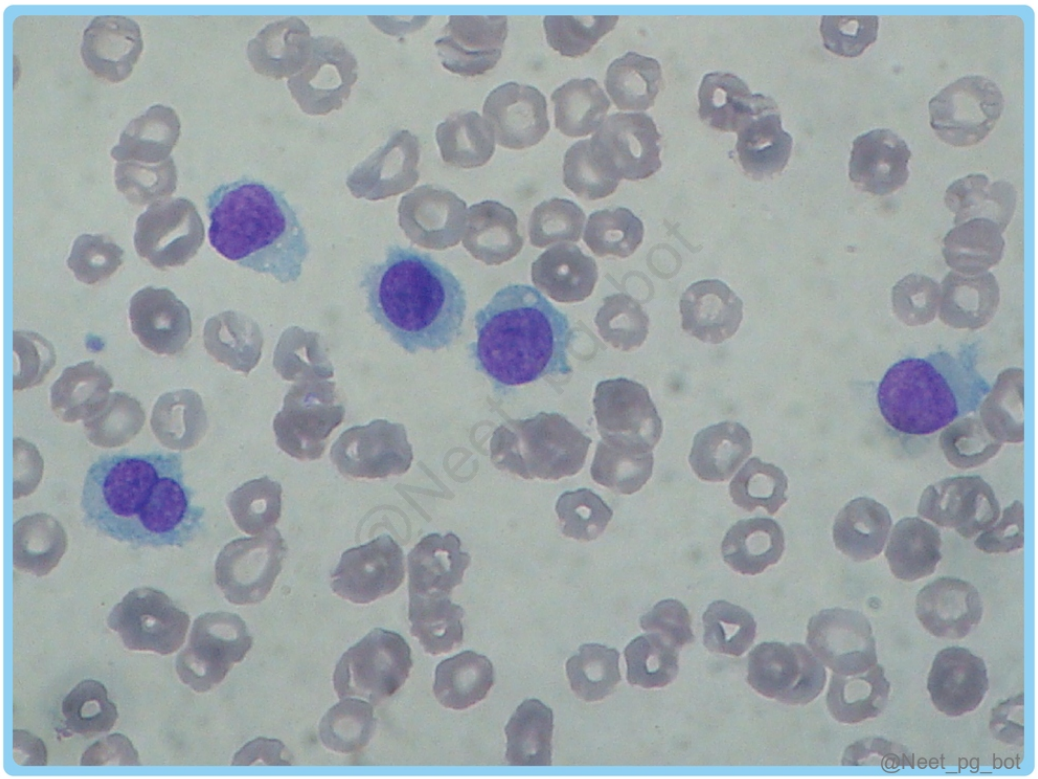
■ *Listen (Hindi)*

Explanation: Lymphoma/Leukemia Type Histopathological Finding HPE image 1. Follicular lymphoma Cleaved lymphocytes. 2. Burkitt’s Lymphoma "Starry sky" appearance with interspersed macrophages. 3. DLBCL Large lymphoid cells with vesicular nuclei and prominent nucleoli. 4. Hairy cell leukemia Cells with fine hair-like projections.









References:

Robbin’s and Cotran, Pathological Basis of Disease, 10th Edition, Pages 599-601 & 604.

↑ *Back to this question in Part A*

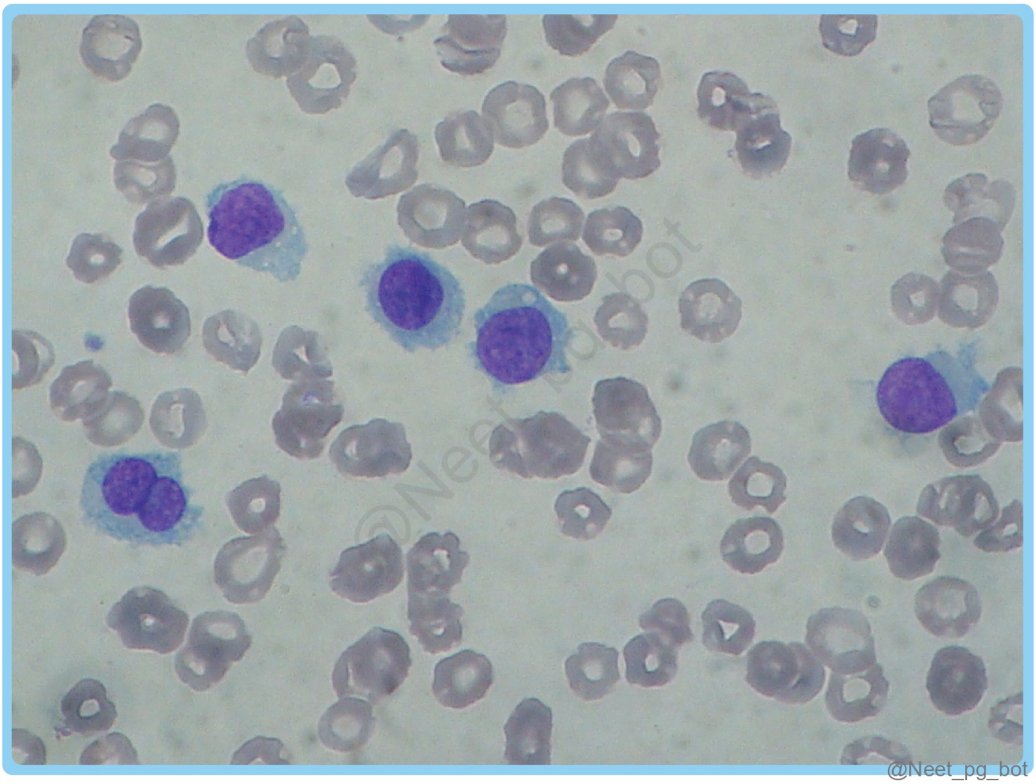
Q40: A 45-year-old male has been complaining of persistent fatigue, recurrent infections, and easy bruising over the past few months. On physical examination, he has a noticeable abdominal mass. A peripheral smear shows the presence of atypical lymphoid cells with cytoplasmic projections, as shown in the image below. Which of the following statements is not true regarding the patient's condition? (Q845834)

A. Associated with the BRAF V600E mutation.

B. Massive splenomegaly is a common clinical feature.

C. The pathogenesis involves the proliferation of immature myeloid cells

D. Typically present with fatigue, infections, and pancytopenia.



Correct Answer: C. The pathogenesis involves the proliferation of immature myeloid cells

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and peripheral smear findings suggest Hairy cell leukemia, which involves abnormal proliferation of Mature B cells. Mutations BRAF V600E (Option A ruled out) Pathogenesis Mutation of BRAF V600E gene → Activation of the BRAF protein → MAPK/ERK signalling pathway → Uncontrolled proliferation and survival of mature B-cells (Hairy cells). Clinical Presentation Presents with fatigue, recurrent infections, easy bruising, (e.g., early satiety, abdominal discomfort), pancytopenia (Option D ruled out) and symptoms related to splenomegaly (Option B ruled out)

References:

Robbin's and Cotran, Pathological Basis of Disease, 10th Edition, Page 604

↑ *Back to this question in Part A*

@Neet_pg_bot

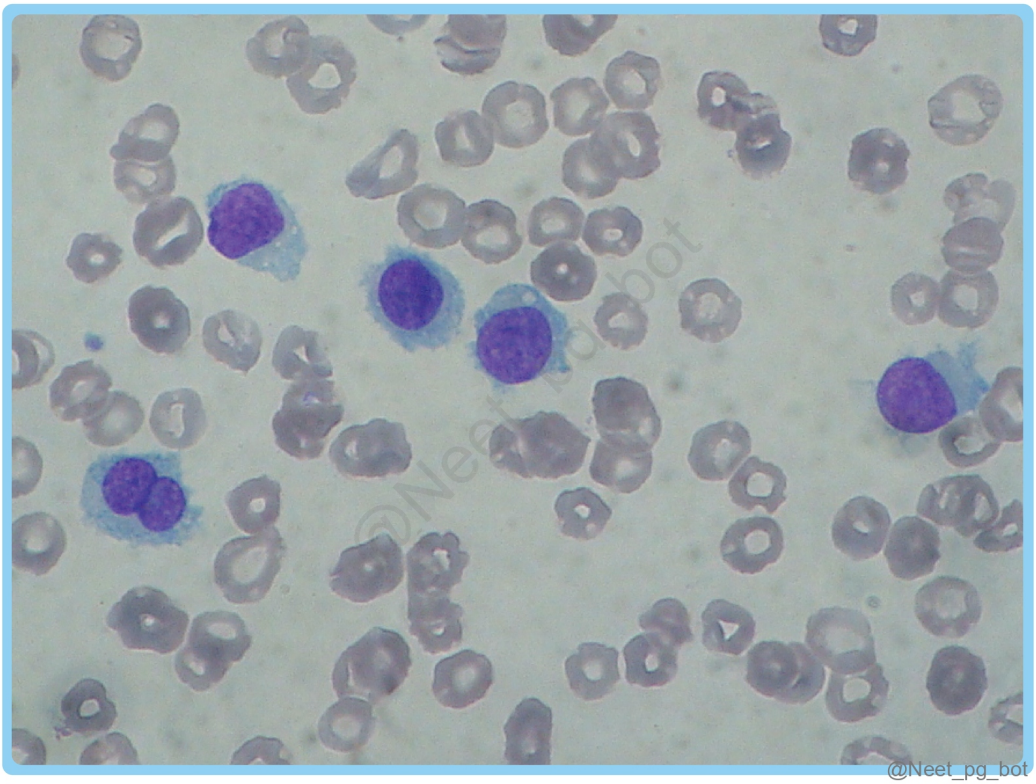
Q41: A 55-year-old male presents with persistent fatigue, splenomegaly, and pancytopenia. Peripheral blood smear shows leukocytosis with mature lymphocytes displaying hairy projections. Flow cytometry confirms the presence of CD11c and CD25 positive cells. Which of the following is the most specific biomarker commonly useful in the diagnosis of condition? (Q845835)

A. CD 20

B. Annexin V

C. Annexin A1

D. Apolipoprotein A1



Correct Answer: C. Annexin A1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and peripheral smear findings are consistent with Hairy Cell Leukemia (HCL). Annexin A1 is a protein specifically expressed on the surface of hairy cells in Hairy Cell Leukemia. It is characterized by a distinctive genetic mutation (BRAF V600E in >90% of cases) and expression of specific B-cell markers Clinical presentation include persistent fatigue, splenomegaly, and pancytopenia and increased susceptibility to infections.. Peripheral smear shows Leukocytosis with mature lymphocytes displaying hairy projections. Marrow exhibits diffuse interstitial infiltrates Flow cytometry markers: The cells in HCL typically expressCD19, CD20, surface Ig (usually IgG), CD11c, CD25, CD103, and annexin A1. CD20 (Option A) is a surface marker present on most B cells and is commonly expressed in a variety of B-cell lymphomas and leukemias. While CD20 can be positive, it is not specific to HCL and is found in many other B-cell neoplasms. Annexin A5 (Option B) is a protein involved in the cellular processes related to apoptosis and phospholipid binding. It is used as a marker to detect apoptotic cells. Apolipoprotein A1 (Option D) is a marker for germ cell neoplasms.

https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4007141/

↑ *Back to this question in Part A*

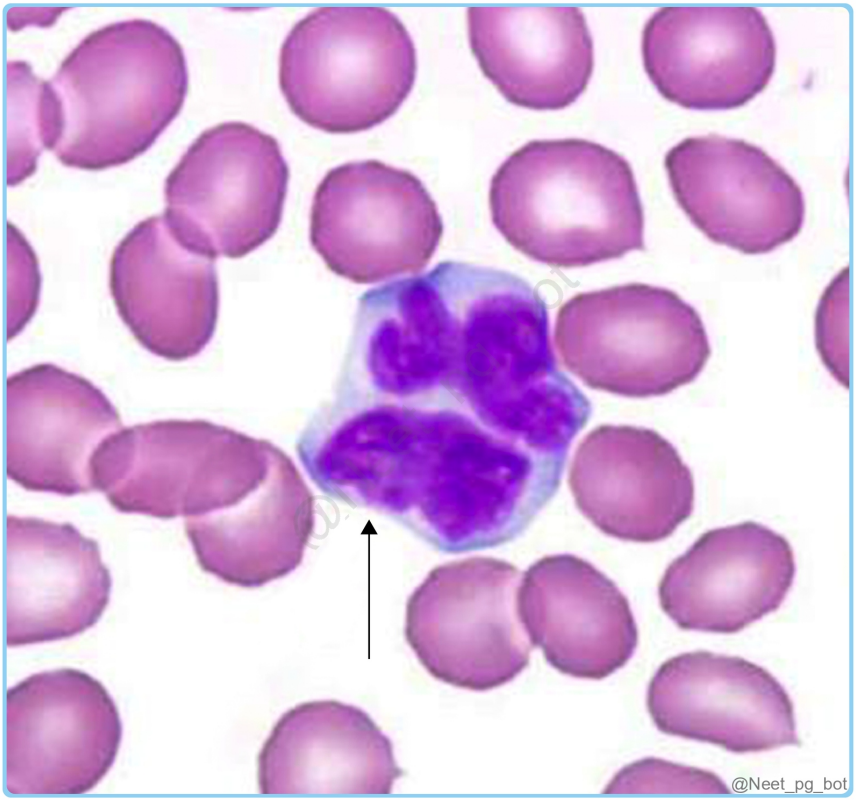
Q42: A 45-year-old male presents with a three-year history of pruritic, erythematous plaques on his trunk and extremities. Physical examination reveals widespread erythematous patches and plaques with a "cerebriform" appearance. Peripheral smear findings reveal the presence of abnormal lymphocytes with convoluted nuclei and abundant cytoplasm. Which of the following is the most likely diagnosis? (Q845836)

A. Mycosis fungoides

B. Adult T-cell leukemia

C. Anaplastic large cell lymphoma

D. Hairy cell leukemia



Correct Answer: A. Mycosis fungoides

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation and peripheral findings is consistent with Mycosis fungoides, a Cutaneous T-cell lymphoma, characterized by pruritic erythematous patches and plaques. Cutaneous lesion : Erythematous plaque with fungal-like appearance → but not fungal. Type : It is a cutaneous T-cell Non-Hodgkin's lymphoma (NHL) . Histology (skin biopsy) : Malignant T-cell collections in epidermis → Pautrier's microabscesses . Blood finding : Atypical lymphocytes with cerebriform nuclei → Sezary cells . Terminology : Skin involvement only → Mycosis fungoides . When cells spill into blood → Sezary syndrome Clinical Stages: Patch (scaly/erythematous) Plaque (elevated/indurated) Tumor (nodular/ulcerated) Erythroderma (Sezary Syndrome: >80% body surface area involved + leukemia). Treatment: Topical corticosteroids, phototherapy (PUVA/UVB), or topical mechlorethamine. Systemic therapy (Interferon, Vorinostat) for advanced stages.

Q1: Which of the following is not true about nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL)? (Q856479)

A. EBV negative

B. CD 30 negative

C. CD 20 positive

D. Poor prognosis compared to classical HL

Correct Answer: D. Poor prognosis compared to classical HL

Explanation: Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) typically has a more favourable prognosis compared to classical Hodgkin lymphoma (HL). It is usually EBV negative, CD30 negative, and CD20 positive , characteristic features of NLPHL. However, it does not generally have a poorer prognosis than classical HL. {{caption_text}} Subtypes and features of Hodgkin's lymphoma: Subtype Morphology and Immunophenotype Typical Clinical Features Nodular Sclerosis Frequent lacunar cells and occasional diagnostic Reed-Sternberg (RS) cells. Background infiltrate includes T lymphocytes, eosinophils, macrophages, and plasma cells. Fibrous bands divide cellular areas into nodules. RS cells: CD15+, CD30+; usually EBV negative. Most common subtype, typically stage I or II with mediastinal involvement . Equal occurrence in males and females . Common in young adults . Mixed Cellularity Frequent mononuclear and diagnostic RS cells. Background infiltrate rich in T lymphocytes, eosinophils, macrophages, and plasma cells. RS cells: CD15+, CD30+; 70% EBV positive . More than 50% present as stage III or IV . More common in males . Biphasic incidence peaks in young adults and those >55 years . Lymphocyte-Rich Frequent mononuclear and diagnostic RS cells. Background infiltrate rich in T

lymphocytes. RS cells: CD15+, CD30+; 40% EBV positive. Uncommon , more frequent in males . Typically seen in older adults . Lymphocyte Depletion Reticular variant with numerous RS cells and few background reactive cells. RS cells: CD15+, CD30+ , most EBV positive . Rare , more common in older men , HIV-infected individuals , and low-income regions . Often presents with advanced disease . Nodular Lymphocyte-Predominant Frequent L&H (popcorn) cell variants in a background of follicular dendritic cells and reactive B cells. RS cells: CD20+, CD15–, CD30–; EBV negative . Uncommon , typically in young males . Presents with cervical/axillary lymphadenopathy . Rarely involves the mediastinum .

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 613

↑ *Back to this question in Part A*

@Neet_pg_bot

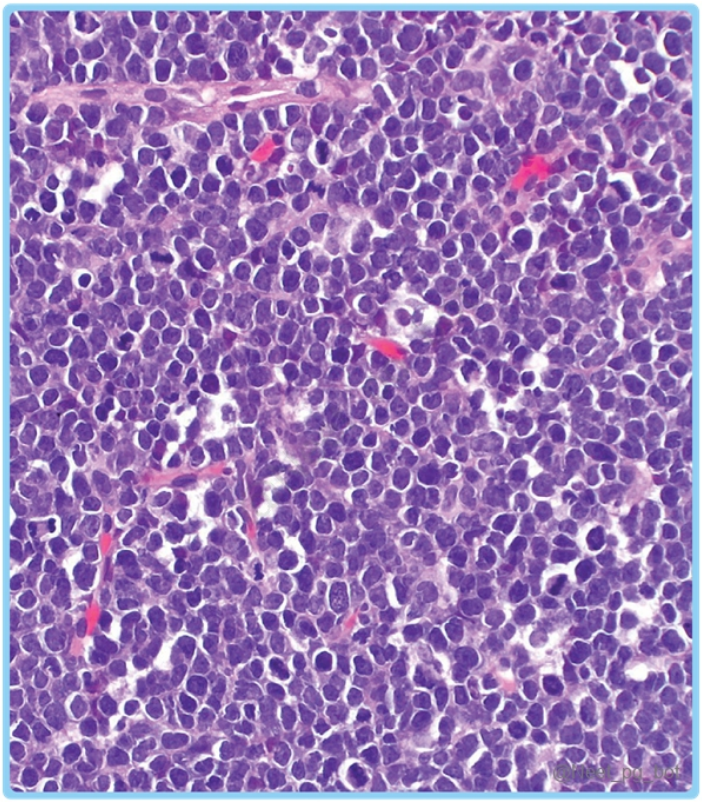
Q2: What is the most likely diagnosis for a 5-year-old boy who has weight loss, fever, and a painless swelling in his jaw area, with anaemia and lymphocytosis revealed by a CBC and biopsy findings shown in the accompanying image?\ (Q857579)

A. Hodgkin’s disease

B. Acute lymphocytic leukemia

C. Chloroma

D. Burkitt’s lymphoma



Correct Answer: D. Burkitt’s lymphoma

Explanation: The clinical presentation of weight loss, fever, painless jaw swelling, along with a starry sky appearance on histology and anaemia with lymphocytosis on CBC, strongly suggests Burkitt’s lymphoma. It is an aggressive B-cell non-Hodgkin lymphoma, typically associated with Epstein-Barr virus (EBV) infection, HIV, and chromosomal translocations leading to c-myc oncogene overexpression. It is classified into three clinical groups: endemic, sporadic, and immunodeficiency-related. Clinical symptoms include: Painless swelling : The most common symptom is the presence of one or more painless, rapidly enlarging masses, typically involving lymph nodes. Heavy night sweating Intermittent high fever Significant weight loss (more than 10% of body weight) Associated with the translocations of the MYC gene on chromosome 8, t(8:14). It has three primary subtypes: Endemic Burkitt's lymphoma: Commonly affects children in malaria-endemic areas of Africa, often presenting with tumours in the jaw or facial bones. Sporadic Burkitt's lymphoma: More frequently seen in non-endemic regions and usually involving the ileocaecal region and peritoneum Immunodeficiency-associated Burkitt's lymphoma: Found in patients with conditions such as HIV/AIDS or other forms of immunodeficiency. {{caption_text}} Hodgkin's disease (Option A) is a cancer of the lymphatic system, characterised by uncontrolled proliferation of lymphocytes. It often presents with painless swollen lymph nodes, but the hallmark feature is the presence of Reed-Sternberg cells (large, abnormal lymphocytes with two nuclei resembling "owl eyes"). HL is treated with chemotherapy, radiation, and stem-cell transplantation. {{caption_text}} Acute lymphocytic leukaemia (ALL) (Option B) is a malignancy of the blood and bone marrow characterised by the rapid production of immature white blood cells. Common symptoms include fatigue, pallor, frequent infections, and unusual bleeding, but it does not typically present with localised swelling, as seen in Burkitt’s lymphoma . {{caption_text}} Chloroma (Option C) , also known as granulocytic sarcoma or myeloid sarcoma , is a rare tumour composed of myeloblasts, usually associated with acute myeloid leukaemia (AML). It can form in various tissues such as the bones, skin, lymph nodes, and central nervous system, but it does not present with the

distinctive symptoms or patterns of Burkitt's lymphoma, such as the characteristic jaw swelling. Chloromas are often nonspecific and can include symptoms like fatigue, weight loss, and pain. {{caption_text}}

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 598-603

↑ *Back to this question in Part A*

@Neet_pg_bot

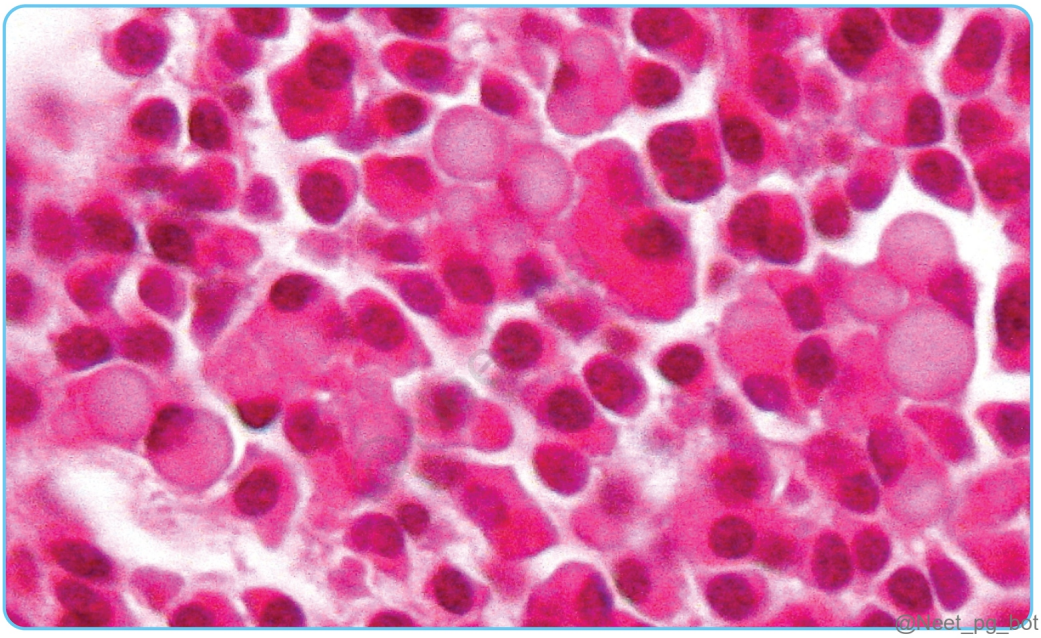
Q3: A 60-year-old male presents with easy fatigability, back pain, and multiple lytic lesions in the skull. The bone marrow biopsy finding is given below. What is the most probable diagnosis? (Q857582)

A. CML (Chronic Myelogenous Leukemia)

B. CLL (Chronic Lymphocytic Leukemia)

C. Multiple Myeloma

D. Hairy Cell Leukemia



Correct Answer: C. Multiple Myeloma

Explanation: The clinical presentation of easy fatigability, back pain, and skull lytic lesions, along with Russell bodies in bone marrow biopsy, strongly suggests multiple myeloma, which commonly causes bone pain and elevated serum proteins. Multiple myeloma is a cancer of plasma cells, which normally produce antibodies to fight infections. In this disease, malignant plasma cells proliferate uncontrollably in the bone marrow, crowding out healthy blood cells and producing abnormal proteins that cause complications. Early symptoms may be absent, but when present, they include: Bone pain, especially in the spine or chest Nausea Constipation Loss of appetite Confusion or mental fogginess Fatigue Frequent infections Weight loss Weakness or numbness in the legs Excessive thirst CML (Chronic Myelogenous Leukemia) (Option A) is a blood and bone marrow cancer that leads to an overproduction of white blood cells. In its chronic phase, the disease can often go unnoticed until detected by

a blood test. Symptoms include: Weakness Fatigue Shortness of breath with daily activities Fever Bone pain Unexplained weight loss Pain or fullness in the left side of the abdomen due to an enlarged spleen Night sweats {{caption_text}} CLL (Chronic Lymphocytic Leukemia) (Option B) is a slow-progressing blood and bone marrow cancer, typically occurring in older adults. It may not cause symptoms in the early stages and is often discovered during a routine blood test. Later symptoms include: Painless swelling of lymph nodes Weakness or fatigue Feeling full due to spleen or liver enlargement Fever and frequent infections Easy bruising or bleeding Unexplained weight loss Drenching night sweats {{caption_text}} Hairy Cell Leukemia (Option D) is a cancer of the B lymphocytes (a type of white blood cell). The leukaemia cells in this condition look "hairy" under a microscope. Symptoms may be absent or include: A feeling of fullness in the abdomen, making it difficult to eat large meals Fatigue Easy bruising Frequent infections Weakness Unintentional weight loss {{caption_text}}

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 607-609

↑ *Back to this question in Part A*

@Neet_pg_bot

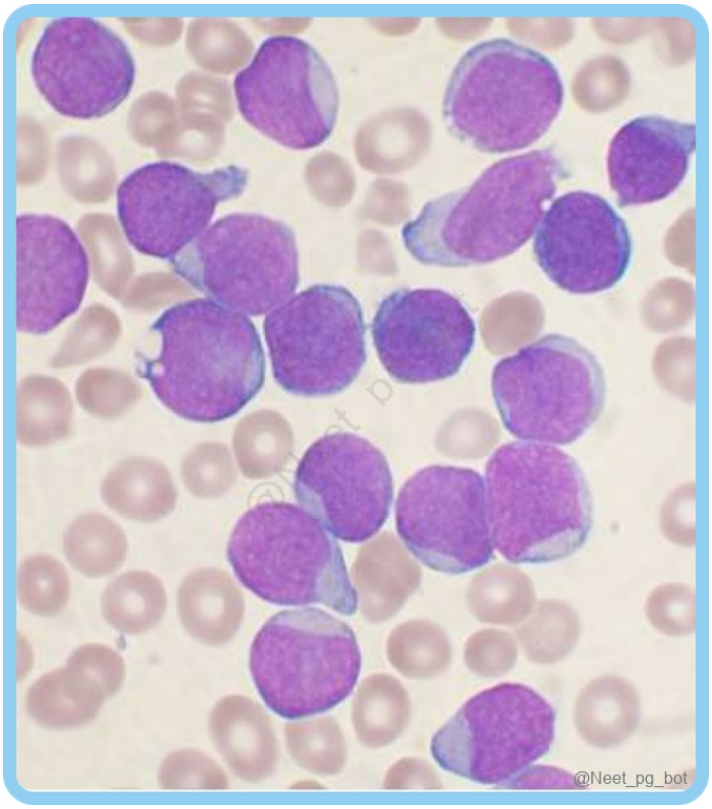
Q4: What is the likely diagnosis for a 10-year-old boy with Down syndrome who presents with a mediastinal mass (SVC-like syndrome), based on the provided bone marrow histology shown below? (Q857605)

A. AML (Acute Myeloid Leukemia)

B. Aplastic anemia

C. ALL (Acute Lymphoblastic Leukemia)

D. Juvenile Myelomonocytic Leukemia (JMML)



Correct Answer: C. ALL (Acute Lymphoblastic Leukemia)

Explanation: Acute Lymphoblastic Leukemia (ALL) is the most common leukemia and cancer in children, often seen in patients with Down syndrome. It is a clonal malignancy where lymphoblasts, early lymphoid precursors, proliferate abnormally, replacing normal hematopoietic cells in the bone marrow. Bone marrow in ALL shows lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm, which are characteristic of lymphoblastic leukemia. Precursor B-cell ALL shows large purple malignant lymphoblasts on

bone marrow aspirate smears. Normal lymphoblasts mature into B-cells or T-cells that fight infections, but in ALL, they fail to mature properly. T-cell ALL may present as a mediastinal mass, potentially causing superior vena cava (SVC) syndrome. Both peripheral blood and bone marrow in ALL show increased lymphoblasts. ALL has a poorer prognosis in adults compared to children. {{caption_text}} Acute Lymphoblastic Leukemia (ALL) Lymphoblasts in bone marrow >=20% Cytoplasmic vacuolations They contain fat (Oil Red O Positive) Hand mirror-shaped cells {{caption_text}} Acute Myeloid Leukemia (AML) Blasts ≥ 20% Myeloblasts with AuerRods AML (Acute Myeloid Leukemia) (Option A) is a blood and bone marrow cancer primarily affecting adults caused by the uncontrolled proliferation of myeloblasts (immature white blood cells). It is characterised by an abundance of abnormal cells that fail to mature into healthy blood cells, leading to symptoms like infections, anaemia, and easy bleeding. Common in infants and children < 3yrs with Down syndrome (M7 subtype), not 10-year-olds. Aplastic Anemia (Option B) is a serious condition where the bone marrow fails to produce enough blood cells, leading to low blood counts and symptoms like easy bruising, heavy menstrual bleeding, shortness of breath, fatigue, and frequent infections. It can be inherited or acquired, with acquired cases often linked to immune system dysfunction. Juvenile Myelomonocytic Leukemia (JMML) (Option D) is a rare blood cancer in young children, characterised by abnormal development of monocytes and myelocytes (types of white blood cells). Treatment often involves chemotherapy followed by a bone marrow transplant. Unlike ALL, JMML does not typically present with lymphoblasts.

@Neet_pg_bot

Q5: A 60-year-old patient presented with scrotal swelling and ataxia. Which among the following could likely be a cause? (Q856695)

A. Glioblastoma multiforme

B. Hodgkin lymphoma

C. Non-Hodgkin lymphoma

D. Non seminomatous germ cell tumor

Correct Answer: C. Non-Hodgkin lymphoma

Explanation: The case scenario of a 60-year-old man with scrotal swelling and ataxia is likely diagnosed as Non-Hodgkin Lymphoma (NHL) , where lymphatic obstruction causes scrotal swelling, and CNS involvement leads to ataxia. It is a type of cancer originating from lymphocytes and is characterized by the growth of lymphoid tissue. Clinical features: Asymptomatic Palpable Lymphadenopathy is the hallmark (neck, armpits, or groin). Lymphadenopathy is not rapidly progressive. B Symptoms (Fever, Night sweats, and Weight loss) Extranodal involvement Ileocecal region (abdominal pain or changes in bowel habits). Lymphomatoid polyposis. The oropharynx, especially Waldeyer's ring (sore throat or difficulty swallowing). Bone marrow involvement (cytopenias-anemia, leukopenia, and thrombocytopenia). Splenomegaly (abdominal discomfort and a sensation of fullness). Hodgkin lymphoma (Option B ruled out) Non-Hodgkin lymphoma (Option C) Age of presentation Bimodal distribution peaks in young adults (15-35 years) and older adults (over 55). More common in older adults but can occur at any age. Localization More often localised to a single axial group of nodes (cervical, mediastinal, para-aortic) More frequent involvement of multiple peripheral nodes Malignant cells Reed-Sternberg cells (owl eye cells) - B cells - induce inflammation and fibrosis Lymphoid cells - many subtypes - most are B cells than T cells Mass composition Inflammatory cells and fibrosis (reactive cells) Lymphoid cells Clinical Painless lymphadenopathy B symptoms Painless lymphadenopathy Mesenteric nodes and Waldeyer ring are involved. Spread Contiguous (touching); rarely extranodal Diffuse; often extranodal Staging Guides therapy Radiation mainstay treatment Limited importance Leukemic phase Doesn't occur Occurs Glioblastoma multiforme (Option A) is a type of brain tumour that arises from glial cells. It typically does not cause scrotal swelling or ataxia. The symptoms associated with glioblastoma multiforme are typically related to the location of the tumour within the brain. Non-seminomatous germ cell tumours (Option D) are a type of testicular cancer that arise from germ cells in the testicles. While they can cause scrotal swelling, ataxia is not a typical presentation of this type of tumour.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 611.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: Which cell is the origin of chronic lymphocytic leukaemia / small lymphocytic lymphoma? (Q856721)

A. Naive B cells

B. Mature T cells

C. Progenitor T cells

D. Granulocytes

Correct Answer: A. Naive B cells

Explanation: The cells of origin of Chronic Lymphocytic Leukemia (CLL) and Small Lymphocytic Lymphoma (SLL) are mature B cells. Genetics: Trisomy 12, deletion 13q14, and others Origin: Post–germinal centre memory B cell or naive B Cells in the mantle zone of the lymph node (Option A) Etiopathogenesis Antiapoptotic protein

BCL2 overexpression. CLL cell growth depends on Bruton Tyrosine kinase (BTK) activity. No association with radiation exposure Clinical Presentation Most common Leukemia in the elderly. Frequently asymptomatic at diagnosis. May present with fatigue, lymphadenopathy, hepatosplenomegaly, or infection due to immunosuppression. Associated with autoimmune hemolytic anaemia- Spherocytes can be seen on peripheral smear It can lead to hypogammaglobulinemia due to abnormal B cells, which impair normal antibody production. Infection is the M/C/C of death in CLL Laboratory diagnosis: Absolute lymphocyte count (ALC) > 5000/mm3 Bone marrow lymphocytes >30% Surface markers using flow cytometry were positive for CD5, CD23, CD19 CD20. CLL co-expresses both T cell (CD5) and B cell (CD20, CD19) markers Mature T cells (Option B) can give rise to several cancers, including Peripheral T-cell lymphoma (PTCL), Cutaneous T-cell lymphoma (CTCL), Adult T-cell leukaemia/lymphoma (ATLL) (associated with HTLV-1), Anaplastic large cell lymphoma (ALCL), and T-cell prolymphocytic leukaemia (T-PLL). Progenitor T cells (Option C) can give rise to cancers such as T-cell acute lymphoblastic leukaemia (T-ALL) and T-cell lymphoblastic lymphoma (T-LBL). Both of these are aggressive hematologic malignancies that involve the malignant transformation of immature T cells (or T-cell precursors), characterized by rapid proliferation of immature T lymphocytes. Granulocytes (Option D) can give rise to acute myelogenous leukaemia (AML), where immature myeloid cells, including granulocyte precursors, proliferate rapidly, and chronic myelogenous leukaemia (CML), characterized by uncontrolled production of mature granulocytes due to the Philadelphia chromosome. Both cancers stem from the malignant transformation of myeloid progenitor cells.

@Neet_pg_bot

Q7: A patient with lytic lesions on the skull is suspected of a diagnosis of Langerhans cell histiocytosis. Which of the following is a characteristic finding of electron microscopy? (Q856725)

A. Histiocytes

B. Birbeck granules

C. Eosinophils

D. Giant cells

Correct Answer: B. Birbeck granules

Explanation: A characteristic finding on electron microscopy in Langerhans cell histiocytosis (LCH) is the presence of Birbeck Granules . These are rod-shaped, tennis racket-like structures that have a central linear striation. {{caption_text}} They are considered to be specific ultrastructural markers for Langerhans cells. These are thought to be derived from the endosomal compartment and are composed of a protein called langerin (CD207), a unique marker for Langerhans cells and is involved in antigen presentation and immune response

regulation. Histiocytes (Option A) are a type of immune cell that plays a key role in the body's defence mechanisms. They are specialized macrophages or dendritic cells found in tissues, where they function to engulf pathogens, dead cells, and foreign substances. Histiocytic disorders can give rise to cancers such as histiocytic sarcoma and Langerhans cell histiocytosis (LCH). Eosinophils (Option C) are a type of white blood cell involved in immune responses, particularly in allergic reactions and parasitic infections. They can give rise to cancers such as eosinophilic leukaemia and eosinophilic lymphoma, which are rare disorders characterized by the uncontrolled proliferation of eosinophils, leading to symptoms like organ infiltration, tissue damage, and inflammation. Giant cells (Option D) are large, multinucleated cells that can arise in response to chronic inflammation or certain infections. They can be found in various cancers, such as giant cell tumours of bone (a benign but locally aggressive tumour) and osteoclast-like giant cell tumours in soft tissues. Additionally, giant cells are often seen in granulomatous diseases like tuberculosis and sarcoidosis, where they form part of the immune response.

Robbins & Cotran Pathologic Basis of Disease,10th Edition, Page 627.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 6-year-old boy came with bilateral cervical lymphadenopathy. What is the probable diagnosis, cell, and virus associated with the image given below? RS cell: Reed Stemberg cell HIV: Human immunodeficiency virus CMV: Cytomegalovirus

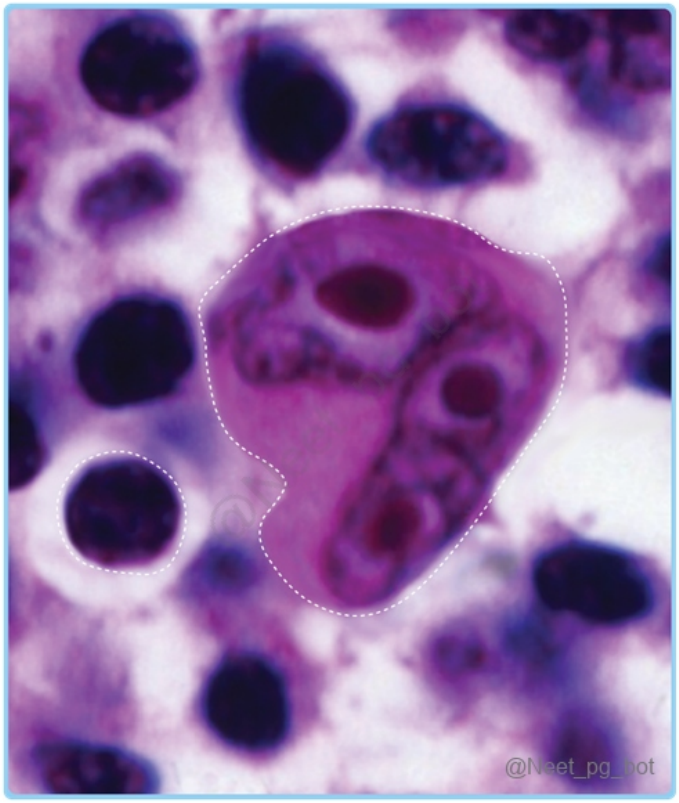
EBV: Epstein–Barr virus (Q856726)

A. Non-Hodgkin’s lymphoma, RS cell, EBV

B. Kaposi sarcoma, Giant cell, HIV

C. Hodgkin’s lymphoma, RS cell, EBV

D. Infectious mononucleosis, RS cell, CMV



Correct Answer: C. Hodgkin’s lymphoma, RS cell, EBV

Explanation: The histopathological image reveals Reed-Sternberg cells , indicating Hodgkin's Lymphoma (HL) , which is associated with EBV (Epstein-Barr virus). Hodgkin's Lymphoma (HL) Etiology M ore common in whites & Males. Bimodal age distribution with peaks in the 20s and 80s. It is not a part of AIDS-defining lymphoma. Risk Factors : HIV infection is a major risk factor. Epstein-Barr virus (EBV). (Option C) Reed-Sternberg (HRS) Cells (Option C) HRS cells are derived from the germinal centre or post-germinal centre B cells (mature B cells in peripheral lymph nodes). Diagnostic of HL. Large, with abundant cytoplasm, bilobed or multinucleated. Typically positive for PAX-5, CD15, and CD30. {{caption_text}} NF-κB Activation Common in cHL, promoting RS cell growth and survival. EBV+ Tumors : Express latent membrane protein-1 (LMP-1) , which activates NF-κB. EBV– Tumors : NF-κB activation may result from loss-of-function mutations in IκB or loss-of-function mutation of TNF-α–induced protein 3, both of which normally inhibit NF-κB. NF-κB activation may rescue "crippled" B cells that can't express Ig, preventing apoptosis and enabling further mutations that form RS cells. Immune Evasion Genetic abnormalities at the PD-L1 locus on chromosome 9p24.1 lead to PD-L1 overexpression, which helps the tumour evade immune detection. Non-Hodgkin’s lymphoma, RS cell, EBV (Option A) : Non-Hodgkin's

lymphoma (NHL) is a diverse group of hematologic cancers marked by lymphoid tissue proliferation, often linked to HIV but not typically associated with Reed-Sternberg cells or EBV. Kaposi sarcoma, Giant cell, HIV (Option B): Kaposi sarcoma is marked by the proliferation of spindle-shaped cells that express markers of both endothelial (vascular or lymphatic) and smooth muscle cells, and is linked to human herpesvirus 8 (HHV-8) , but is not typically associated with Reed-Sternberg cells or EBV. {{caption_text}} Infectious mononucleosis, RS cell, CMV (Option D) : Infectious mononucleosis, a benign and self-limited lymphoproliferative disorder caused by Epstein-Barr virus (EBV), is characterized histopathologically by atypical lymphocytes—large, irregularly shaped cells with abundant cytoplasm and prominent nuclei. It is not typically associated with Reed-Sternberg cells. {{caption_text}}

Robbins & Cotran Pathologic basis of disease, 10th Edition, Page 611, 612.

Harrison’s Principles of Internal Medicine, 21st Edition Page 852.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 30-year-old male has been complaining of fatigue for the past year. The examination revealed massive splenomegaly. His blood workup shows the presence of anemia, TLC 150,000/microL, and PBS shows 60% neutrophils, 6% basophils, 4% eosinophils, myeloblasts, myelocytes, and metamyelocytes. The myeloid-to-erythroid ratio was 18:1. Which of the following is the most sensitive investigation in this case? (Q856102)

A. Immunophenotyping

B. LAP score

C. FISH and PCR

D. Flow cytometry

Correct Answer: C. FISH and PCR

Explanation: The clinical presentation with massive splenomegaly, anaemia, and a markedly elevated TLC with myeloblasts, myelocytes, and basophils is highly suggestive of Chronic Myelogenous Leukemia (CML), and the most sensitive test for diagnosing CML is FISH and PCR . Investigations to find CML CBC Normal RBC + Elevated TLC + Elevated platelets Peripheral smear Left shift with predominant segmented neutrophils, myelocytes, and metamyelocytes. College girl/garden party appearance. Bone marrow aspirate Increased Myeloid: Erythroid ratio. Dwarf megakaryocytes. Sea blue histiocytes (blue-coloured cytoplasm) Pseudo Gaucher cells {{caption_text}} NAP/LAP score The leukocyte alkaline phosphatase (LAP) score is low in CML and can be used to differentiate it from other leukaemias, but it’s not the most sensitive test. (Option B ruled out) FISH (IOC) Confirms t(9:22) translocation. Analysis to quantify Philadelphia chromosome-positive cells. Estimates the tumour load. {{caption_text}} PCR To quantify BCR-ABL-1. It can be a false negative or a false positive. False negative: Early part of the disease. Immunophenotyping (Option A) can be useful for characterising cell surface markers in hematologic malignancies, but it is not the most sensitive test for CML . It is more helpful in identifying acute leukaemias or lymphoproliferative disorders but does not directly detect the genetic mutation responsible for CML. Flow cytometry (Option D) is primarily used to analyse the immunophenotype of hematologic cells and is useful for detecting acute leukaemias and lymphoproliferative disorders . However, it does not directly detect the Philadelphia chromosome or the BCR-ABL fusion gene , which are key to diagnosing CML.

Robbins and Cotran Pathologic Basis of Disease, 10th edition, Page 622

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: Which of the following is a poor prognostic marker of multiple myeloma? (Q856140)

A. β-2 microglobulin

B. Calcium levels

C. Serum creatinine

D. Protein levels

Correct Answer: A. β-2 microglobulin

Explanation: In multiple myeloma , one of the most significant poor prognostic markers is β-2 microglobulin. Elevated levels of β-2 microglobulin correlate with a higher tumour burden and more aggressive disease Prognosis of Multiple Myeloma is determined by: Durie-Salmon staging system (earlier) International Staging System (ISS): Three-stage system to predict survival based on: β2-microglobulin Albumin levels Calcium levels (Option B) : Hypercalcemia is a common marker in multiple myeloma, but it is often a late-stage complication and does not directly indicate poor prognosis compared to β-2 microglobulin . Serum creatinine (Option C) , when elevated, indicates renal impairment , which is a common complication of multiple myeloma. While kidney function is important for prognosis, serum creatinine is not a prognosis indicator compared to β-2 microglobulin . Protein levels (Option D) are commonly elevated and serve as disease markers, but they do not directly indicate a poor prognosis.

References:

Harrison’s Principles of Internal Medicine, 21st Edition, Page 871

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: A 54-year-old patient presents to the outpatient department with fatigue, tiredness, and cervical lymphadenopathy. The TLC and DLC were normal, with no immature cells. A lymph node biopsy showed diffuse effacement of the lymph node architecture and cells with an indented nucleus and prominent nucleolus that are atypical. CD10 and BCL2 are positive. What is the likely diagnosis? (Q856147)

A. Follicular lymphoma

B. Burkitt lymphoma

C. Mycosis fungoides

D. Chronic myeloid leukaemia

Correct Answer: A. Follicular lymphoma

Explanation: Given the lymphadenopathy , the findings on lymph node biopsy (indented nuclei, BCL2 positivity), and the normal blood counts (no immature cells), Follicular lymphoma is the most likely diagnosis. Follicular lymphoma (FL) is a malignant neoplasm originating from germinal centre B-cells, characterised by the t(14;18) translocation leading to overexpression of BCL2. Clinically, it presents with painless lymphadenopathy and may include systemic symptoms. Histopathologically, FL exhibits a nodular growth pattern with centrocytes(Small cells with cleaved nuclei and scanty cytosol) and centroblasts(Larger cells with open nuclear chromatin and several nucleoli) Immunohistochemistry shows positivity for CD10/19/20, BCL2, and BCL6, and negativity for CD5. Management focuses on palliative approaches due to their indolent but incurable nature. {{caption_text}} Burkitt lymphoma (Option B) is a type of B-cell lymphoma characterised by rapidly growing tumours , typically extranodal , most commonly in the abdomen or jaw . It often presents as large masses rather than just cervical lymphadenopathy . It has a "starry sky" pattern on histology due to macrophages phagocytosing apoptotic tumour cells, which was not noted in the biopsy here. Mycosis fungoides (Option C) is a cutaneous T-cell lymphoma that primarily affects the skin and presents as patches, plaques , or tumours . It does not typically present with lymphadenopathy as a primary feature; its main involvement is in the skin rather than the lymph nodes. Chronic myeloid leukemia (Option D) is a myeloproliferative disorder that is marked by the presence of the Philadelphia chromosome (t(9;22) translocation), which leads to the production of the BCR-ABL fusion gene .

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 589, 599 - 603

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: Which of the following is a possible explanation for the presence of pancytopenia as indicated by the blood examination results? A. Megaloblastic anemia B. Hairy cell leukemia C. MDS with hypocellular BM D. APML (Q856922)

A. B, D

B. A, B, C

C. B, C, D

D. A, B, D

Correct Answer: B. A, B, C

Explanation: Megaloblastic anaemia is caused by impaired DNA synthesis, leading to the production of abnormally large and immature red blood cells (megaloblasts). Pancytopenia occurs due to reduced production of red blood cells, white blood cells, and platelets. Hairy cell leukaemia is a rare form of chronic lymphocytic leukaemia characterized by abnormal B lymphocytes with hair-like projections on their surface. It can lead to pancytopenia by infiltrating the bone marrow with these atypical cells, which disrupt normal blood cell production. MDS with hypocellular bone marrow : Myelodysplastic syndromes (MDS) are a group of disorders marked by ineffective blood cell production. In some cases, MDS leads to a hypocellular bone marrow, where the number of blood-forming cells is lower than usual, resulting in pancytopenia due to a reduction in the production of all types of blood cells. Causes of pancytopenia in hypocellular marrow: Hypocellular MDS Some Lymphomas and ALL Copper deficiency Acquired aplastic anemia Causes of pancytopenia in cellular bone marrow: Myelodysplastic syndromes (MDS) Systemic Lupus Erythematosus (SLE) Megaloblastic anemia Hairy cell leukemia Myelofibrosis Paroxysmal Nocturnal Hemoglobinuria (PNH) Sarcoidosis, HIV, Brucellosis,Leishmaniasis Hypersplenism Bone marrow lymphoma

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: 2-year-old with fever, lymphadenopathy and H&E has hallmark cells. The diagnosis of anaplastic large cell lymphoma was made. Most likely translocation? (Q866673)

A. t(8;14)

B. t(8;22)

C. t(2;5)

D. t(14;18)

Correct Answer: C. t(2;5)

Explanation: Anaplastic Large Cell Lymphoma (ALCL) is most often associated with the t(2;5) translocation. t(2;5) → creates the NPM-ALK fusion gene NPM - nucleophosmin (chromosome 5) ALK - anaplastic lymphoma kinase (chromosome 2) This fusion leads to constitutive activation of ALK tyrosine kinase, driving uncontrolled cell growth. ALCL histology shows hallmark cells, large pleomorphic cells with horseshoe- or kidney-shaped nuclei and abundant cytoplasm. Incorrect Options: t(8;14) (Option A): Seen in Burkitt lymphoma . MYC gene on chromosome 8 translocates to Ig heavy chain locus on chromosome 14 → MYC overexpression. It is a very aggressive B-cell lymphoma; common in children in malaria-endemic areas. t(8;22) (Option B) : Variant of Burkitt lymphoma involving MYC and Ig lambda light chain locus (chromosome 22). t(14;18) (Option D): Seen in Follicular lymphoma. BCL2 gene (chromosome 18) translocates to Ig heavy chain locus (chromosome 14) → BCL2 overexpression → apoptosis inhibition. It usually has an indolent course.

References:

.

@Neet_pg_bot

Q14: Identify the correct statement regarding immune surveillance. (Q856493)

A. Anti-CTLA-4 Ab is a new modality in the treatment of advanced cancers

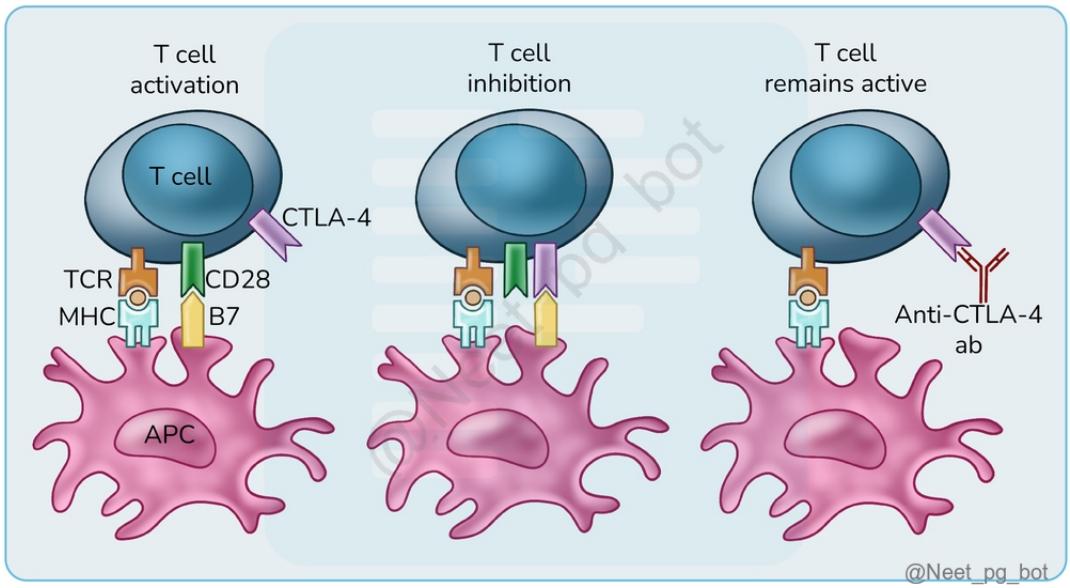
B. Mutation of tumour suppressor genes decreases antigen toxicity

C. PD1/PDL1 activation leading to tumour suppression

D. Binding of CD28 leads to immune tolerance

Correct Answer: A. Anti-CTLA-4 Ab is a new modality in the treatment of advanced cancers

Explanation: Anti-CTLA-4 antibody (Ab) is an emerging treatment in immunotherapy, especially in advanced cancers. It works by blocking the CTLA-4 receptor , enhancing T-cell activation and immune response against tumour cells. Immune surveillance: Immune surveillance refers to the immune system's ability to detect and eliminate cancerous cells, thereby preventing cancer development and progression. CTLA-4 (cytotoxic T-lymphocyte-associated protein 4) is a checkpoint protein that negatively regulates T-cell activation. Immunotherapeutic agents, such as ipilimumab , target CTLA-4 to enhance T-cell activation, boosting the immune response against tumours and showing promising results in treating advanced cancers. Mutations in tumour suppressor genes typically increase tumorigenicity and antigenicity (Option B) , not decrease antigen toxicity. PD1/PDL1 activation generally inhibits immune responses (Option C) , leading to immune evasion by tumours, not suppression. Binding of CD28 to CD80/86 enhances immune activation, not tolerance (Option D) . Immune tolerance is more associated with inhibitory signals like CTLA-4.



References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 312

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: All-trans retinoic acid (ATRA) is used in the treatment of tumours associated with which of the following genetic aberrations? (Q854879)

A. PML-RARA

B. BCR-ABL

C. cMYC

D. RUNX1-ETO

Correct Answer: A. PML-RARA

Explanation: All-trans retinoic acid (ATRA) is specifically used in the treatment of acute promyelocytic leukaemia (APL) , which is associated with the genetic fusion of PML (promyelocytic leukaemia gene) and RARA (retinoic acid receptor alpha) genes. The fusion disrupts the normal differentiation of promyelocytes, and ATRA helps reverse this block by promoting differentiation. M3 AML/ Acute promyelocytic leukaemia: Genetics : t(15:17) translocation causes PML-RARA (retinoic acid receptor alpha) fusion protein formation. Blocks promyelocyte → myelocyte maturation. Diagnosis of choice: FISH Smear findings: Increased promyelocytes. Auer Rods : Fused granules in promyelocytes Faggot Cells: Auer rods with a crisscross pattern. Laboratory : Low haemoglobin and platelets. > 20% blasts on peripheral and bone marrow smear Stain: PAS + CD markers: CD 13, 33 + Complication : Disseminated intravascular coagulation therefore, chemotherapy is not recommended. Treatment : ATRA (All-trans-retinoic-acid) + As 2 O 3 (arsenic trioxide) Best prognosis among all AML. {{caption_text}} BCR-ABL (Option B) fusion gene is characteristic of chronic myelogenous leukemia (CML) . The treatment for CML typically involves tyrosine kinase inhibitors (e.g., imatinib) rather than ATRA. cMYC (Option C) is an oncogene often implicated in Burkitt lymphoma and other cancers, but it is not treated with ATRA. Treatment for cMYC-related tumours typically involves chemotherapy and targeted therapy based on the specific malignancy. RUNX1-ETO (Option D) fusion gene is associated with acute myeloid leukemia (AML) , but it does not respond to ATRA treatment. Treatment for AML often includes chemotherapy and other agents.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 617-620

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 70-year-old man has presented with chronic lower back pain, fatigue, and headaches for the last few weeks. On examination, he has pallor and bony tenderness. Lab investigations revealed an increased ESR, and his skull radiograph revealed several punched-out lytic lesions. Which of the following is the best investigation for this patient among the following options? (Q859274)

A. Serum electrophoresis showing IgG

B. Serum levels of CA 15-3

C. Whole-body scan

D. CT head with contrast

Correct Answer: A. Serum electrophoresis showing IgG

Explanation: The patient's pain, fatigue, multiple punched-out lytic lesions on X-ray, and elevated ESR suggest Multiple myeloma. The best investigation is serum electrophoresis , which detects monoclonal immunoglobulins, such as IgG, confirming the diagnosis and quantifying the abnormal proteins. Incorrect Options: Serum levels of CA 15-3 (Option B): CA 15-3 is a tumour marker primarily used for monitoring breast cancer. Whole-body scan (Option C) : While imaging studies such as whole-body scans may be useful in assessing the extent of multiple myeloma involvement, they are not typically the initial investigation for diagnosis. CT head with contrast (Option D) is not necessary for multiple myeloma.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Pages 607- 610

↑ *Back to this question in Part A*

@Neet_pg_bot

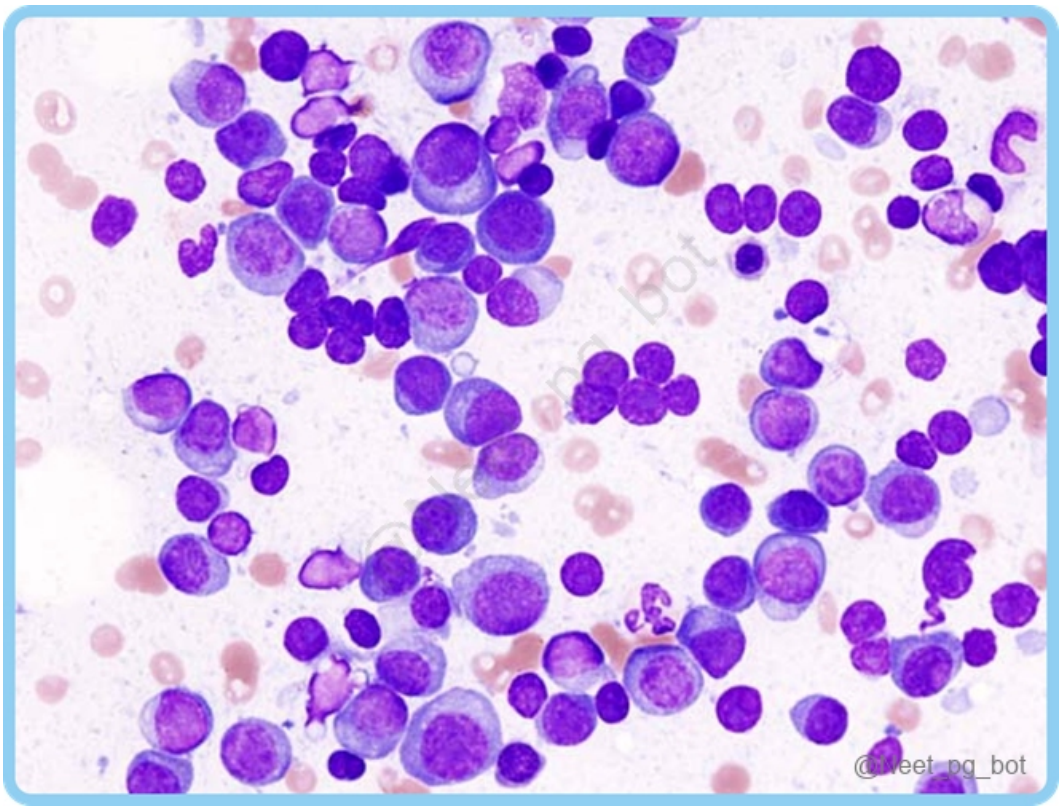
Q17: A 65-year-old male underwent a bone marrow examination, which revealed the presence of the following findings, as shown in the image. What is the likely diagnosis of this patient? (Q859279)

A. Multiple myeloma

B. ALL

C. Tuberculosis

D. Sickle cell disease



Correct Answer: A. Multiple myeloma

Explanation: Multiple myeloma is a plasma cell malignancy characterised by the uncontrolled proliferation of clonal plasma cells in the bone marrow. Bone Marrow Examination: Presence of ≥10% clonal plasma cells in bone marrow. Atypical plasma cells with features such as binucleation, prominent nucleoli, and perinuclear hof (Golgi clearing). Serum and Urine Electrophoresis: Detection of monoclonal (M) protein in serum or urine (commonly IgG or IgA). Free light chains may be detected in urine (Bence Jones proteins). CRAB Criteria (End-Organ Damage): Calcium elevation (hypercalcemia). Renal dysfunction (elevated creatinine). Anaemia (normocytic, normochromic). Bone lesions (osteolytic lesions on skeletal imaging). Incorrect Options: ALL (Acute Lymphoblastic Leukemia) (Option B) is characterised by increased bone marrow and peripheral blood lymphoblasts but lacks the plasma cell morphology seen in multiple myeloma. Tuberculosis (Option C) of the bone marrow usually shows granulomas with caseous necrosis, not plasma cells. Sickle Cell Disease (Option D): Bone marrow findings in sickle cell disease may show erythroid hyperplasia and abnormal erythrocytes, but plasma cells are not a feature.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 607, 608, 609

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 10-year-old boy with Down syndrome presents with mediastinal mass (presenting as SVC-like syndrome), and Peripheral blood and bone marrow have increased lymphoblasts. What is the probable diagnosis? (Q859296)

A. Acute myeloblastic leukemia

B. Chronic lymphoblastic leukemia

C. Acute lymphoblastic leukemia

D. Chronic myeloid leukemia

Correct Answer: C. Acute lymphoblastic leukemia

Explanation: The diagnosis is based on the presence of increased lymphoblasts in peripheral blood and bone marrow, along with a mediastinal mass causing SVC-like syndrome, a characteristic feature of T-cell Acute Lymphoblastic Leukaemia (ALL). The strong association with Down syndrome further supports the diagnosis. Common in children, with a worse prognosis in adults. T-cell ALL often presents with a mediastinal mass. Immunophenotyping: TdT+ (a marker of pre-T and pre-B cells), CD10+ (a marker of pre-B cells). Incorrect Options: Acute Myeloblastic Leukemia (AML) (Option A) typically presents with symptoms such as fatigue, recurrent infections, bleeding tendencies, and bone pain. It is less commonly associated with hepatosplenomegaly and sternal tenderness. Chronic Lymphoblastic Leukemia (CLL) (Option B) usually occurs in older individuals and is characterised by lymphocytosis, lymphadenopathy, and splenomegaly. It is less likely to present with hepatomegaly, sternal tenderness, and petechiae in a 10-year-old patient. Chronic Myeloid Leukemia (CML) (Option D) typically presents in adults and is characterised by an elevated white blood cell count, splenomegaly, and a characteristic genetic abnormality called the Philadelphia chromosome. It is less common in children and may not present with the described symptoms.

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 594-596.

↑ *Back to this question in Part A*

@Neet_pg_bot

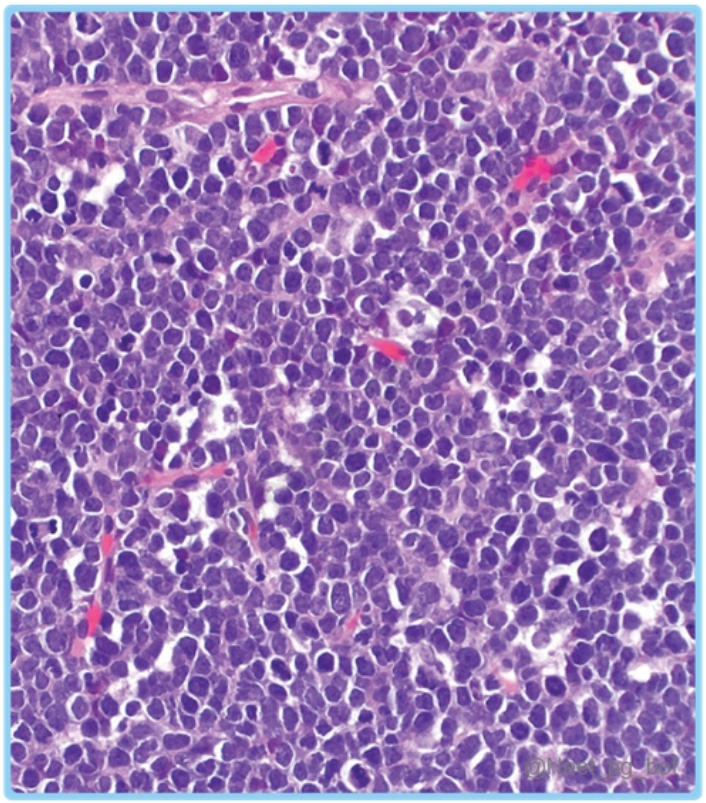
Q19: What is the diagnosis for a 5-year-old boy who has weight loss, fever, and a painless swelling in his jaw area? CBC results indicate anaemia and lymphocytosis. The image below shows biopsy findings from the swelling. (Q859847)

A. Kikuchi disease

B. Infectious mononucleosis

C. Hodgkins lymphoma

D. Burkitt lymphoma



Correct Answer: D. Burkitt lymphoma

Explanation: The histopathological picture is of a Classical Burkitt Lymphoma involving a lymph node. The most characteristic finding is a “starry sky” pattern. At high-power magnification, the neoplastic cells are of intermediate size, similar to the size of benign histiocyte nuclei. The neoplastic cells have round nuclear contours, multiple nucleoli, frequent mitoses, and basophilic cytoplasm. Macrophages with engulfed pyknotic nuclei and nuclear debris are also present. Burkitt's lymphoma Aspects Description Definition An aggressive form of non-Hodgkin lymphoma characterised by the proliferation of mature B-cells. Epidemiology Endemic (African) form : Common in children, associated with Epstein-Barr virus (EBV) infection. Sporadic form : Worldwide distribution, more common in children and young adults. Immunodeficiency-related : Often seen in HIV/AIDS patients. Etiology Strong association with EBV (especially in the endemic form). Translocations involving the MYC gene (chromosome 8). Genetic Abnormality t(8;14): MYC gene translocated next to the IgH locus (most common). t(2;8) or t(8;22) : Less common, involving MYC and Ig light chain loci. Clinical Features Endemic form : Presents with jaw or facial bone tumours. Sporadic form : Often involves the abdomen (e.g., ileum, cecum) and may cause bowel obstruction. Systemic symptoms : Fever, night sweats, weight loss. Pathology Histology : "Starry-sky" appearance due to numerous apoptotic cells and macrophages. Tumor cells are medium-sized with round nuclei, coarse chromatin, and high mitotic activity. Immunophenotype Positive for CD19 , CD20 (B-cell markers), and CD10 . Expresses surface IgM . High proliferation index (Ki-67 > 95%). Diagnosis Biopsy : Histological examination showing "starry-sky" appearance. Cytogenetics : Detection of MYC translocations. Immunohistochemistry : Positive for B-cell markers (CD19, CD20). Prognosis Highly aggressive but potentially curable with prompt treatment. Favorable response to chemotherapy in many cases. Treatment Chemotherapy : Intensive regimens like cyclophosphamide, doxorubicin, vincristine, and methotrexate (CODOX-M) . CNS prophylaxis : Methotrexate or cytarabine. Supportive care for tumour lysis syndrome. Complications Risk of

tumour lysis syndrome due to rapid tumour breakdown. It may progress to involve bone marrow or CNS if untreated. Differential Diagnosis Diffuse large B-cell lymphoma. Other high-grade B-cell lymphomas. Lymphoblastic lymphoma. Hodgkin lymphoma (rarely resembles). Kikuchi disease (Option A) is a subacute necrotising lymphadenopathy affecting young adults, predominantly women, especially in Japan and neighbouring Asian countries. It presents with painless lymphadenopathy, moderate fever, chills, myalgia, sore throat, and skin rashes . Histopathology reveals necrotising lymphadenitis with histiocyte proliferation and reactive germinal centres. Infectious mononucleosis (Option B) presents with a triad of fever, pharyngitis, and cervical or generalised lymphadenopathy. Histopathology reveals Paracortical hyperplasia with a mottled ("moth-eaten") lymph node architecture. Hodgkin lymphoma (HL) (Option C) is characterised by a heterogeneous cellularity comprising a minority of specific neoplastic cells—the Hodgkin cells, the Reed-Sternberg cells, and a majority of reactive non-neoplastic cells. {{caption_text}}

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Pages 601, 602

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 60-year-old male patient presented with anaemia and hepatosplenomegaly. A peripheral smear showed teardrop cells, nucleated RBCs, and giant abnormal platelets. A biopsy showed marrow fibrosis and a few characteristics, as given below.

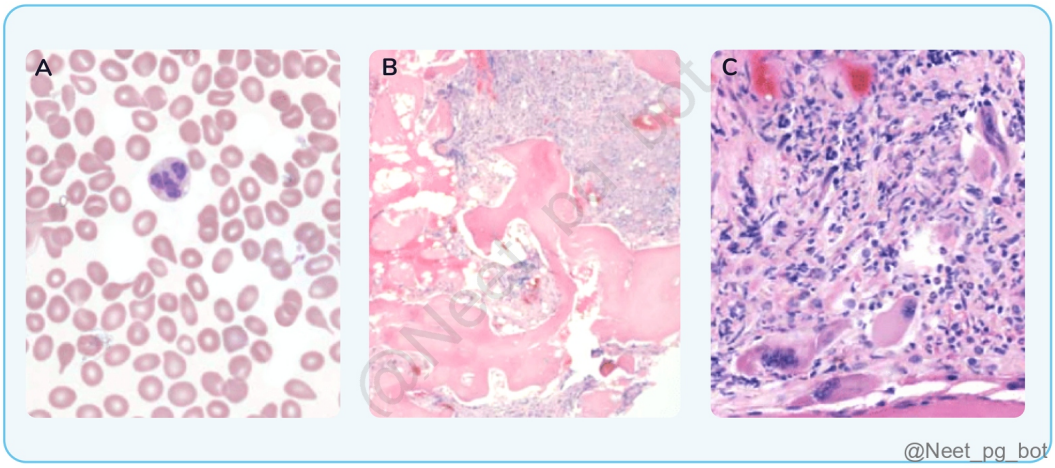
The most likely diagnosis is: (Q859854)

A. Polycythemia vera

B. Essential thrombocythemia

C. Primary myelofibrosis

D. Chronic myeloid leukemia



Correct Answer: C. Primary myelofibrosis

Explanation: Primary myelofibrosis (PMF) is a chronic myeloproliferative neoplasm characterised by the development of extensive marrow fibrosis , which impairs normal hematopoiesis. This fibrosis is driven by the inappropriate release of fibrogenic factors, such as platelet-derived growth factor and TGF-β, from neoplastic megakaryocytes. Clinically, PMF presents with progressive anaemia, splenomegaly, and symptoms like fatigue and weight loss. {{caption_text}} WHO diagnostic criteria: Major criteria: Megakaryocyte proliferation and atypia, usually with reticulin or collagen fibrosis. Not meeting WHO criteria for BCR-ABL1 + CML, PV, ET, MDS, or other myeloid neoplasm. Presence of JAK2, CALR, or MPL mutation or in the absence of these mutations, presence of other clonal markers, or absence of minor reactive BM reticulin fibrosis. Minor criteria: Leukocytosis ≥ 11 × 10 9 /L. Increased Serum Lactate Dehydrogenase (LDH). Anaemia is not attributed to another condition. Palpable Splenomegaly. Polycythemia vera (Option A) : Given that the patient presents with anaemia, the diagnosis is unlikely to be polycythemia vera. Essential thrombocythemia (Option B): In Essential thrombocythemia, patients usually present erythromelalgia and elevated platelet count, and there is an absence of marrow fibrosis. Chronic myeloid leukaemia (Option D): Though CML presents with anaemia and splenomegaly, bone marrow aspirate in CML is likely to show dwarf megakaryocyte and characteristic garden party appearance.

@Neet_pg_bot

Q21: A 35-year-old man presents with nosebleeds, bleeding gums, and multiple ecchymoses. Lab investigations show: Haemoglobin: 8.5 g/dL Platelet count: 12,000 platelets/mm3 Total leucocyte count: 52,000 cells/mm3 with 83% blasts, as seen below. The blasts are CD33 +ve. The most likely diagnosis is: (Q859860)

A. Acute myeloid leukemia

B. Acute lymphoblastic leukemia

C. Chronic lymphocytic leukemia

D. Myelodysplastic syndrome

Correct Answer: A. Acute myeloid leukemia

Explanation: The patient's presentation with nosebleeds, bleeding gums, and multiple ecchymoses with anaemia, thrombocytopenia, and leukocytosis with 83% blast, which is CD33+ve, and peripheral smear showing myeloblasts is suggestive of acute myeloid leukemia. AML arises due to genetic mutations in hematopoietic stem cells, leading to the accumulation of immature myeloblasts in the bone marrow, resulting in marrow failure. Patients often present with pancytopenia-related symptoms, including easy bruising (due to thrombocytopenia), fatigue (due to anaemia), and infections (due to leukopenia with dysfunctional blasts). Acute Lymphoblastic Leukemia (Option B): In ALL, the lymphoblasts are CD33-ve and myeloperoxidase-ve. Chronic Lymphocytic

Leukemia (Option C) : Smudge cells characteristic of CLL are CD33-ve, CD20+ve, and CD5+ve. Myelodysplastic Syndrome (Option D) is a heterogeneous group of hematologic neoplasms classically described as a clonal disorder of hematopoietic stem cells leading to dysplasia and ineffective hematopoiesis in the bone marrow. Some patients with MDS may have a transformation into acute myeloid leukemia.

@Neet_pg_bot

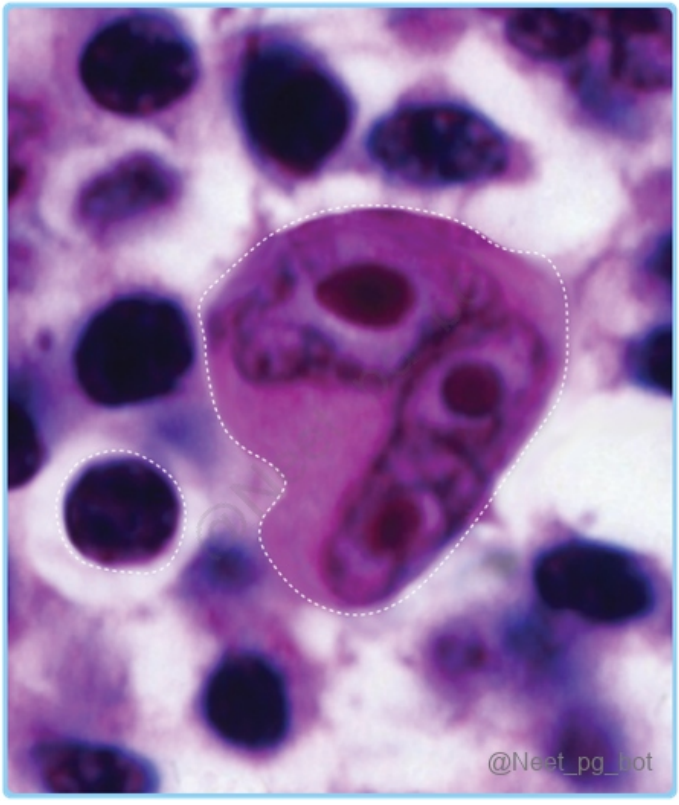
Q22: What is the type of cell from which the cell displayed below originates? (Q859892)

A. NK cells

B. CD4 cells

C. B cells

D. CD8 cells



Correct Answer: C. B cells

Explanation: B cells express CD19, CD20, and CD21 markers. When activated, they differentiate into plasma cells , which have an eccentric nucleus, basophilic cytoplasm, and a perinuclear halo (indicative of the Golgi apparatus involved in antibody production). Plasma cells secrete immunoglobulins (IgG, IgA, etc.) , essential for humoral immunity. Incorrect options: NK (Natural Killer) (Option A) cells are innate immune cells. NK cells are lymphocytes that arise from the same common lymphoid progenitor that gives rise to T lymphocytes and B lymphocytes. CD4 (Option B) and CD8 (Option D) are expressed on distinct T-cell subsets and act as coreceptors during T-cell activation.CD4 is expressed in 50% to 60% of T cells, whereas CD8 is expressed in about 40% of T cells. The CD4- and CD8-expressing T cells—called CD4+ and CD8+ cells, respectively

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 611 to 613

↑ *Back to this question in Part A*

@Neet_pg_bot

Q23: A 56-year-old man presents with dragging pain in the abdomen. On examination, there is a massive splenomegaly. A peripheral smear shows leukocytosis with increased myelocytes, metamyelocytes, and basophils. Which of the following translocations is seen in this condition? (Q855983)

A. t(9;22)

B. t(8;21)

C. t(15;17)

D. t(8;14)

Correct Answer: A. t(9;22)

Explanation: one marrow aspirate to confirm diagnosis Peripheral smear: shows many mature neutrophils, some metamyelocytes, and myelocytes. {{caption_text}} On FISH - the presence of BCR ABL fusion gene product can be seen. Management Tyrosine kinase inhibitors such as Imatinib. t(8;21) (Option B) translocation results in the RUNX1-RUNX1T1 fusion gene , which is commonly seen in acute myeloid leukemia (AML) . t(15;17) (Option C) translocation results in the PML-RARA fusion gene, which is also characteristic of AML. t(8;14) (Option D) translocation involves the MYC gene on the chromosome, which is characteristic of Burkitt lymphoma.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 152, 600,

NIHLink,Link

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: A 62-year-old man presents with generalised lymphadenopathy and splenomegaly. Peripheral smear shows small to medium-sized lymphoid cells with irregular nuclear contours. Cytogenetic analysis demonstrates a t(11;14) (q13;q32) translocation. Which of the following markers is most closely associated with the pathogenesis? Cyclin D SOX 11 CD -200 D CD10 (Q879203)

A. 1, 2, 3

B. 1, 2

C. 1, 2, 4

D. 2, 3, 4

Correct Answer: B. 1, 2

Explanation: The described case is Mantle Cell Lymphoma (MCL) - characterised by t(11;14)(q13;q32) translocation → overexpression of Cyclin D1 . Cyclin D1 : Directly involved in pathogenesis via cell cycle dysregulation (G1→S transition). (Option 1) SOX11 : A diagnostic marker often co-expressed with Cyclin D1, helping confirm MCL, especially in Cyclin D1-negative variants. (Option 2) Conditions Surface IHC marker Follicular Lymphoma CD5 -ve, CD10+ve, CD19+ve, CD20+ve, BCL2+ve, BCL6+ve, Surface Ig+ve Follicular Hyperplasia CD3+ve, CD10+ve, CD20+ve, BCL2 -ve, BCL6+ve Mantle Cell Lymphoma Cyclin D1+ve, CD19+ve, CD20+ve, Surface Ig (usually IgM and IgD) +ve, CD5+ve, CD23 -ve Burkitt's Lymphoma IgM+ve, CD19+ve, CD20+ve, CD10+ve, BCL6+ve, BCL2 -ve CD200 (Option 3) is seen in CLL, not MCL. CD23 (Option 4) is negative in MCL but positive in CLL/SLL.

Robbins & Cotran, Pathologic Basis of Diseases, 10th Edition, Page 602,603

↑ *Back to this question in Part A*

@Neet_pg_bot

Q25: A 30-year-old male presents with fatigue for the past year. Examination reveals massive splenomegaly. His blood workup shows the following findings: Anemia Total leukocyte count (TLC): 150,000/microliter Peripheral smear: 60% neutrophils, 6% basophils, 4% eosinophils, myeloblasts, myelocytes, and metamyelocytes Myeloid to erythroid ratio: 18:1 What is the most likely diagnosis? (Q857164)

A. Acute Lymphoblastic Leukemia (ALL)

B. Acute Myeloid Leukemia (AML)

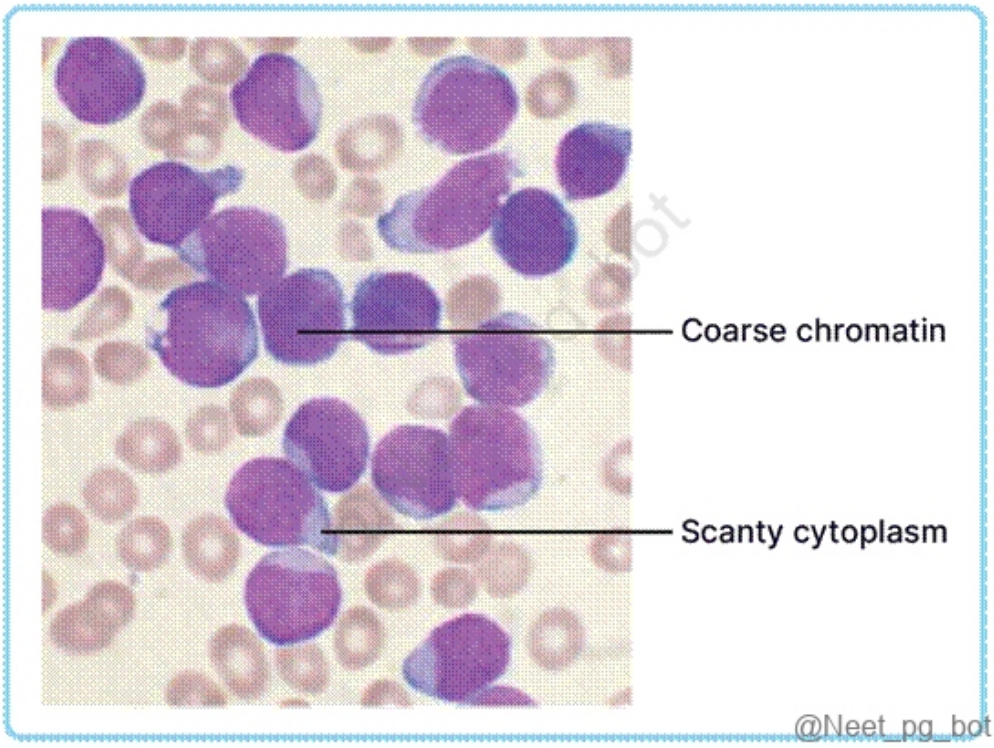
C. Chronic Myelogenous Leukemia (CML)

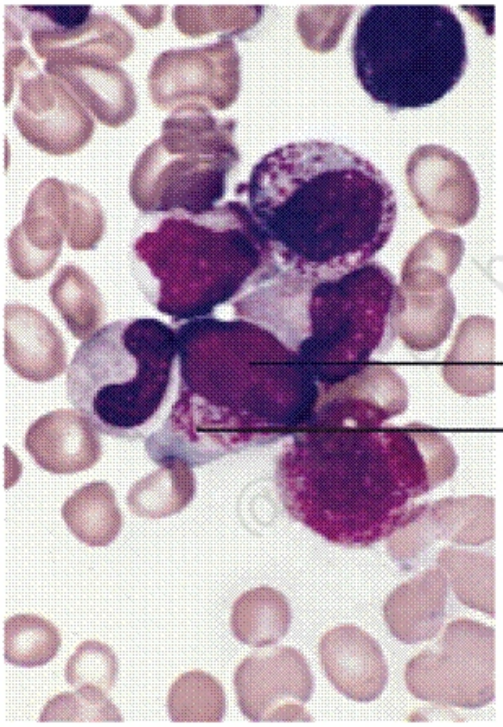
D. Chronic Lymphocytic Leukemia (CLL)

Correct Answer: C. Chronic Myelogenous Leukemia (CML)

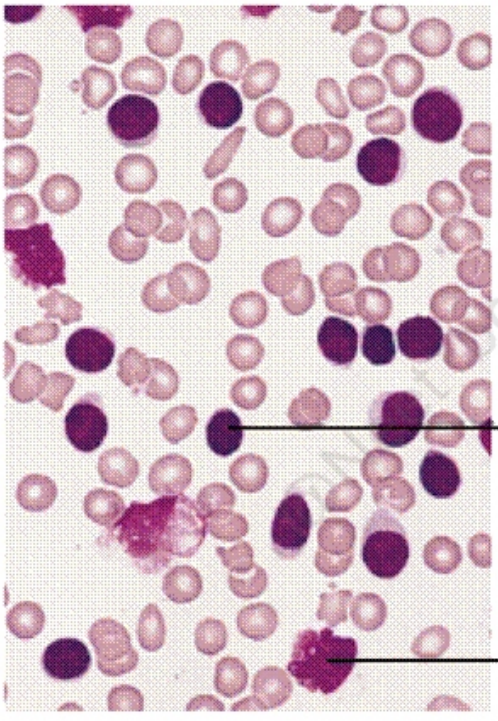
Explanation: Chronic Myelogenous Leukemia (CML) is the most likely diagnosis due to: Massive splenomegaly , which is a hallmark of CML. Marked leukocytosis (TLC of 150,000/microliter) with a predominance of neutrophils and the presence of immature myeloid cells (myeloblasts, myelocytes, metamyelocytes) on the peripheral smear. These are key features of CML. Basophilia (6%) and the myeloid-to-erythroid ratio of 18:1 , characteristic of CML, further support this diagnosis. Here is the revised table: Aspect Details Genetics Philadelphia chromosome (t(9;22)) Origin Myeloid lineage Etiopathogenesis BCR-ABL fusion gene causes overactive tyrosine kinase activity and is associated with radiation exposure. Clinical Features Common in adults, presenting with splenomegaly, fatigue, weight loss, night sweats, and abdominal discomfort. It can progress to a blast crisis with acute leukaemia features. Diagnosis Bone marrow aspirate to confirm diagnosis FISH to detect

BCR-ABL fusion gene product Management Tyrosine kinase inhibitors (e.g., Imatinib) The 3 phases of CML and their characteristics are: 1) Chronic phase: Leukocytosis, < 10% blast cells, basophils <20% and monocytosis < 3% 2) Accelerated phase: 10%-19% blasts, ≥ 20% basophils in the peripheral blood or bone marrow Persistent or increasing WBC (>10 × 10^9/L) and splenomegaly, unresponsive to therapy Persistent thrombocytosis (>1000 × 10^9/L), unresponsive to therapy Persistent thrombocytopenia (<100 × 10^9/L) unrelated to therapy This phase often leads to the terminal blast crisis within 6-12 months. 3) Blast Crisis: ≥20% blasts in peripheral blood or bone marrow In 50% of patients, the blast crisis occurs abruptly without an accelerated phase. Extensive extramedullary hematopoiesis occurs to compensate for CML and leads to significant splenomegaly. Transformation into AML is more predominant than ALL. {{caption_text}} Acute Lymphoblastic Leukemia (ALL) Lymphoblasts in bone marrow >=20% Cytoplasmic vacuolations They contain fat (Oil Red O Positive) Hand mirror-shaped cells {{caption_text}} Acute Myeloid Leukemia (AML) Blasts ≥ 20% Myeloblasts with AuerRods {{caption_text}} 3. Chronic Lymphocytic Leukemia (CLL): Smudge cells (or parachute/basket cell): Due to the fragility of lymphocytes during slide preparation Convent Girl Appearance: Lot of homogenous, small, mature-like, round lymphocytes with scant cytoplasm {{caption_text}} Chronic Myeloid Leukemia (CML) Leukocytosis Cell Types: Neutrophils(multilobed nucleus), metamyelocytes (indented nucleus), myelocytes (D-shaped nucleus), and eosinophils (orange cells) College girl/garden party appearance: Due to the variety of cell appearances Shift to the Left: Presence of immature cell types, mainly immature neutrophils, in the blood.





@Neet_pg_bot



@Neet_pg_bot

↑ *Back to this question in Part A*

@Neet_pg_bot

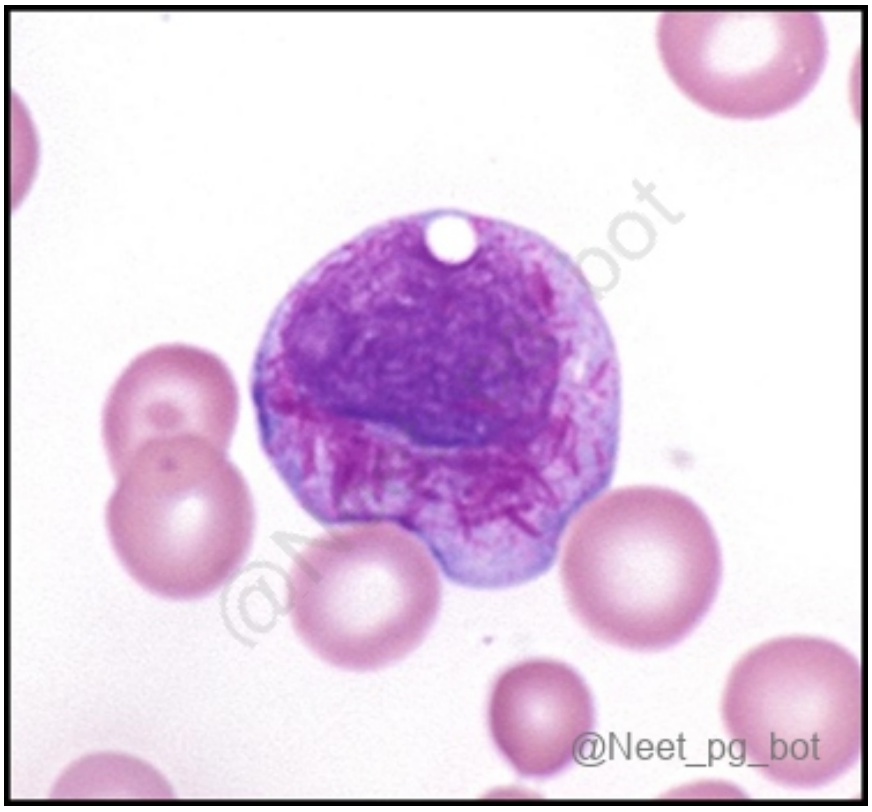
Q26: A 68-year-old man presents with bleeding manifestations. The peripheral smear shows the presence of the cells shown below. Which of the following is the most common chromosomal abnormality seen in this condition? (Q866343)

A. t(8:21)

B. t(15:17)

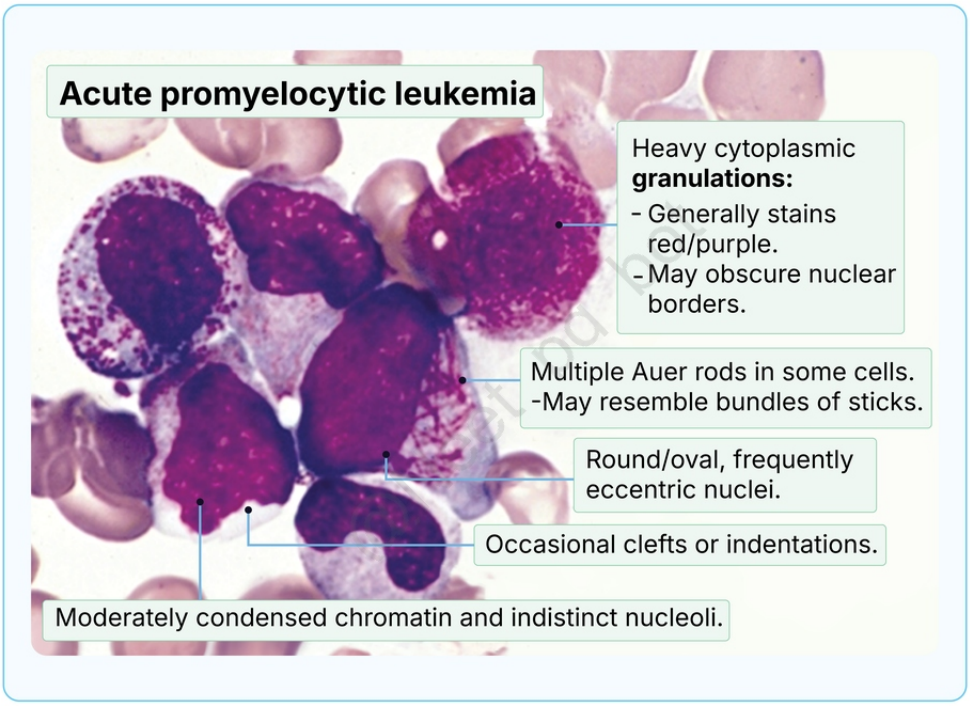
C. t(14:18)

D. Inv(16)



Correct Answer: B. t(15:17)

Explanation: This patient's history of 68 year old man with bleeding manifestations and Auer-rods on blood smear suggests disseminated intravascular coagulation secondary to acute promyelocytic leukaemia associated with t(15:17) translocation. M3 AML/ Acute promyelocytic leukaemia: Genetics: t(15:17) translocation causes PML-RARA (retinoic acid receptor alpha) fusion protein formation. Blocks promyelocyte → myelocyte maturation. Diagnosis of choice: FISH Smear findings: Increased promyelocytes. Auer Rods : Fused granules in promyelocytes Faggot Cells: Auer rods with a crisscross pattern. Laboratory: Low haemoglobin and platelets. > 20% blasts on peripheral and bone marrow smear Stain: PAS + CD markers: CD 13, 33 + Complication: Disseminated intravascular coagulation; therefore, chemotherapy is not recommended. Treatment: ATRA (All-trans-retinoic-acid) + As 2 O 3 (arsenic trioxide) Best prognosis among all AML. Incorrect Options: t(8 : 21) (Option A): AML with maturation (FAB M2); often associated with large myeloblasts and abundant Auer rods, but not the classic multiple “faggot cell” picture of APL. It is associated with Chloroma. t(14 : 18) (Option C): Follicular lymphoma; involves BCL2 gene rearrangement, unrelated to AML. inv(16) (Option D): Associated with AML with abnormal eosinophils (FAB M4Eo), not APL.



@Neet_pg_bot

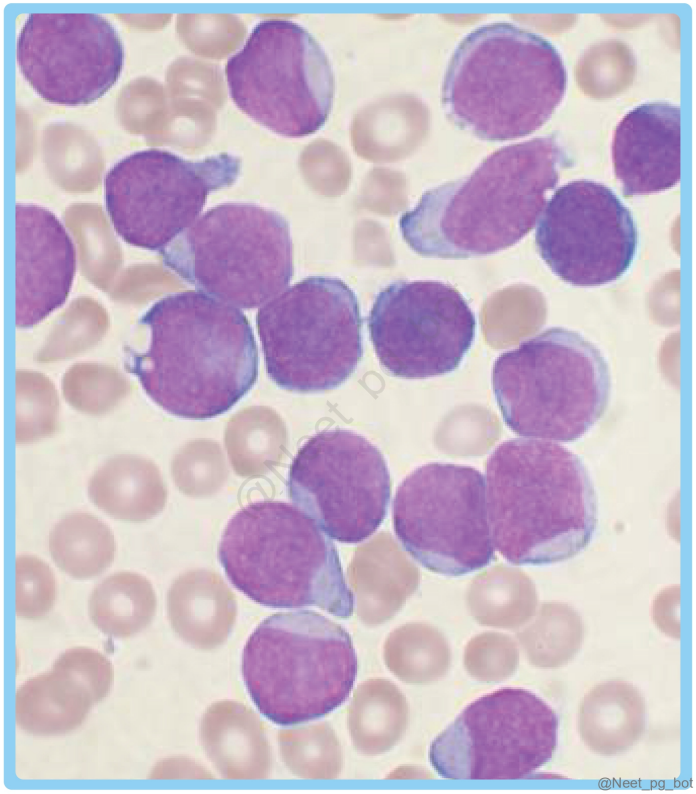
Q27: A young child presents with bleeding gums and bruising for the past two weeks. Bone marrow biopsy and flow cytometry have been performed. What is the diagnosis? (Q853374)

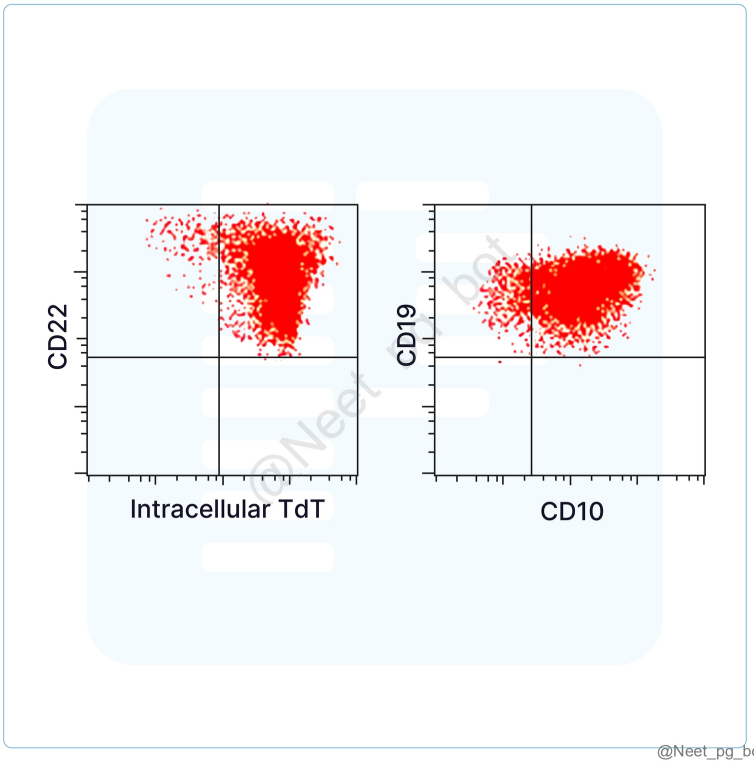
A. Acute myeloid leukemia

B. CLL

C. ALL: B Phenotype

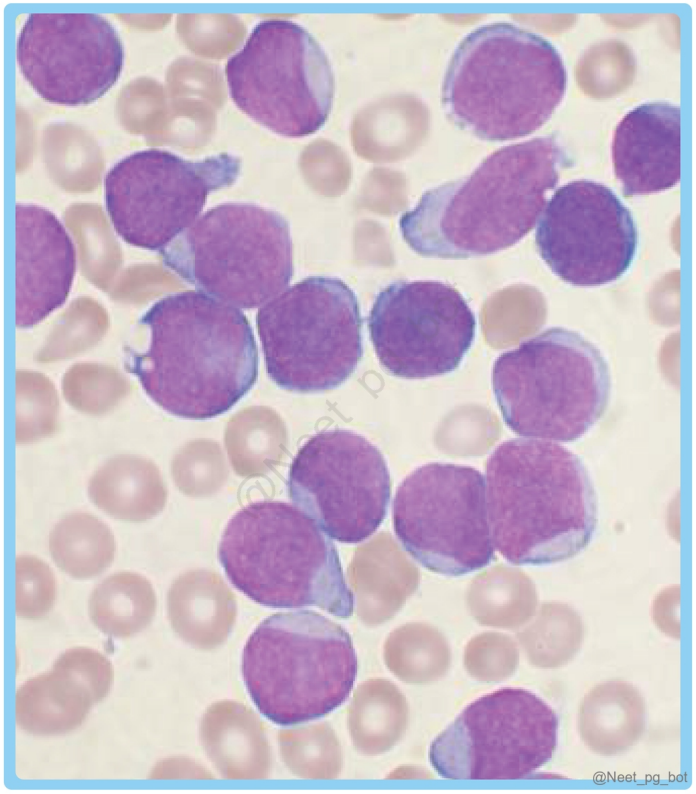
D. ALL: T Phenotype

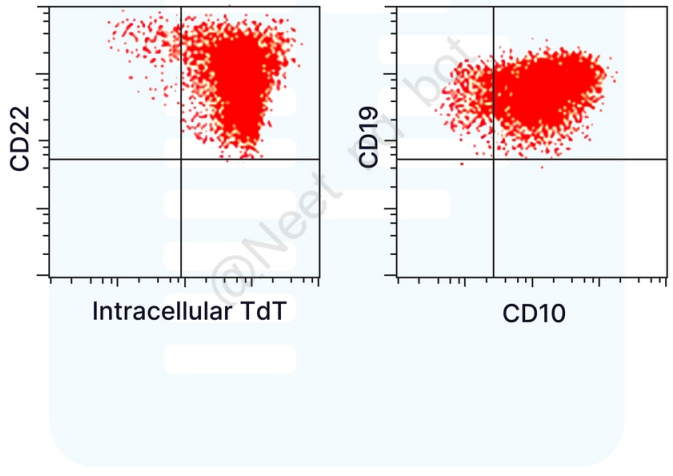




Correct Answer: C. ALL: B Phenotype

Explanation: The clinical presentation, along with histopathological and flow cytometry findings, confirms a diagnosis of Acute Lymphoblastic Leukemia (ALL) with a B-cell phenotype based on the following results: Histopathological examination reveals lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. Flow cytometry analysis: Image B: The lymphoblasts (indicated by red dots) expressing terminal deoxynucleotidyl transferase (TdT) and the B-cell marker CD22. Image C: The cells test positive for two other markers, CD10 and CD19, commonly found on pre-B lymphoblasts. Acute Lymphoblastic Leukemia (ALL) ALL is an acute-onset blood and bone marrow malignancy of B and T lymphoblasts characterised by the uncontrolled proliferation of abnormal and immature lymphocytes Clinical features Age : 2-8 years (Fast disease progression), adults: > 50 years. Weight loss, Night sweats Anemia : Easy fatigability and pallor Bleeding : Epistaxis, easy bruising. Leucocytopenia : Recurrent infections Bone Marrow proliferation : Bone pain, sternal tenderness Hepatosplenomegaly, Lymphadenopathy CNS leukemia : Raised ICP, vomiting, and 6th nerve palsy T cell tumors : Mediastinal and testicular mass. Diagnosis CBC is the first investigation performed while suspecting ALL: Hemoglobin (Hb) : Decreased, indicating normocytic normochromic anemia. Hyperleukocytosis : TLC >100,000/µL can lead to leukostasis (more common in AML than ALL) with >20% Blasts. Elderly Presentation : TLC often remains low throughout ALL. Thrombocytopenia may be present. Peripheral smear: The smear shows a high percentage of lymphoblasts , which are larger than normal lymphocytes and have a high nucleus-to-cytoplasm ratio. They often have a scant amount of cytoplasm and may exhibit nucleoli. Bone Marrow aspiration shows blasts >20% . It is also used to classify morphological types into L1, L2, and L3 in the FAB classification system. FISH- Fluorescent in situ hybridization shows translocation of genes/chromosomes. t(9:22) - ALL associated with the Philadelphia chromosome . t(8:14) - Associated with Burkitt's leukemia t(4:11) t(1:19) Flow cytometry: CD10, also known as common acute lymphoblastic leukaemia antigen (CALLA), is a cell surface marker commonly used in the classification and diagnosis of leukaemias and lymphomas, particularly acute lymphoblastic leukaemia (ALL). B cell type - CD19+, CD79a+. (Option C) T cell type - CD3+ (Option D ruled out) Acute myeloid leukaemia (Option A) is a malignancy of hematopoietic progenitors caused by oncogenic mutations that prevent differentiation, leading to the accumulation of immature myeloid blasts. These blasts have delicate chromatin, two to four nucleoli, and more cytoplasm than lymphoblasts, often containing peroxidase-positive azurophilic granules. Auer rods , needle-like azurophilic granules, are also commonly present. CLL (Chronic Lymphocytic Leukemia) (Option B) is characterised by lymph node infiltration with small lymphocytes featuring condensed chromatin and scant cytoplasm, along with larger activated lymphocytes forming proliferation centres, which are pathognomonic for CLL/SLL. The blood shows small lymphocytes and smudge cells, while the bone marrow, spleen, and liver are typically involved to varying degrees.





@Neet_pg_bot

Q28: Which gene mutation is most commonly associated with Burkitt's lymphoma? (Q852602)

A. C-myc

B. P-21

C. Rb

D. p53

Correct Answer: A. C-myc

Explanation: Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma that is strongly associated with a translocation involving the C-myc oncogene. Burkitt’s lymphoma. Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma associated with the translocations of the MYC gene on chromosome 8, t(8:14). It has three primary subtypes: Endemic Burkitt's lymphoma: Commonly affects children in malaria-endemic areas of Africa, often presenting with tumours in the jaw or facial bones. Sporadic Burkitt's lymphoma: More frequently seen in non-endemic regions and usually involving the ileocaecal region and peritoneum. Immunodeficiency-associated Burkitt's lymphoma: Found in patients with conditions such as HIV/AIDS or other forms of immunodeficiency. P-21 (Option B): P-21 (CDKN1A) is a cyclin-dependent kinase inhibitor that regulates the cell cycle by inhibiting cyclin-CDK complexes. It plays a role in cell cycle arrest but is not primarily associated with Burkitt's lymphoma. Rb (Option C) : The Retinoblastoma (Rb) gene is a tumor suppressor that controls the G1/S checkpoint of the cell cycle. Its mutations are primarily associated with retinoblastoma and osteosarcoma , not Burkitt's lymphoma. p53 (Option D): The p53 gene (TP53) is a tumor suppressor involved in DNA repair and apoptosis. While TP53 mutations are found in various cancers, they are not the characteristic mutation seen in Burkitt's lymphoma.

@Neet_pg_bot

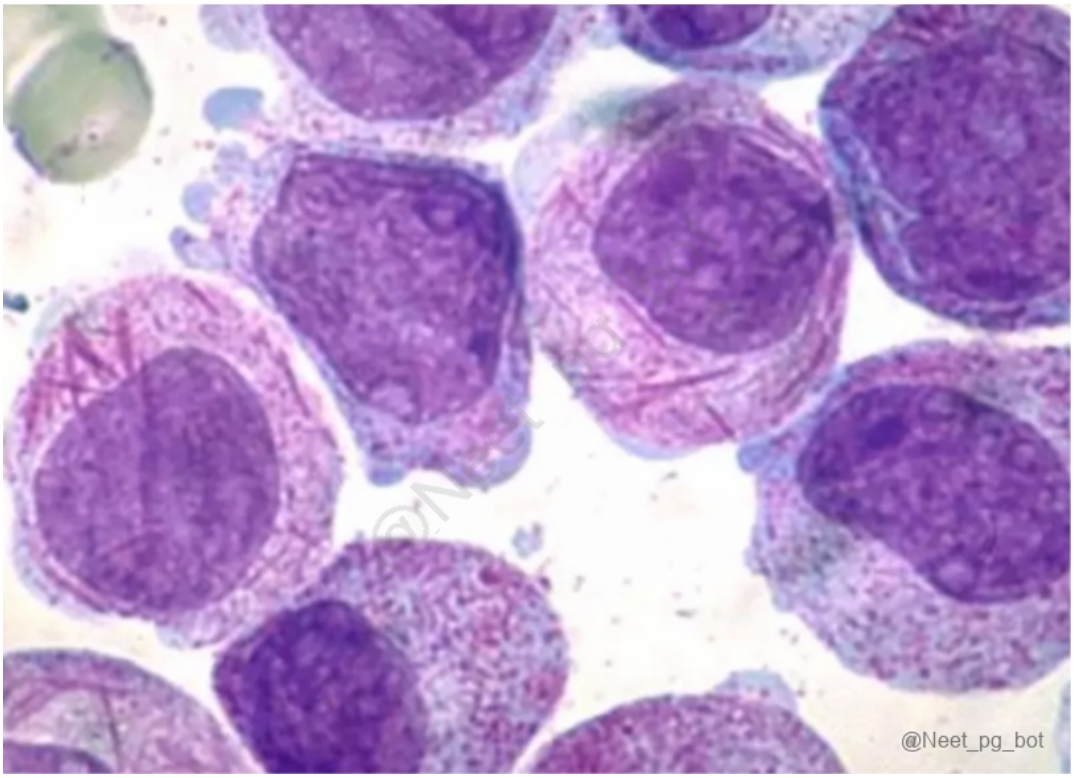
Q29: A 34-year-old female presents with low hemoglobin, platelet count of 25,000/mm 3 , and raised PT and APTT. The peripheral smear image is shown below. Which of the following fusion genes is likely affected? (Q843988)

A. PML-RARA

B. RUNX1-RUNX1T1

C. INV 16

D. IGH-NSD2



Correct Answer: A. PML-RARA

Explanation: Correct Option A - PML-RARA: The given image shows faggot cells containing Auer rods, which is a characteristic feature of Acute myeloid leukemia M3. In AML M3, t(15:17) - PML-RARA fusion gene is affected. Incorrect Options: Options B, C, and D are not affected in AML M3.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q30: A patient presents with fever, hepatosplenomegaly, abdominal pain, and WBC count > 50,000/mm 3 . Which of the following genetic abnormalities is involved? (Q844072)

A. t(9;22)

B. del(1q)

C. t(15;17)

D. del 3q

Correct Answer: A. t(9;22)

Explanation: Correct Option A - t(9;22): The given clinical features are suggestive of chronic myeloid leukemia, and the genetic abnormality associated with it is translocation of t(9;22). Incorrect Options: Options B, C, and D are not associated with CML.

↑ *Back to this question in Part A*

@Neet_pg_bot

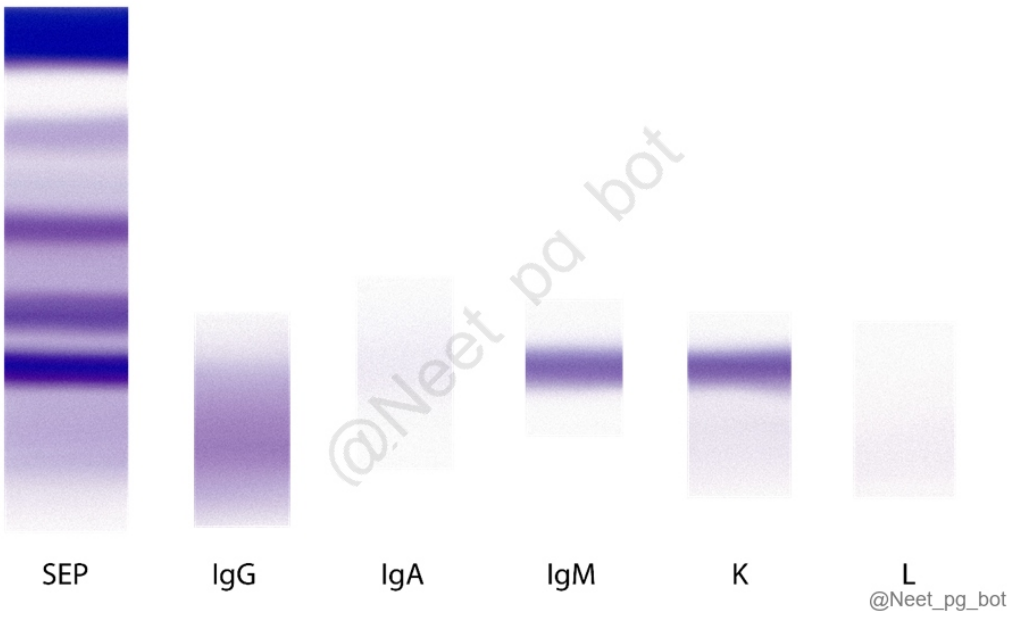
Q31: An elderly patient presents with elevated calcium levels, increased serum creatinine levels, and decreased hemoglobin. Electrophoresis reveals a monoclonal spike. Her immunofixation test findings are given below. Which of the following best describes her condition? (Q844198)

A. Multiple myeloma with increased IgG

B. Multiple myeloma with increased IgM

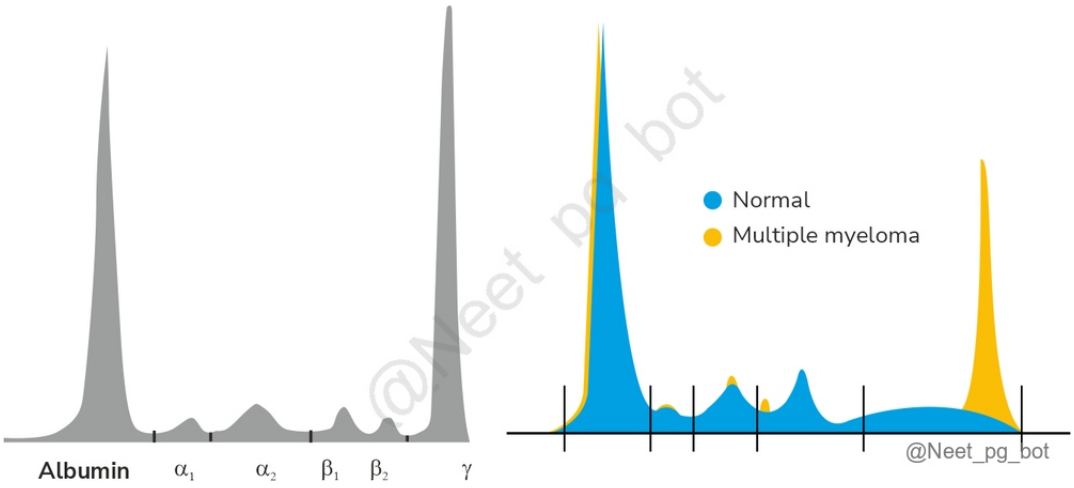
C. Multiple myeloma with increased IgA

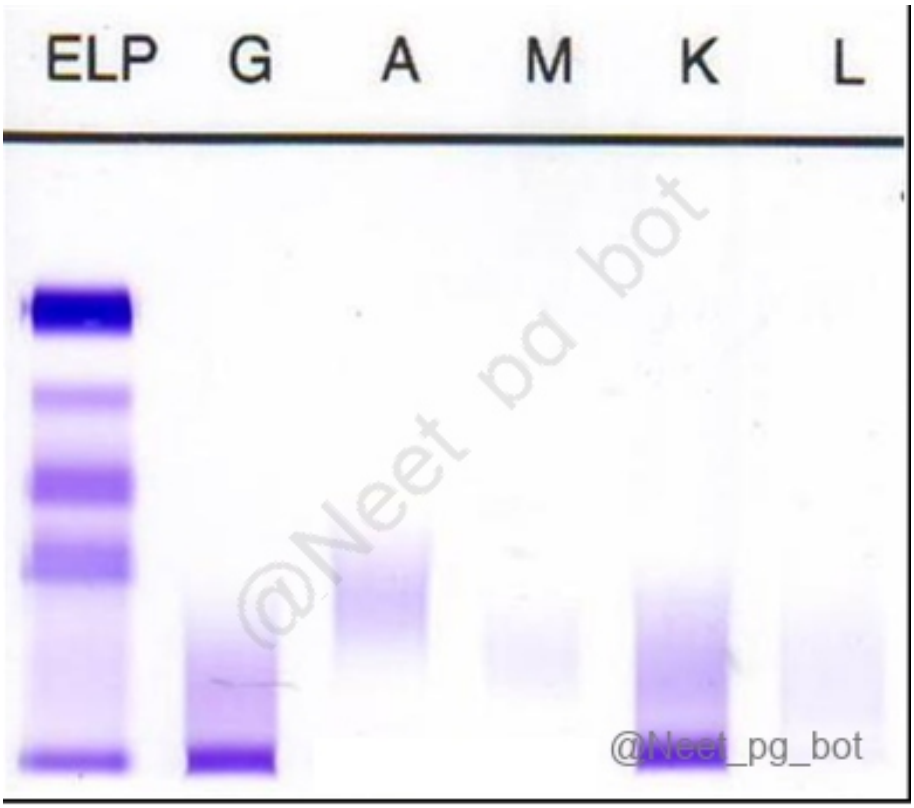
D. Monoclonal gammopathy of unknown significance



Correct Answer: B. Multiple myeloma with increased IgM

Explanation: Multiple myeloma is characterized by a monoclonal spike on electrophoresis, and the immunofixation test revealed increased IgM levels (a distinct band can be seen, whereas the smear pattern without any band formation above IgG is insignificant) Serum Protein Electrophoresis in Multiple Sclerosis: The gamma (Ig) will increase and show a spike an M spike - monoclonal or myeloma spike Immunofixation - will tell the type of immunoglobulin Immunofixation of Multiple myeloma with increased IgG Incorrect Options: Multiple myeloma with increased IgG (Option A): Smear pattern without any bands, so its not IgG Multiple myeloma with increased IgA (Option C) : No protein fixation, so its not IgA MGUS (Option D): In MGUS, gammaglobulins levels are <3gm/dL





References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q32: Which of the following is the investigation of choice for CML? (Q860526)

A. LAP score

B. FISH

C. Karyotyping

D. Reciprocal translocation

Correct Answer: B. FISH

Explanation: Fluorescence in situ hybridisation (FISH) is the choice of investigation for detecting the Philadelphia chromosome in CML. It makes a cytogenetic analysis of the Philadelphia chromosome. The presence of the Philadelphia chromosome, resulting from the reciprocal translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)], or detection of the BCR-ABL1 fusion gene on mRNA , confirms the diagnosis of CML. Diagnosis of Chronic Myeloid Leukemia (CML) CBC Normal RBC + Elevated TLC + Elevated platelets Peripheral smear Left shift with predominant segmented neutrophils, myelocytes, and metamyelocytes. College girl/garden party appearance: Due to non-uniform appearance (every cell appears different). {{caption_text}} Bone marrow aspirate Increased Myeloid: Erythroid ratio. Dwarf megakaryocytes. Sea blue histiocytes (blue-coloured cytoplasm) Pseudo Gaucher cells {{caption_text}} The image shows Pseudo-Gaucher cells NAP (Neutrophil Alkaline Phosphatase)/LAP score (Leukocyte Alkaline Phosphatase) (Option A ruled out) Decreased FISH (IOC) (Option B) Confirms t(9:22) translocation. Analysis to quantify Philadelphia chromosome-positive cells. Estimates the tumour load. {{caption_text}} The image shows BCR-ABL gene fusion (red + green) in fluorescence in-situ hybridisation (FISH; the ABL gene is red, and the BCR gene is green). PCR To quantify BCR-ABL-1 It can be a false negative or false positive False negative: Early part of the disease Karyotyping (Option C) examines chromosomes to detect abnormalities like Down syndrome or the Philadelphia chromosome in CML. While it can identify chromosomal abnormalities, it is less sensitive than FISH for detecting the Philadelphia chromosome. Reciprocal translocation (Option D) is a chromosomal abnormality where segments of two chromosomes are exchanged, such as the Philadelphia chromosome in CML. It results in the BCR-ABL fusion gene, detectable by FISH or karyotyping, but is not an independent diagnostic test.

@Neet_pg_bot

Q33: Mark the incorrect statement regarding Hodgkin Lymphoma: (Q840028)

A. Reed Sternberg cells are of B-cell origin

B. Waldeyer's ring is involved

C. Nodular sclerosing is the most common subtype and involves mediastinum

D. CD 15, 30 Positivity in Reed Sternberg cells

Correct Answer: B. Waldeyer's ring is involved

Explanation: Correct Option B - Waldeyer's ring is involved Waldeyer’s ring involvement is rare in classical Hodgkin lymphoma. HL more commonly involves cervical, mediastinal, and supraclavicular lymph nodes.

Primary Waldeyer’s ring involvement is unusual and more typical of non-Hodgkin lymphoma. Incorrect Options: Option A - Reed Sternberg cells are of B-cell origin: True; derived from germinal center B cells. Option C - Nodular sclerosing is the most common subtype and involves mediastinum: Most common HL subtype, frequently involves mediastinum, especially in young adults. Option D - CD 15, 30 Positivity in Reed Sternberg cells: Classic immunophenotype of Reed-Sternberg cells in classical HL.

@Neet_pg_bot

Q34: A patient with elevated calcium and normal alkaline phosphatase undergoes a skull X-ray. What is the likely diagnosis? (Q860163)

A. Grave’s disease

B. Paget’s disease

C. Multiple myeloma

D. CML

Correct Answer: C. Multiple myeloma

Explanation: The clinical scenario of a patient with elevated calcium, normal alkaline phosphatase, and osteolytic lesions on a skull X-ray suggests Multiple Myeloma . It is a plasma cell neoplasm associated with (Mnemonic: CRAB features with immune abnormalities) C - Hyper c alcemia R - R enal failure A - A naemia B - Lytic b one lesions, and Immune abnormalities. Antibodies in Multiple Myeloma: Monoclonal Immunoglobulins Free Light Chains IgG: Most common (55% of patients). IgA: Seen in 25% of cases. IgM, IgD, IgE: Less common. Often produced in excess, these are called Bence Jones proteins . It can cause myeloma kidney (renal disease). Pathogenesis of Multiple Myeloma: There are 3 main cytogenetic abnormalities seen in MM. Deletion of chromosome 13q (also seen in CLL). Translocation t (11;14) (also seen in mantle cell lymphoma). Deletion of chromosome 17p (TP53). IL-6 is essential for plasma cell growth , and its elevated levels are linked to poor prognosis. Clinical features: It is seen in patients 60-70 years of age. Increased osteoclastic activity leads to bone resorption hypercalcemia and lytic punched-out lesions. Decreased osteoblastic activity (Normal or ↓ ALP levels). {{caption_text}} Multiple Punched-out Osteolytic Lesions on the Lateral Skull Radiograph in a patient with Multiple Myeloma Grave's disease (Option A) is an autoimmune disorder that causes hyperthyroidism, characterised by an overactive thyroid gland. It results in symptoms like weight loss, heat intolerance, tremors, and bulging eyes (exophthalmos). It is caused by autoantibodies that stimulate the thyroid-stimulating hormone (TSH) receptor. It involves thyroid hormone imbalance and does not typically cause hypercalcemia or specific bone lesions on X-ray. Paget's disease (Option B) is a bone disorder marked by abnormal bone remodelling, leading to enlarged and weakened bones. It causes bone pain, deformities, and fractures with elevated alkaline phosphatase levels. It typically causes elevated alkaline phosphatase due to abnormal bone remodelling. Chronic myeloid leukaemia (CML) (Option D) is a bone marrow cancer characterised by excessive white blood cell production and the presence of the Philadelphia chromosome . It typically causes fatigue, weight loss, and splenomegaly but does not present with hypercalcemia or lytic bone lesions .

@Neet_pg_bot

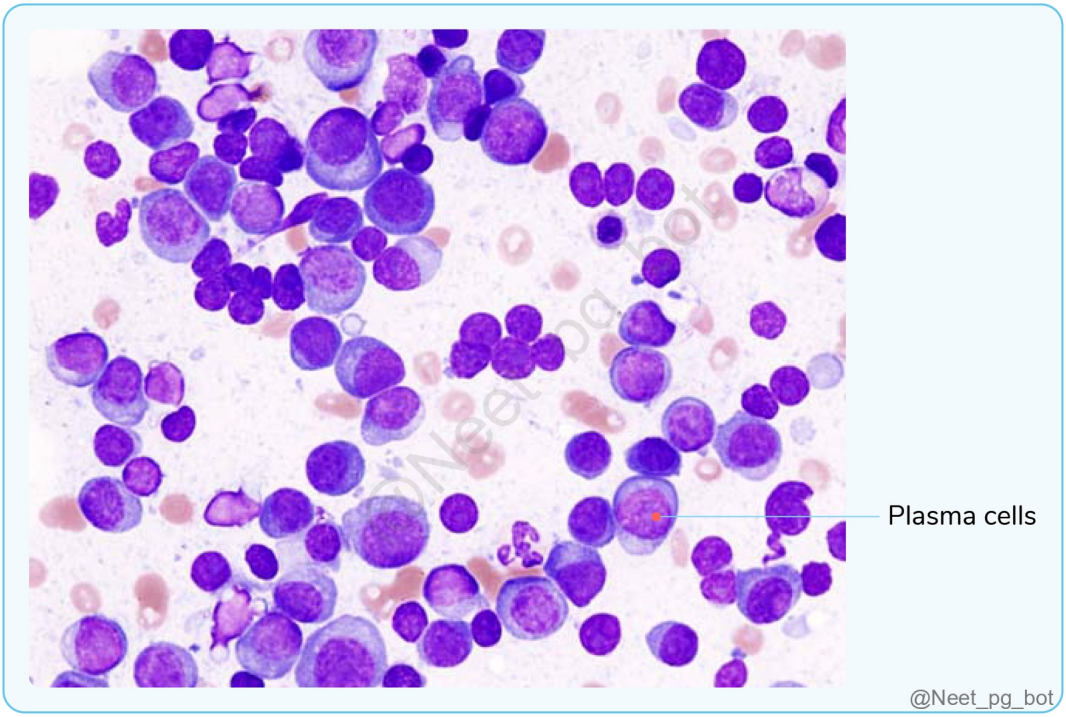
Q35: A 50-year-old male complains of lower back pain with a 1-1.5 mm osteolytic lesion at the T10 vertebra. Histopathological findings are given below. Which of the following options is correct regarding this condition? (Q860232)

A. Presence of Bence-Jones proteinuria

B. Absence of Rouleaux formation

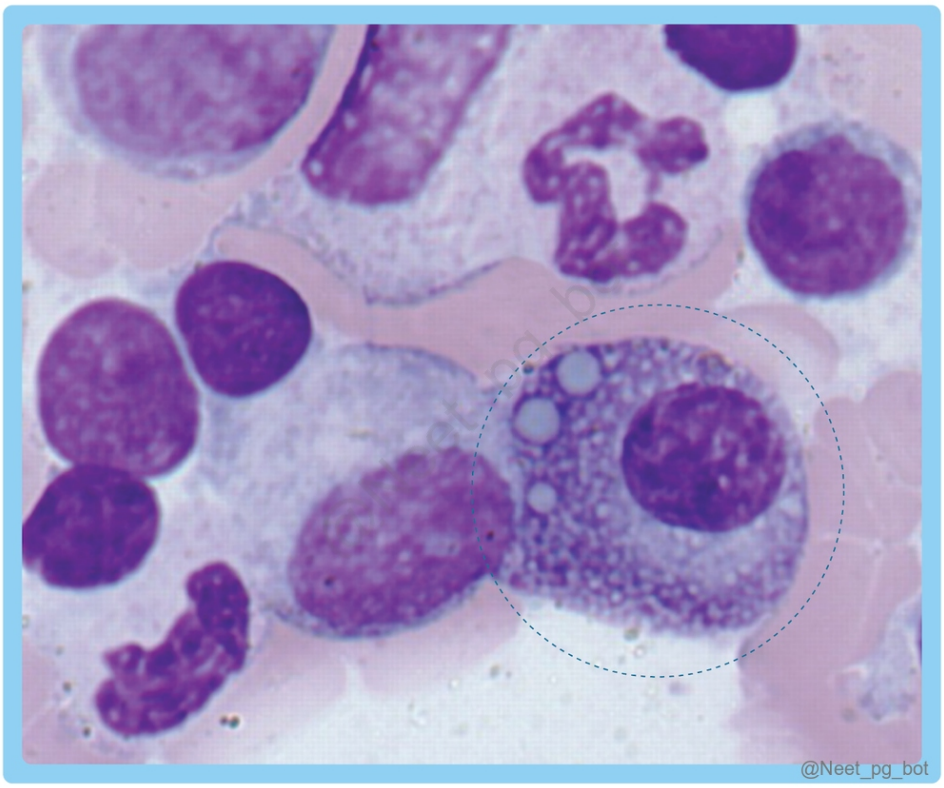
C. Absence of free light chains

D. Decreased Calcium levels in the blood



Correct Answer: A. Presence of Bence-Jones proteinuria

Explanation: The scenario describing lower back pain with a 1-1.5 mm osteolytic lesion at the T10 vertebra and a histopathological image showing intracytoplasmic inclusions (Russell bodies) suggests Multiple Myeloma , which is characterised by the presence of Bence-Jones proteinuria. It is caused by increased antibody production. It is a plasma cell neoplasm associated with (Mnemonic: CRAB features with immune abnormalities) C - Hyper c alcemia (Option D ruled out) R - R enal failure A - A naemia B - Lytic b one lesions, and Immune abnormalities. The cells produce excess free light chains, either alongside complete immunoglobulins or independently. (Option C ruled out) Due to their small size, free light chains (Bence Jones proteins) can pass through the glomeruli of the kidneys and appear in the urine. This is a diagnostic marker for multiple myeloma. Inclusion Bodies Seen In Multiple Myeloma Russel bodies: {{caption_text}} Location: Intracytoplasmic Composition: Eosinophilic Round Dilated endoplasmic reticulum cisternae filled with condensed immunoglobulin. . Dutcher bodies {{caption_text}} Location: Intranuclear. Composition: Globular inclusions containing accumulated immunoglobulin. Plasma Cell Variants In Multiple Myeloma Mott cells {{caption_text}} Contain Grape-like cytoplasmic droplets. Composition: Inclusion bodies, fibrils, crystalline rods, and globules. Flame cells {{caption_text}} Appearance : Fiery red cytoplasm. Cause : High concentration of immunoglobulin as bright red granules within the cytoplasm. Often seen in IgA subtype myeloma. Rouleaux formation {{caption_text}} High levels of M protein in the blood cause red cells to stick to one another in linear arrays in smears, a finding referred to as rouleaux formation. (Option B ruled out) It is also seen in s lupus erythematosus and early HIV infection.



@Neet_pg_bot

Q36: Which among the following is associated with Cryoglobulinemia? (Q860258)

A. Hepatitis C infection

B. Ovarian cancer

C. Diabetes

D. Leukaemia

Correct Answer: A. Hepatitis C infection

Explanation: Hepatitis C infection is associated with Cryoglobulinemia . Cryoglobulinemia : Cryoglobulins are proteins that precipitate from serum or plasma at low temperatures (<37°C). They can be a mixture of immunoglobulin and complement components or immunoglobulins alone. They deposit in medium and large-sized blood vessels throughout the body, causing endothelial injury and end-organ damage known as cryoglobulinemia. It is often associated with Hepatitis C virus infection Hepatitis B virus infection HIV Autoimmune diseases (mainly SLE and Sjogren’s syndrome) Lymphoproliferative disorders. Ovarian cancer (Option B) is a type of cancer that begins in the ovaries (female reproductive organs). It often goes undiagnosed in the early stages due to vague symptoms like abdominal bloating, pelvic pain, and early satiety. Risk factors include age, family history, and genetic mutations (such as BRCA1 and BRCA2). Diabetes (Option C) is a chronic condition where the body can't properly regulate blood sugar. Type 1 is insulin deficiency due to an autoimmune response, while Type 2 is caused by insulin resistance, often linked to obesity. Symptoms include thirst, frequent urination, and fatigue. Treatment involves lifestyle changes and medication, with long-term risks to organs like the heart and kidneys. Leukaemia (Option D) is a type of cancer that affects the blood and bone marrow, leading to the abnormal production of white blood cells. It is classified into acute and chronic forms, with acute leukaemia progressing rapidly and chronic leukaemia developing more slowly. Symptoms include fatigue, fever, frequent infections, easy bruising, and weight loss.

@Neet_pg_bot

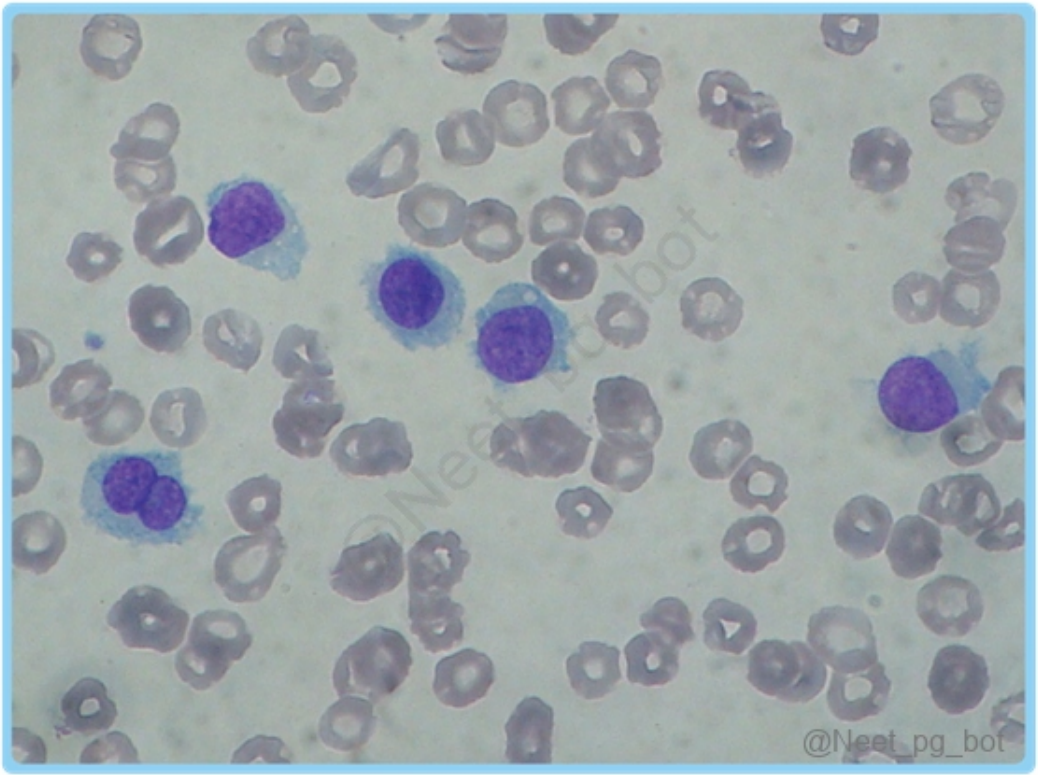
Q37: Which of the following cells is shown in the given image? (Q857427)

A. Hairy cell

B. Gaucher cell

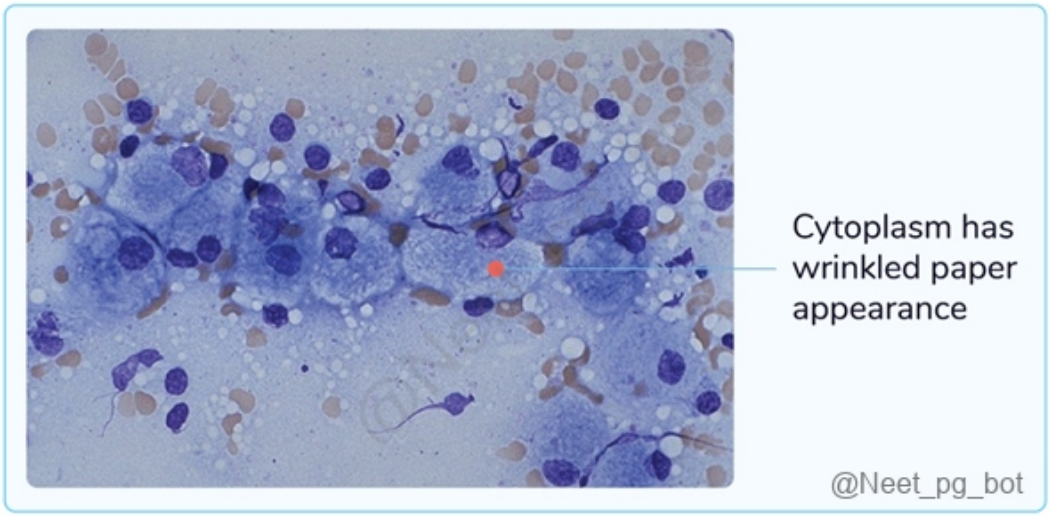
C. Sickle cell

D. Target cell



Correct Answer: A. Hairy cell

Explanation: The given image depicts a Hairy cell, which is characterised by the presence of fine, hair-like projections on the surface of the cell. It is a characteristic type of cell found in Hairy Cell Leukemia, which involves abnormal proliferation of Mature B cells. These cells have a round, oblong, or reniform nucleus and pale blue cytoplasm. Gaucher cells (Option B) are lipid-laden macrophages found in Gaucher's disease , an autosomal recessive disorder caused by mutations in the GBA1 gene, resulting in deficient glucocerebrosidase enzyme activity. These cells appear as foamy macrophages with a crumpled tissue-paper appearance due to the accumulation of glucocerebroside in the cytoplasm. {{caption_text}} Crinkled paper macrophages in the marrow space Sickle cells (Option C) are abnormally shaped red blood cells that resemble a crescent or sickle due to the presence of abnormal haemoglobin (haemoglobin S) . These cells are not characterized by cytoplasmic projections like hairy cells. {{caption_text}} Target cells (Option D) are red blood cells that have a bull's-eye appearance due to an increase in cell membrane relative to the volume of the cytoplasm. This condition can occur in several disorders, such as thalassemia , but they do not have the cytoplasmic projections seen in hairy cells. {{caption_text}}



Cytoplasm has wrinkled paper appearance

Q38: A 70 year old male presents with low back ache and progressive pallor. On work up: KFT is deranged, LFT is normal with normal level of albumin and gamma globulin increased disproportionately. X-ray spine shows multiple lytic lesions. Which of the following is the most probable diagnosis? (Q820525)

A. Multiple myeloma

B. MGUS

C. Immunoglobulin light chain amyloidosis (AL)

D. Solitary plasmacytoma.

Correct Answer: A. Multiple myeloma

Explanation: Correct Option A - Multiple myeloma: Multiple myeloma is a malignancy of plasma cells, a type of white blood cell that produces antibodies. It is characterized by the presence of abnormal plasma cells in the bone marrow, which can lead to bone destruction and the release of monoclonal (abnormal) immunoglobulins or light chains into the bloodstream. The clinical presentation of low back ache, progressive pallor (anemia), deranged kidney function tests (KFT), disproportionately increased gamma globulin levels, and lytic lesions on X-ray spine are all consistent with multiple myeloma. Incorrect Options: Option B - MGUS (Monoclonal Gammopathy of Undetermined Significance): MGUS is a benign condition where a small amount of abnormal plasma cells produce a monoclonal protein (usually immunoglobulin) in the blood. It is generally asymptomatic and does not cause significant organ damage. The patient in the scenario has more severe symptoms and findings that are not typical for MGUS. Option C - Immunoglobulin Light Chain Amyloidosis (AL) : AL amyloidosis is a rare condition where abnormal light chain proteins are deposited as amyloid in various organs, including the kidneys. This can lead to organ dysfunction. While AL amyloidosis can cause kidney involvement and abnormal levels of light chains, the lytic bone lesions seen on X-ray and the disproportionately increased gamma globulin levels are not characteristic of AL amyloidosis. Option D - Solitary Plasmacytoma: Solitary plasmacytoma is a localized tumor of plasma cells that typically presents as a single mass in bone or soft tissue. It is less likely in this case because the patient has multiple lytic lesions on X-ray spine, which indicates widespread bone involvement. Solitary plasmacytoma typically doesn't show this pattern of multiple bone lesions.

Q39: A 55-year-old male patient presents with fever, night sweats, and pleural effusion. On further investigation, he is diagnosed with Primary Effusion Lymphoma. What is the most likely causative agent responsible for this condition? (Q820628)

A. HHV-8

B. EBV

C. HPV

D. HIV

Correct Answer: A. HHV-8

Explanation: Correct Option A - HHV-8 (Human Herpesvirus 8): This is the most likely causative agent responsible for Primary Effusion Lymphoma (PEL), a rare and aggressive form of non-Hodgkin lymphoma. PEL primarily affects immunocompromised individuals, such as those with advanced HIV infection. HHV-8 is also known as Kaposi's sarcoma-associated herpesvirus (KSHV) and is strongly associated with both Kaposi's sarcoma and Primary Effusion Lymphoma Incorrect Options: Option B - EBV (Epstein-Barr Virus) : Epstein-Barr virus is associated with several types of lymphomas, including Burkitt lymphoma, Hodgkin lymphoma, and some cases of non-Hodgkin lymphoma. However, it is not typically associated with Primary Effusion Lymphoma. Option C - HPV (Human Papillomavirus) : Human Papillomavirus is known to cause cervical cancer and is not associated with Primary Effusion Lymphoma. Option D - HIV (Human Immunodeficiency Virus) : While HIV infection can lead to immunosuppression and an increased risk of certain infections and cancers, including Primary Effusion Lymphoma, it is not the direct causative agent. The underlying infection in this case would be HHV-8.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q40: What further test should be conducted for a 60-year-old male patient who has presented with widespread lymph node enlargement, elevated white blood cell count, and smudge cells observed on peripheral smear? (Q854682)

A. Cytogenic study

B. Bone marrow biopsy

C. Flow cytometry from peripheral blood

D. X-ray crystallography

Correct Answer: C. Flow cytometry from peripheral blood

Explanation: The given clinical presentation of a 60-year-old male with lymph node enlargement, elevated WBC, and smudge cells (characteristic cells) on the peripheral smear strongly suggests Chronic Lymphocytic Leukemia (CLL). Flow cytometry is a highly sensitive technique used to identify the specific cell surface markers on the abnormal lymphocytes in CLL. It helps distinguish CLL from other types of lymphoma and leukaemia. Flow cytometry markers of CLL include CD 5+, CD10-, CD19+, CD20+, CD 23+ and CD 200+ Cytogenic studies (Option A), including Fluorescence In Situ Hybridization (FISH) , are helpful in identifying specific genetic mutations associated with CLL, which have prognostic implications. However, flow cytometry is a more immediate and critical step for diagnosis, as it directly assesses the immunophenotype of the cells. Bone marrow biopsy (Option B) might be performed later to evaluate marrow involvement or disease progression , but it is not the first-line investigation for CLL. Given the peripheral smear findings, Flow cytometry helps to assess the immunophenotype of the lymphocytes. X-ray crystallography (Option D) is a technique used to determine the atomic and molecular structure of crystals. It is irrelevant in the context of diagnosing CLL.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 597, 604

↑ *Back to this question in Part A*

@Neet_pg_bot

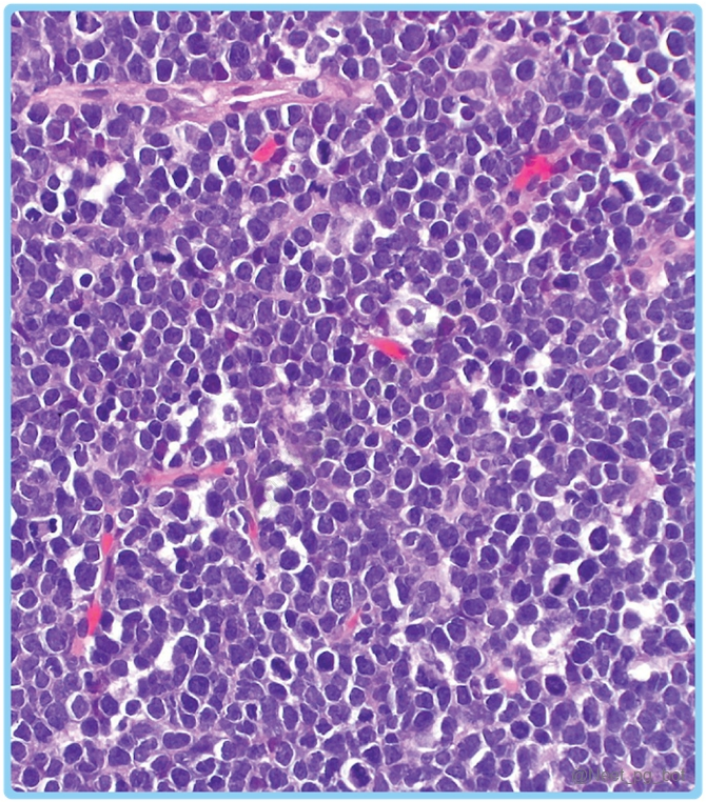
Q41: An African child is found to have a mass in the jaw. A biopsy of the mass was done, and it appears as shown in the image below. The child also has a translocation, t(8;14). What is the probable diagnosis? (Q855405)

A. Acute myeloid leukemia

B. Follicular lymphoma

C. Multiple myeloma

D. Burkitt lymphoma



Correct Answer: D. Burkitt lymphoma

Explanation: The "starry sky" appearance and t(8;14) translocation are characteristic of Burkitt lymphoma , a high-grade B-cell lymphoma. The translocation involves the MYC gene on chromosome 8, leading to uncontrolled cell proliferation. All forms of Burkitt’s lymphoma (Endemic, Sporadic, and HIV associated) are associated with such translocations. The most common translocations are t (8:2), t(8:14) , and t(8:22) Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma associated with the translocations of the MYC gene on chromosome 8, t(8:14). It has three primary subtypes: Endemic Burkitt's lymphoma: Commonly affects children in malaria-endemic areas of Africa, often presenting with tumours in the jaw or facial bones. Sporadic Burkitt's lymphoma: More frequently seen in non-endemic regions and usually involving the ileocaecal region and peritoneum. Immunodeficiency-associated Burkitt's lymphoma: Found in patients with conditions such as HIV/AIDS or other forms of immunodeficiency.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 598-603

↑ *Back to this question in Part A*

@Neet_pg_bot

Q42: A 25-year-old male presented with low haemoglobin, a platelet count of 25,000/mL, gum bleeding, and raised PT and aPTT. The image of his peripheral

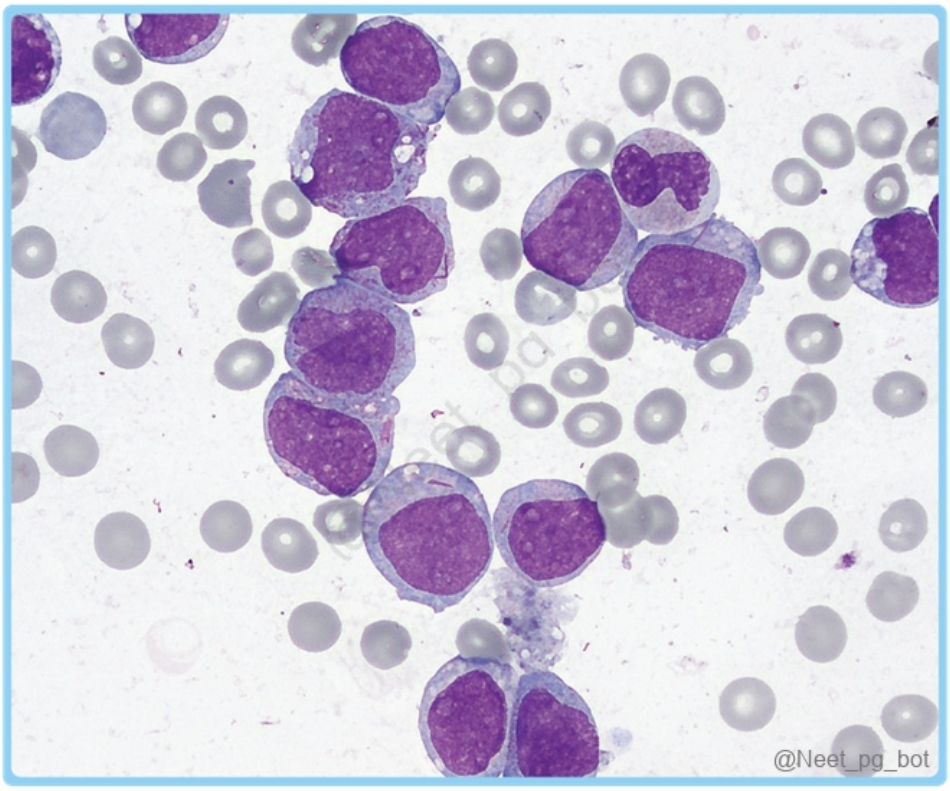
smear is shown below. What is the likely diagnosis? (Q855440)

A. AML with t(8;21)

B. AML with inv(16)

C. AML with t(15;17)

D. AML with t(11;22)



Correct Answer: C. AML with t(15;17)

Explanation: AML with t(15;17) is characteristic of acute promyelocytic leukaemia (APML) , which typically presents with Auer rods on the peripheral smear. The patient also exhibits typical features like low haemoglobin , low platelet count , gum bleeding , and prolonged PT and aPTT , which are seen in this condition due to disseminated intravascular coagulation (DIC). M3 AML/ Acute promyelocytic leukaemia: Genetics : t(15:17) translocation causes PML-RARA (retinoic acid receptor alpha) fusion protein formation. Blocks promyelocyte → myelocyte maturation. Diagnosis of choice: Fluorescence In Situ Hybridization (FISH) Smear findings: Increased promyelocytes. Auer Rods : Fused granules in promyelocytes Faggot Cells: Auer rods with a crisscross pattern. Laboratory : Low haemoglobin and platelets. > 20% blasts on peripheral and bone marrow smear Stain: PAS + CD markers: CD 13, 33 + Complication : Disseminated intravascular coagulation therefore, chemotherapy is not recommended. Treatment : ATRA (All-trans-retinoic-acid) + As 2 O 3 (arsenic trioxide) Best prognosis among all AML. FAB classification of AML Subtype Name Features AML-M0 AML undifferentiated MPO negative AML-M1 AML without maturation MPO + AML-M2 AML with maturation Most common t(8:21) RUNX1-RUNX1T1 fusion Associated with chloroma. AML-M3 Acute promyelocytic leukemia t(15:17) -

PML-RAR■ fusion Blocks promyelocyte → myelocyte transformation. Bone marrow: Auer rods form criss-cross called faggot cell. {{caption_text}} Can cause disseminated intravascular coagulation (DIC) PAS+ AML-M4 Acute myelomonocytic leukemia (Option C) Associated with inv 16 and CBF-MYH fusion gene Gums: Gum hypertrophy Skin: Leukaemia cutis MPO+, NSE + AML-M5 Acute monocytic leukemia Gums: Gum hypertrophy Skin: Leukaemia cutis MPO-, NSE + AML-M6 Acute erythroid leukemia Also called Di Guglielmo Disease Diffuse PAS+, cd71 AML-M7 Acute megakaryocytic leukemia Bone Marrow aspiration gives a dry tap PAS+, cd41 and cd61

@Neet_pg_bot

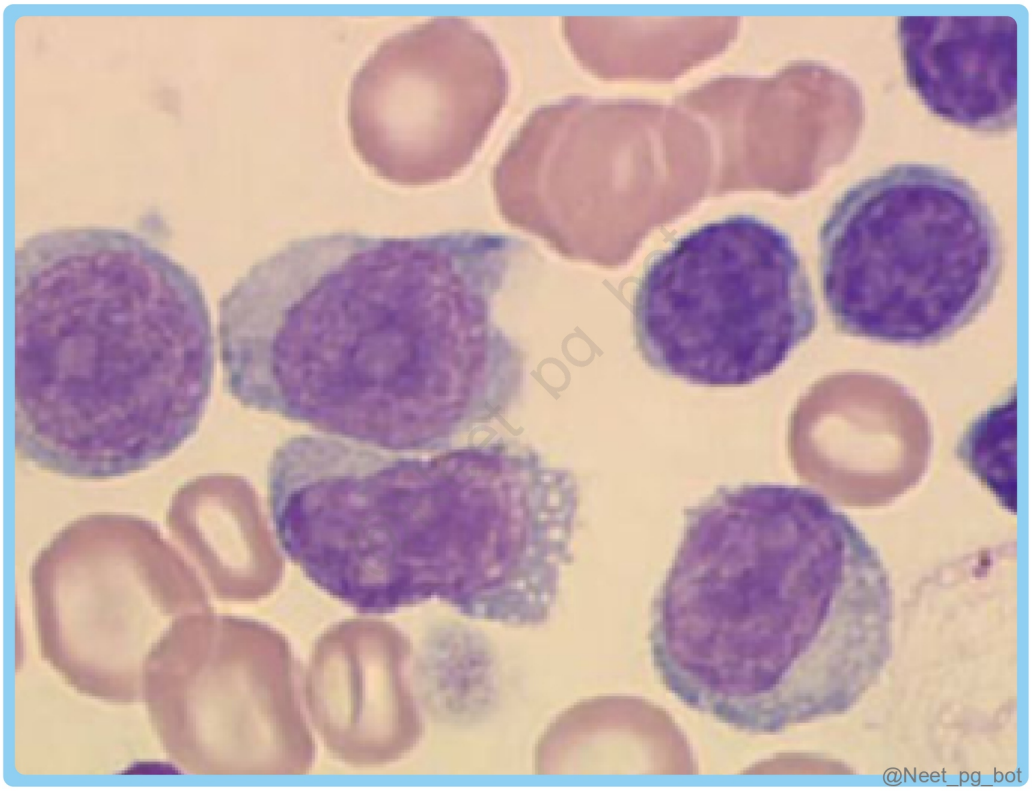
Q43: Which of the following leukaemias is associated with the given peripheral smear? (Q855099)

A. Acute lymphoblastic leukemia

B. Chronic lymphocytic leukemia

C. Acute myeloid leukemia

D. Chronic myelogenous leukemia



Correct Answer: B. Chronic lymphocytic leukemia

Explanation: The peripheral smear showing an increased number of small, mature lymphocytes with a characteristic smudge appearance is indicative of Chronic lymphocytic leukaemia (CLL) . {{caption_text}} Acute Lymphoblastic Leukemia (ALL): (Option A) Lymphoblasts in bone marrow >=20% Cytoplasmic vacuolations They contain fat (Oil Red O Positive) Hand mirror-shaped cells {{caption_text}} Acute Myeloid Leukemia (AML) (Option C) Blasts ≥ 20% Myeloblasts with Auer rods {{caption_text}} Chronic Lymphocytic Leukemia (CLL): Smudge cells (or parachute/basket cell): Due to the fragility of lymphocytes during slide preparation Convent Girl Appearance: Lot of homogenous, small, mature-like, round lymphocytes with scant cytoplasm {{caption_text}} Chronic Myeloid Leukemia (CML) (Option D) Leukocytosis Cell Types: Neutrophils(multilobed nucleus), metamyelocytes (indented nucleus), myelocytes (D-shaped nucleus), and eosinophils (orange cells) College girl/garden party appearance: Due to the variety of cell appearances Shift to the Left: Presence of immature cell types, mainly immature neutrophils, in the blood.

@Neet_pg_bot

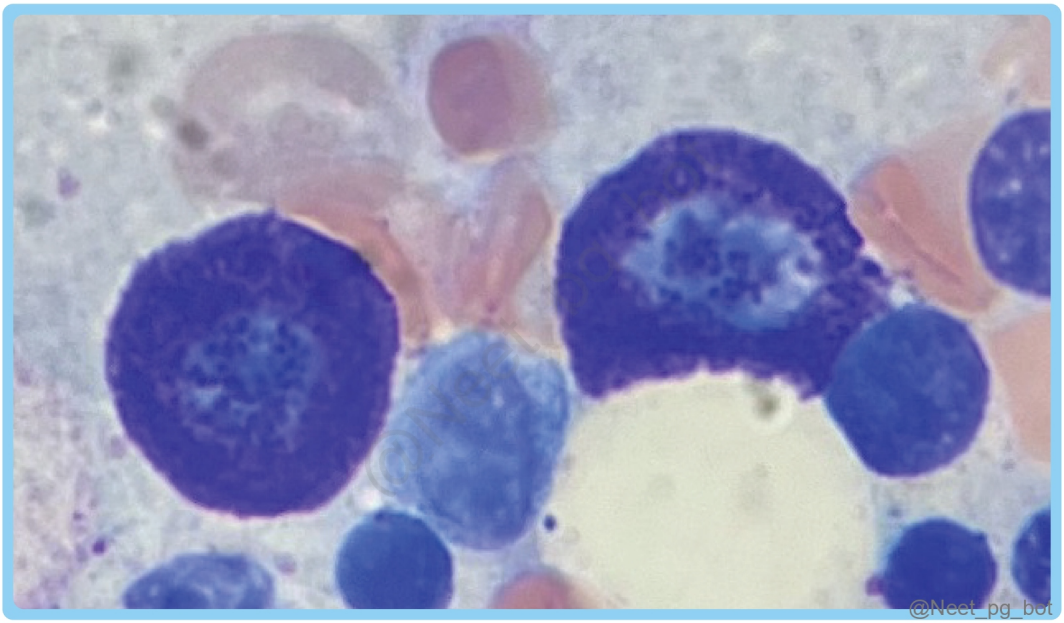
Q44: Identify the cell in the image below: (Q855101)

A. Mast cell

B. Macrophage

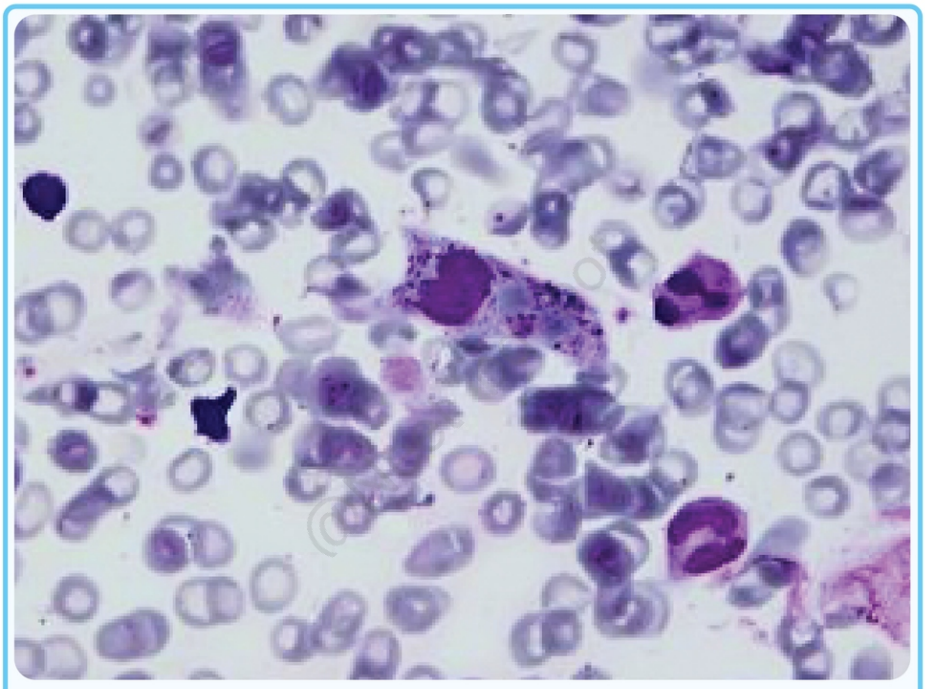
C. Plasma cell

D. Fibroblast



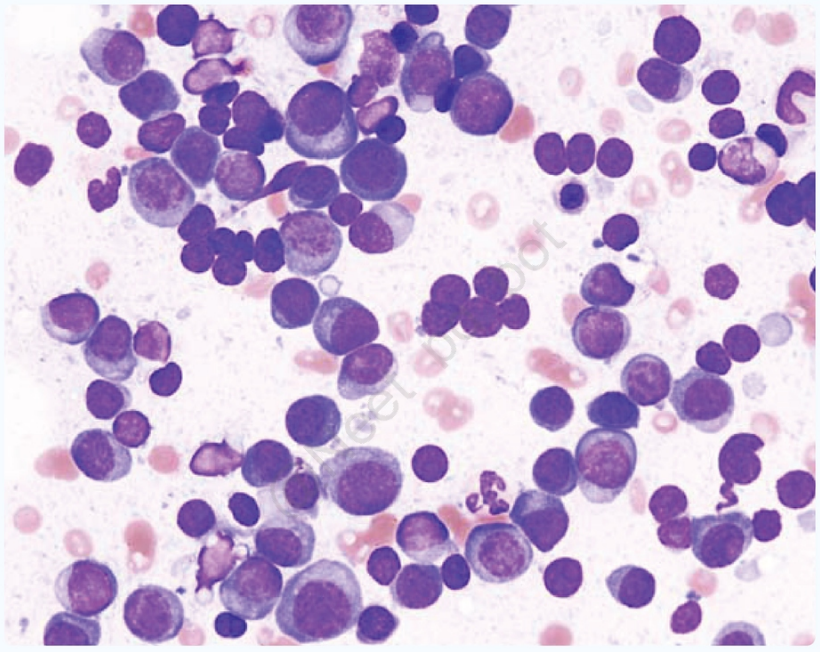
Correct Answer: A. Mast cell

Explanation: The given image shows mast cells stained with toluidine blue. It contains the acid proteoglycan that binds basic blue. Mast cells are characterized by the presence of large granules & stains with toluidine blue, giving them a distinct purple-blue colour. It plays a crucial role in allergic reactions and inflammation by releasing histamine and other mediators from their granules. Macrophages (Option B) are large phagocytic cells with abundant cytoplasm and a kidney-shaped nucleus. They lack metachromatic granules and do not stain with toluidine blue. {{caption_text}} Plasma cells (Option C) have an eccentric nucleus with a clock-face chromatin pattern and a perinuclear hof due to the prominent Golgi apparatus; they produce antibodies but lack granules. {{caption_text}} Fibroblasts (Option D) are spindle-shaped cells involved in collagen and extracellular matrix synthesis, lacking granules and immune functions. Histopathologically, they appear as elongated, fusiform cells with a pale, slightly granular cytoplasm and a single, elongated nucleus. {{caption_text}}



A macrophage with phagocytosis of red blood cells and platelets

@Neet_pg_bot



An HPE image of plasma cell, identified by its eccentrically located nucleus, a clear perinuclear zone and a basophilic cytoplasm

↑ *Back to this question in Part A*

@Neet_pg_bot

Q45: A patient with cervical lymphadenopathy has a positive t(11;14) translocation. Which of the following markers should be used to confirm the diagnosis? A. CD10 B. CD200 C. SOX11 D. Cyclin D1 (Q856913)

A. A, B

B. B, D

C. A, C

D. C, D

Correct Answer: D. C, D

Explanation: The t(11;14) translocation is a characteristic feature of mantle cell lymphoma. Immunohistochemistry for Cyclin D1 is crucial to confirm the diagnosis, as it is overexpressed in mantle cell lymphoma due to this translocation. SOX11 is another marker commonly expressed in mantle cell lymphoma and

can help in diagnosis. Neoplasm Cell of origin Description Diffuse large B-cell lymphoma Germinal/post-germinal center B cells Most common NHL. Associated with BCL6 gene rearrangement If CLL transforms into DLBCL, it is called Richter's Syndrome. Hairy cell leukemia Memory B cells More common in boys. BRAF V600E Mutation + It presents with massive splenomegaly affecting the red pulp of the spleen. Mantle cell lymphoma Naive B cell Translocation t(11:14). Associated with GIT polyps. Cyclin D1 and SOX11 +ve Mycosis Fungoides Helper T cells Cutaneous T-cell NHL . Presents with erythema and pruritus. If it affects the blood vessels, it is known as Sezary syndrome. CD10, also known as CALLA (Common Acute Lymphoblastic Leukemia Antigen), is a cell surface marker commonly used in the diagnosis of follicular lymphoma and Burkitt lymphoma, as well as other B-cell lymphomas. However, CD10 is not typically expressed in mantle cell lymphoma. CD200 is more commonly associated with other lymphoproliferative disorders, such as chronic lymphocytic leukaemia (CLL) , rather than mantle cell lymphoma.

References:

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 594, 595

↑ *Back to this question in Part A*

@Neet_pg_bot

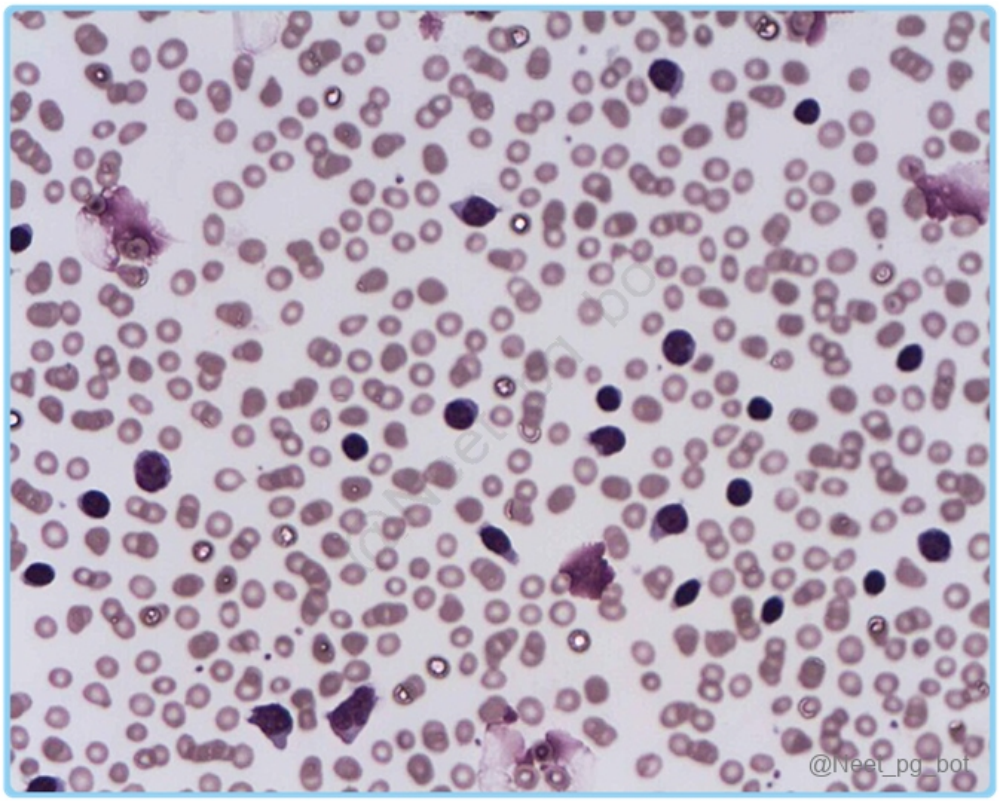
Q46: An elderly male presents for a routine medical examination. Laboratory investigations reveal a very high total leukocyte count (TLC). The peripheral smear shows findings as shown in the image. What is the appropriate next step for this patient? (Q855433)

A. Stem cell transplantation

B. Bone marrow biopsy

C. Flow cytometry

D. Start high-dose chemotherapy



Correct Answer: C. Flow cytometry

Explanation: An elderly male with a high total leukocyte count (TLC) and the presence of smudge cells on the peripheral smear is likely to have Chronic Lymphocytic Leukemia (CLL) . The next appropriate step for confirming the diagnosis is flow cytometry , which analyses cell surface markers and helps identify abnormal lymphocytes characteristic of CLL. Chronic Lymphocytic Leukemia Genetics: Trisomy 12, deletion 13q14 , and others Origin: Post–germinal centre memory B cell or naive B Cells in the mantle zone of the lymph node. Etiopathogenesis Antiapoptotic protein BCL2 overexpression. CLL cell growth depends on Bruton Tyrosine kinase (BTK) activity. No association with radiation exposure Clinical Presentation Most common Leukemia in the elderly. Frequently asymptomatic at diagnosis. May present with fatigue, lymphadenopathy, hepatosplenomegaly, or infection due to immunosuppression. Associated with autoimmune hemolytic anemia-spherocytes can be seen on peripheral smear Can l/t Hypogammaglobulinemia(highlight)as B cells are abnormal - Infection is the M/C/C of death in CLL Laboratory diagnosis: Absolute lymphocyte count (ALC) > 5000/mm3 Bone marrow lymphocytes >30% Surface markers using flow cytometry were positive for CD5, CD23, CD19, and CD20. CLL co-expresses both T cell (CD5) and B cell (CD20, CD19) markers Incorrect Options: Stem cell transplantation (Option A) : This is not the first-line treatment for CLL. It is typically considered in more advanced or refractory cases, but the initial approach for most patients involves observation or targeted therapy. Bone marrow biopsy (Option B) : Although bone marrow biopsy can help in finding the extent of infiltration., it is not the first choice for diagnosing CLL. Flow cytometry usually confirms the diagnosis, which is more specific for CLL. High-dose chemotherapy (Option D) is generally not the first treatment for CLL. Most patients with early-stage CLL are observed without immediate chemotherapy. Treatment is usually initiated if there are symptoms or complications and targeted therapies are often used instead of high-dose chemotherapy.

Robbins and Cotran Pathologic Basis of Diseases, 10th Edition, Page 597

↑ *Back to this question in Part A*

@Neet_pg_bot

Q47: A 38-year-old man presented with bleeding gums for 20 days. He has gingival hyperplasia and hepatosplenomegaly. On investigation, Hb-11 g/dL, platelet count-95,000 platelets/mm3, and WBC count-45000 cells/mm3. A bone marrow biopsy shows 100% cellularity, with many blast cells that are peroxidase-negative and non-specific esterase-positive . The most likely diagnosis is: (Q793658)

A. Acute myeloid leukemia M2 (AML M2)

B. Acute myeloid leukemia M0 (AML M0)

C. Acute myeloid leukemia M5 (AML M5)

D. Acute myeloid leukemia M7 (AML M7)

Correct Answer: C. Acute myeloid leukemia M5 (AML M5)

Explanation: Correct Option C - Acute myeloid leukemia M5 (AML M5): The patient's presentation with bleeding gums, gingival hyperplasia, hepatosplenomegaly, and bone marrow biopsy findings, which indicate 100% cellularity with many blast cells that are peroxidase negative and non-specific esterase positive, is suggestive of acute myeloid leukemia M5 (AML M5). Acute myeloid leukemia M5 (AML M5) is also known as acute monocytic leukemia. Incorrect Options: Option A - Acute Myeloid Leukemia M2 (AML M2): It is characterized by the presence of abnormal promyelocytes in the bone marrow and blood. Option B - Acute Myeloid Leukemia M0 (AML M0): It is characterized by the absence of surface markers on the blast cells. Option D - Acute Myeloid Leukemia M7 (AML M7): It is characterized by the presence of abnormal megakaryocytes in the bone marrow, which can lead to thrombocytopenia and bleeding.

Prepladder Notes

↑ *Back to this question in Part A*

@Neet_pg_bot

Q48: What is the most accurate test for evaluating the effectiveness of treatment in chronic myeloid leukemia (CML)? (Q857166)

A. ■■■

B. RT PCR

C. Cytogenetic test

D. FISH

Correct Answer: B. RT PCR

Explanation: RT-PCR is the most sensitive test for monitoring treatment response in chronic myeloid leukemía (CML). It accurately detects and quantifies the BCR-ABL1 fusion gene, allowing for precise assessment of treatment response and minimal residual disease (MRD) status in CML patients. Regular monitoring with RT-PCR guides treatment decisions for optimal patient outcomes. Chronic Myeloid Leukemia: It occurs due to the translocation of Philadelphia chromosome t (9:22) (q34.1, q11.2). BCR-ALB1 is a hybrid gene. It is a translocation with respect to the long arm of chromosome no. 9 to the long arm of chromosome no. 22 BCR : Breakpoint cluster region ALB1 : Abelson leukemia BCR-ALB1 results in the production of novel oncoproteins (Molecular weight: 210 kilodaltons) CBC (Complete Blood Count) (Option A): While CBC indicates changes in blood cell levels, it may not detect MRD or early treatment failure as sensitively as RT-PCR. Cytogenetic Test (Option B): Although cytogenetic tests reveal chromosomal abnormalities like the Philadelphia chromosome, they may not detect low levels of disease or MRD as effectively as molecular techniques like RT-PCR. FISH (Fluorescence In Situ Hybridization) (Option D): While FISH detects genetic sequences like the BCR-ABL1 fusion gene, it may not quantify residual disease or assess treatment response as accurately as RT-PCR.

CML

↑ *Back to this question in Part A*

@Neet_pg_bot

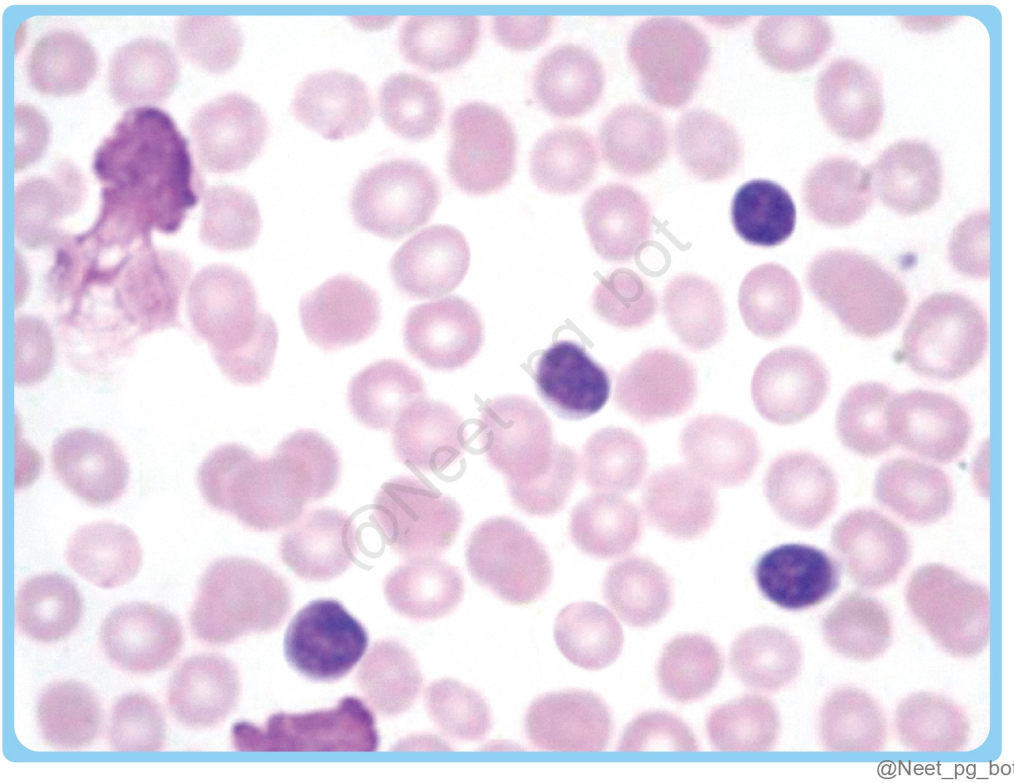
Q49: Which CD markers are typically positive in Chronic Lymphocytic Leukaemia (CLL)? . (Q866672)

A. CD3, CD5, CD8

B. CD10, CD19, CD22

C. CD19, CD20, CD23, CD5

D. CD13, CD33, CD117



Correct Answer: C. CD19, CD20, CD23, CD5

Explanation: In Chronic Lymphocytic Leukaemia (CLL) , the hallmark immunophenotype is: B-cell markers: CD19, CD20, CD23 Aberrant co-expression of T-cell marker: CD5 (this is unusual for B-cells and is a diagnostic clue) CLL is a mature B-cell neoplasm → expresses typical B-cell surface antigens (CD19, CD20, CD23). Uniquely, it abnormally expresses CD5 , which is normally a T-cell marker, this feature helps distinguish CLL from other B-cell leukemias/lymphomas. Incorrect Options: CD3, CD5, CD8 (Option A): T-cell markers (CD8 = cytotoxic T cells), not CLL. CD10, CD19, CD22 (Option B): seen in precursor B-cell ALL (CD10 - CALLA antigen), not mature CLL. CD13, CD33, CD117 (Option D): myeloid lineage markers (seen in AML), not lymphoid.

Q19 (p. 3089)	*Q20 (p. 3090)*	*Q21 (p. 3091)*	*Q22 (p. 3092)*	*Q23 (p. 3093)*	

Q1: An 8-year-old girl has been brought to the pediatric clinic by her parents. She has been suffering from tiny cutaneous haemorrhages spread all over her body. She has been recovering for a week from a flu-like condition. Her Physical examination is unremarkable, and she is vitally stable. Her Laboratory investigations revealed a platelet count of 20,000/mL. The number of megakaryocytes in her bone marrow has increased. Which of the following is the most likely diagnosis for this girl? (Q882287)

A. Antiphospholipid antibody syndrome

B. Disseminated intravascular coagulation

C. Hemolytic-uremic syndrome

D. Idiopathic thrombocytopenic purpura

Correct Answer: D. Idiopathic thrombocytopenic purpura

Explanation: It is a quantitative disorder of platelets caused by antibodies directed against platelet or megakaryocytic antigens. Related to antibody-mediated immune destruction of platelets or their precursors. The peripheral blood smear in ITP exhibits numerous large platelets, and the bone marrow shows a compensatory increase in megakaryocytes. Clinical Features: Petechia Purpura Hemorrhagic bullae Gum bleeding Hematuria Melena Classification of ITP: ITP is primarily classified by duration and cause . By Duration: Newly Diagnosed: Less than 3 months since diagnosis. Persistent: Lasting 3 to 12 months from diagnosis. Chronic: Lasting more than 12 months (more common in adults). By Cause: Primary ITP: Occurs in isolation without an underlying trigger (accounts for 80% of cases). Secondary ITP: Associated with another condition, such as: Infections: HIV, Hepatitis C, H. pylori. Autoimmune diseases: Systemic Lupus Erythematosus (SLE). Malignancies: Chronic Lymphocytic Leukemia (CLL). Treatment of ITP: Phase Treatment Options Mechanism First-Line Corticosteroids (Prednisone/Dexamethasone) Suppress immune destruction of platelets. IVIG (Intravenous Immunoglobulin) "Distracts" the spleen from destroying platelets (fast-acting). Anti-D IG Only for Rh-positive, non-splenectomized

patients. Second-Line TPO-RAs (Eltrombopag, Romiplostim) Stimulate the bone marrow to produce more platelets. Rituximab Depletes B-cells that produce the auto-antibodies. Splenectomy Surgical removal of the primary site of platelet destruction. Emergency Platelet Transfusion + High-dose IVIG Used only in life-threatening bleeding (rarely used alone as the body destroys them quickly). Thrombocytopenia may be observed in the other choices but is usually associated with other systemic signs and symptoms. Option A: Anti-Phospholipid Antibody Syndrome The antiphospholipid antibody syndrome is the most common form of acquired thrombophilia. Antiphospholipid antibodies include lupus anticoagulant antibodies and anticardiolipin antibodies. They can occur as a manifestation of various conditions, such as systemic lupus erythematosus and other rheumatic disease, infections, and drug reactions. Women who sustain recurrent spontaneous abortions or a thromboembolic event during pregnancy should also undergo evaluation for the disorder Option B: Disseminated Intravascular Coagulation Disseminated intravascular coagulation is a rare but serious condition that causes abnormal blood clotting throughout the body's blood vessels. An infection usually follows it. It can present with any of the following: Bleeding at wound sites or from the nose, gums, or mouth Blood in the stool or urine Bruising in small dots or larger patches on the body Chest pain Pain, redness, warmth, and swelling of the leg Option C: Hemolytic Uremic Syndrome Hemolytic uremic syndrome (HUS) is a condition that affects the blood and blood vessels. It results in: destruction of blood platelets (cells involved in clotting) a low red blood cell count (Anemia) kidney failure due to damage to the tiny blood vessels of the kidneys However, in this case, the triad is not present

↑ *Back to this question in Part A*

@Neet_pg_bot

Q2: A 62-year-old hospitalized woman is evaluated for worsening skin lesions. She was admitted 6 days ago for total hip replacement surgery. The surgery was uncomplicated. She is receiving low-dose subcutaneous heparin for prophylaxis of DVT. O/E, there are several large purple/ black patches seen in the periumbilical region surrounded by erythema. Which of the following is true regarding heparin-induced thrombocytopenia (HIT)? (Q845960)

A. Type 1 is more common than type 2

B. Type 1 is due to antibodies against PF 4

C. HIT can lead to elevated fibrinogen levels

D. Type 2 occurs immediately after the initiation of heparin.

Correct Answer: A. Type 1 is more common than type 2

Explanation: This patient, who underwent a Total hip replacement seven days ago on low-dose subcutaneous heparin, now has purple/black-colored skin necrosis at the abdominal injection site. This is a classic thrombotic complication of Heparin-induced thrombotic thrombocytopenia, commonly observed following the administration of unfractionated heparin. Heparin Induced Thrombocytopenia is of 2 types: HIT type 1 HIT type 2 Epidemiology More common (Option A) Less common Timeline Occurs immediately Occurs 5 - 14 days after therapy (Option D) Prognosis Self-resolving Can lead to life-threatening arterial or venous thrombosis Pathogenesis This occurs due to the platelet aggregating effects of heparin Antibodies against PF4 that lead to platelet aggregation and thrombosis. (Option B) Heparin-induced thrombocytopenia type 2 (HIT type 2) is an immune-mediated adverse reaction where antibodies form against complexes of heparin and platelet factor 4 (PF4). These antibodies activate platelets, leading to their consumption and a pro-thrombotic state, resulting in both thrombocytopenia and an increased risk of thrombosis. Fibrinogen levels usually decrease due to clot formation and consumption. (Option C).

@Neet_pg_bot

Q3: A 45-year-old woman presents with easy bruising and recurrent nosebleeds. Laboratory investigations reveal a prolonged aPTT. A mixing study is performed, and the aPTT corrects after mixing with normal plasma. What is the most likely diagnosis? (Q845970)

A. Factor deficiency

B. Platelet dysfunction

C. Presence of lupus anticoagulant

D. Vitamin K deficiency

Correct Answer: A. Factor deficiency

Explanation: Mixing studies are done when there's a prolonged aPTT with normal BT and PT. This could be due to factor deficiency, like Factor VIII deficiency (hemophilia), or increased antibodies, as seen in Anti-phospholipid antibody syndrome (APLA), including lupus anticoagulant (LAC). Platelet dysfunction(Option B): Platelet dysfunction typically presents with symptoms such as easy bruising and recurrent nosebleeds. However, a prolonged aPTT typically indicates a defect in the coagulation cascade rather than platelet dysfunction. Vitamin K deficiency(Option D): Vitamin K is crucial for synthesizing coagulation factors II, VII, IX, and X. Its deficiency

can lead to prolonged PT and aPTT. However, in this case, the aPTT corrects after mixing with normal plasma, indicating that clotting factors are present. Hence, vitamin K deficiency is less likely.

@Neet_pg_bot

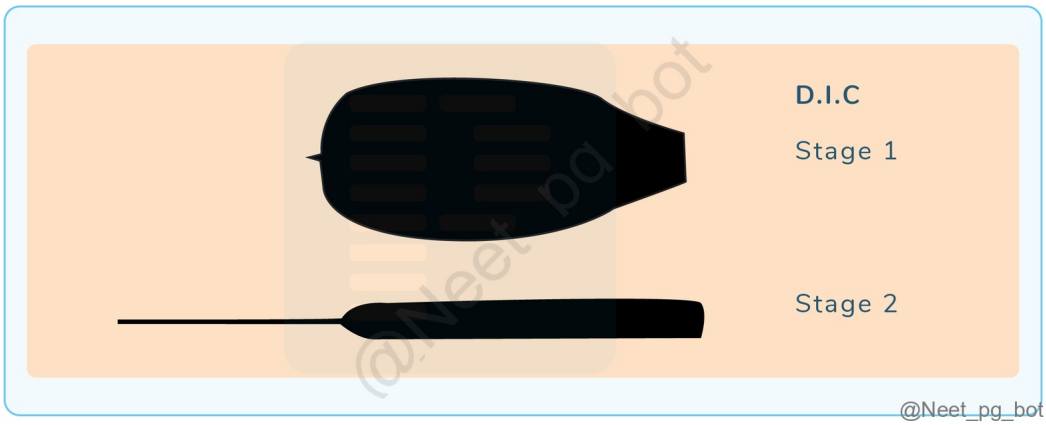
Q4: A 45-year-old male is admitted to the ICU following a road traffic accident. Upon arrival, he is hypotensive and tachycardic. Despite fluid resuscitation and transfusion of packed red blood cells, his condition deteriorates rapidly. Lab investigations show a sudden drop in platelet count and prolonged PT and aPTT. DIC is suspected. The thromboelastogram (TEG) graph is shown below: Which of the following is correct? (Q845969)

A. R time is more in Stage 1

B. K time is more in stage 2

C. Maximum amplitude is more in stage 2

D. Maximum amplitude is less in stage 1



Correct Answer: B. K time is more in stage 2

Explanation: K time is more in stage 2 of DIC due to the increased time for the clot to reach firmness, as there is fibrinogen dysfunction in this stage. Stages of DIC: Stage 1- Hypercoagulable state with multiple clots being formed in vessels throughout the body. The graph shows decreased R time (Option A) , decreased K time, higher maximum amplitude (Option C) , and higher LY30 from subsequent fibrinolysis. Stage 2- Widespread bleeding due to used-up clotting factors and platelets. The graph shows an increased R time, higher K time, lower maximum amplitude (Option D), and lower LY30. The image below depicts how a TEG graph is formed.

@Neet_pg_bot

Q5: A 60 y/o man is brought to the hospital following a high-speed head-on collision. O/E, BP is 80/50mmhg and HR is 130bpm. Laboratory studies indicate a significant drop in platelet count, prolonged PT, and aPTT. DIC is suspected, and a thromboelastogram is performed. What term represents the time from the initiation of the test until the initial formation of the clot? (Q845968)

A. R time

B. K Time

C. Maximum Amplitude (MA)

D. LY30

Correct Answer: A. R time

Explanation: A thromboelastogram is a test that studies the ability of blood to form a clot by studying its viscoelastic properties. Stages of Thromboelastogram (TEG): Definition Normal value Problem it indicates Treatment Reaction time (Option A) Time taken for the clot to start forming 7.5-15 mins Increased: Deficiency in clotting factors Decreased: Hypercoagulable states Fresh frozen plasma K time- clot firmness (Option B) Time for the clot to reach fixed strength 3-6 mins Fibrinogen dysfunction Cryoprecipitate Alpha angle Fibrin linking speed 45° and 55° Fibrinogen dysfunction Cryoprecipitate Maximum amplitude (Option C) The highest vertical amplitude of TEG 50-60 mm Platelets (most often) Clotting factors Platelets Lysis in 30 mins (Option D) Percentage of amplitude reduction 30 minutes after maximum amplitude 0-8% A high value indicates excess lysis of the clot Tranexamic acid

	Normal

	• ↑ R time
	  ○ Clotting factors deficiency
	  ○ Cause - hemophilia

	• Maximum amplitude ↓
	  ○ Primarily measure of platelets
	  ○ Cause - use of platelet blockers

	LY30 ↑ - case of fibrinolysis

	• Disseminated Intravascular coagulation
	  ○ Hypercoagulable state - stage 1
	  → R time ↓
	  → Maximum Amplitude is ↑
	  ○ Consumptive coagulopathy - stage 2
	  → platelets and clotting factors ↓
	  → R time ↑
	  → Maximum amplitude ↓

@Neet_pg_bot

@Neet_pg_bot

Q6: A 10 y/o boy presents with a history of recurrent nosebleeds and easy bruising since early childhood. O/E, there are multiple petechiae and ecchymoses on his skin. Laboratory investigations reveal normal platelet count but markedly decreased platelet aggregation. Bernard-Soulier Syndrome is suspected. Which of the following features would commonly be observed in platelet aggregometry for this patient? (Q845967)

A. Normal aggregation with ristocetin

B. No aggregation with ristocetin

C. No aggregation with collagen

D. No aggregation with epinephrine

Correct Answer: B. No aggregation with ristocetin

Explanation: In platelet aggregometry, ristocetin enhances the binding of glycoprotein Ib/IX and von Willebrand factor, assessing platelet adhesion. In Bernard-Soulier Syndrome (glycoprotein Ib/IX complex deficiency) and von Willebrand disease (vWF deficiency), platelet aggregation in response to ristocetin is typically abnormal (Option A). In contrast, aggregation responses to ADP, collagen, and epinephrine are typically normal (Options C and D).

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 666

www.ncbi.nlm.nih.gov/pmc/articles/PMC5578190/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 6-year-old girl presents with persistent bleeding from minor cuts and bruises since early childhood. On examination, there are multiple bruises and petechiae on her limbs. Lab investigations reveal normal platelet count but markedly decreased platelet aggregation. Glanzmann thrombasthenia is suspected. Which of the following agonists will be able to demonstrate decreased platelet aggregation? (Q845966)

A. Adenosine diphosphate (ADP)

B. Collagen

C. Epinephrine

D. All of the above

Correct Answer: D. All of the above

Explanation: In Glanzmann thrombasthenia, platelet aggregation is impaired due to dysfunctional glycoprotein IIb/IIIa. During platelet aggregometry, ADP, epinephrine, and collagen are added to stimulate platelet aggregation by increasing the binding of glycoprotein IIb/IIIa. However, in Glanzmann thrombasthenia, platelets fail to aggregate in response to these agonists due to dysfunctional glycoprotein IIb/IIIa. Thus, Option D, "All of the above," is correct.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 666

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: A 45-year-old man presents with a history of easy bruising and recurrent nosebleeds. Laboratory investigations reveal normal platelet count but prolonged bleeding time. A Platelet aggregometry test is performed, showing a decrease in light transmission. What is the most likely interpretation of the platelet aggregometry results in this patient? (Q845965)

A. Platelet aggregation

B. No platelet aggregation

C. Increase in serum sodium

D. Increase in plasma fibrinogen

Correct Answer: B. No platelet aggregation

Explanation: The decrease in light transmission observed during platelet aggregometry indicates no platelet aggregation. This test measures platelet adhesion, secretion, and aggregation by passing light through platelet-rich plasma. Initially, light transmission is reduced as the cells are dispersed through plasma. Then we add a "clumping trigger" (Agonist). Common agonists include: ADP, Epinephrine, Collagen, or Arachidonic Acid. Ristocetin (unique because it tests the interaction between vWF and the GpIb receptor). Reaction: Normal Response: Platelet aggregation occurs → Plasma becomes clearer → Light transmission increases. (Option A). Abnormal Response:

Platelets aggregation does not occur → Plasma stays cloudy → Light transmission stays low (Option B) Serum sodium (Option C): Serum sodium levels are not directly assessed or measured during platelet aggregometry. Increase in plasma fibrinogen (Option D): Platelet aggregometry primarily assesses platelet function and aggregation, not plasma fibrinogen levels. Therefore, a decrease in light transmission during the test is unrelated to increased plasma fibrinogen.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 665, 668, 669, 670

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: A 35-year-old mother underwent a C-section. On post-op day 1, she complains of shortness of breath and bleeding from catheter sites. Her vitals are unstable. Which of the following statements is false concerning her condition? (Q845963)

A. PT, and APTT are normal.

B. AMLM3 is associated with DIC

C. FDP & D-dimer levels are elevated

D. Meningococcemia is associated with DIC

Correct Answer: A. PT, and APTT are normal.

Explanation: This 35-year-old mother just delivered one day ago and is now having symptoms of Disseminated intravascular coagulation (DIC) . DIC is classified as an acute, subacute, or chronic thrombo-hemorrhagic illness characterized by excessive coagulation activation and microvascular thrombi formation. Common causes include sepsis, significant trauma, malignant neoplasms, and complications during pregnancy. Acute promyelocytic leukemia (AML M3) and adenocarcinomas of the stomach, colon, pancreas, and lung are frequently associated with DIC. (Option B) DIC is triggered by two main mechanisms: Extensive endothelial cell damage and Release of tissue factor or other procoagulants into the bloodstream. Additionally, widespread endothelial damage can

result from the deposition of antigen-antibody complexes, extremes in temperature, or infections like meningococci and rickettsiae (Option D). Signs and symptoms of DIC may include hemorrhage due to depleted hemostatic components, tissue hypoxia, and infarction due to microthrombi, or both. Diagnosis: ↓ platelet count, ↓ fibrinogen levels; ↑ PT, ↑ aPTT, and ↑ fibrin breakdown products, especially D-dimers (Option C).

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 669.

↑ *Back to this question in Part A*

@Neet_pg_bot

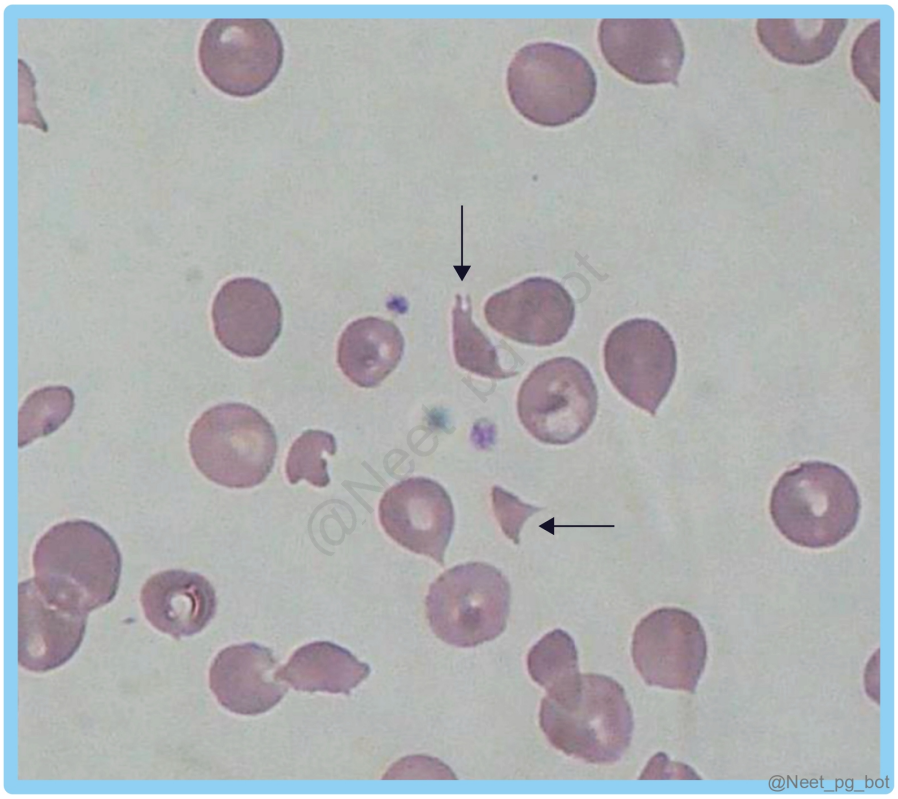
Q11: A 4-year-old child is brought to the emergency department with a history of bloody diarrhea followed by pallor, fatigue, and reduced urine output. Laboratory investigations reveal anemia, thrombocytopenia, and elevated serum creatinine. A peripheral blood smear is done and is given below. What is the most likely cause of this child's diarrhea? (Q845962)

A. O157:H7

B. Defect in ADAM-TS 13

C. Mutation in TGF-beta

D. Prosthetic valves



Correct Answer: A. O157:H7

- *Listen (English)*
- *Listen (Hindi)*

Explanation: This child with symptoms of bloody diarrhea followed by symptoms of renal failure, anemia, and thrombocytopenia has Hemolytic Uremic Syndrome (HUS) Types of HUS and its risk factors: Both types of HUS lead to endothelial injury, resulting in thrombus formation. The characteristic features include renal involvement, hemolytic anemia with schistocytes, thrombocytopenia, and elevated bleeding time. Defect in ADAM-TS 13 (Option B): A defect in ADAM TS 13 (breaks multimers of VWF) is seen in Thrombotic Thrombocytopenic Purpura (TTP). It usually presents as a pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, temporary neurologic impairments, and renal failure. Mutation in TGF-beta (Option C): .Osler-Weber-Rendu syndrome also known as hereditary hemorrhagic telangiectasia(HHT) is an autosomal dominant disorder characterized by multiple AV malformations in viscera and mucocutaneous structures such as the lips,tongue,buccal mucosa and fingertips. Prosthetic valves (Option D): Prosthetic heart valves can cause macroangiopathic hemolytic anemia due to mechanical stress, where red blood cells fracture from increased blood flow around the valve. The spleen removes damaged cells that do not hemolyse in circulation through extravascular hemolysis. However, this is not a specific risk factor for HUS.

@Neet_pg_bot

Q12: A 5-year-old boy is brought to the clinic with recurrent episodes of spontaneous bleeding into his joints. Laboratory tests reveal a prolonged activated partial thromboplastin time (aPTT) and reduced factor VIII levels. Based on these findings, what is the most likely diagnosis? (Q845961)

A. Hemophilia A

B. Hemophilia B

C. Hemophilia C

D. Pseudohemophilia

Correct Answer: A. Hemophilia A

Explanation: This 5-year-old boy has Hemophilia A, caused by a factor VIII deficiency. Factor VIII is a necessary cofactor for factor IX in the coagulation cascade. Hemophilia is an X-linked recessive disorder. Hence, only males are affected. Aspect Hemophilia A (Option A) Hemophilia B (option B) Deficient factor Factor 8 deficiency Factor 9 deficiency Pathway affected in the cascade Intrinsic pathway defect APTT Elevated BT, PT, and TT Normal Treatment Cryoprecipitate, Recombinant factor 8 (Humate) Fresh frozen plasma (FFP) Hemophilia C (Option C): Hemophilia C is due to factor 11 deficiency, an autosomal recessive condition. Bleeding episodes are generally milder than in Hemophilia A and B, and hemarthrosis is rare. Pseudohemophilia (Option D): Pseudohemophilia, also termed von Willebrand disease (vWD), involves a deficiency or dysfunction of von Willebrand factor (vWF), crucial for platelet adhesion and factor VIII stabilization. Symptoms include prolonged aPTT and bleeding due to impaired platelet function and reduced facto

Hemansky-pudlak syndrome

Gray platelet syndrome

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: A 34-year-old man comes to the physician complaining of occasional dizziness and palpitations in crowded spaces. He is an executive who travels frequently and reports high-stress levels at work. Labs: Hb= 14.0 Platelets = 80,000 Leukocytes = 7,200 RBCs= 5 million Peripheral smear shows a reduced platelet count without clumping or malignant cells. Which of the following is the most appropriate next test for this patient? (Q845958)

A. EBV virus titers

B. Rapid plasma reagin test

C. Schilling test

D. HIV antibody test

Correct Answer: D. HIV antibody test

Explanation: Isolated thrombocytopenia without anemia or leukopenia suggests Immune Thrombocytopenic Purpura (ITP), diagnosed after excluding other causes. Thrombocytopenia may occur in chronic HIV infection; thus, HIV and hepatitis C testing are essential. ITP is a diagnosis of exclusion, requiring exclusion of other causes of thrombocytopenia. Pathogenesis: Autoantibodies (usually IgG) are formed against platelet membrane glycoproteins GpIIb/IIIa or GpIb/IX . Antibody-coated platelets are destroyed in the spleen → thrombocytopenia, increased megakaryocytes in marrow → large platelets in smear . Features Acute ITP Chronic ITP Age Child Adult (<40 yrs) Common in M=F Females Etiology Often follows viral infections Can be primary (idiopathic) or secondary to SLE, HIV, CLL Laboratory Findings Isolated thrombocytopenia (<20,000/μL), normal PT and aPTT, ↑BT Isolated thrombocytopenia (30,000-80,000/μL), normal PT and aPTT, ↑BT; Hypercellular marrow with megakaryocytic hyperplasia; Megathrombocytes in peripheral blood Autoantibodies IgG (short-lived and often

transient) IgG (persistent) Resolution Normal within 6 months > 6 months Treatment Often self-limited Steroids. Splenectomy in refractory cases. EBV virus titers (Option A) titers are useful for diagnosing infectious mononucleosis. Patients with infectious mononucleosis usually present with fatigue, sore throat, fever, palatal petechiae, posterior cervical lymphadenopathy, and splenomegaly. Labs show lymphocytosis and possible thrombocytopenia. This patient does not have findings of infectious mononucleosis. Rapid plasma reagin test (Option B) is a non-treponemal antigen test used to screen for syphilis. However, syphilis is not associated with thrombocytopenia. Schilling test (Option C) determines if vitamin B12 deficiency is due to pernicious anemia or a malabsorption syndrome. It is not used to diagnose ITP.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 664

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 14-year-old adolescent presents with recurrent episodes of unexplained swelling and pain following minor injuries or physical activity. Upon examination, there are signs of localized swelling and tenderness. Lab investigations reveal normal platelet counts and bleeding time, but clotting times are prolonged. Which symptom would strongly suggest a coagulation defect in this patient? (Q845957)

A. Petechiae

B. Purpura

C. Ecchymosis

D. Hemarthrosis

Correct Answer: D. Hemarthrosis

Explanation: Coagulation factor abnormalities, or defects in secondary hemostasis, may manifest as bleeding into soft tissues like muscles or joints. Hemarthrosis, characterized by bleeding into joints following minor trauma, is a specific feature associated with hemophilia. Clinical manifestation Platelet disorders Coagulation disorders Bleeding site Mucous membranes Muscles and joints Presentation Superficial bleeds like Petechia , purpura, mucosal bleeds; multiple sites Deep tissue bleeds like Hematoma , intracranial bleeds (most dangerous) , joint bleeds/ hemarthroses (most common); localized Bleeding onset Prolonged bleeding from cuts May be delayed at onset Family history Rare Common Treatment response Immediately Insidious Petechiae(Option A): Petechiae (minute 1 to 2-mm hemorrhages) arise due to a defect in platelet function. They occur as pinpoint hemorrhages in the dependent areas where the capillary pressure is higher. Purpura (Option B): Purpura are slightly larger than petechiae (>3 mm) and can be palpable. They are often seen in conditions like Henoch-Schonlein purpura. Ecchymoses(Option C): Ecchymoses, or bruises, are 1 to 2-cm hemorrhages. The volume of blood that has been extravasated in purpura and ecchymoses may be sufficient to form a palpable mass of blood called a hematoma.

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 125.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q17: A 22-year-old woman presents to the clinic with a history of frequent nosebleeds and heavy menstrual periods. She reports prolonged bleeding after minor cuts and has noticed easy bruising. On physical examination, multiple small bruises are on her arms and legs. Which of the following tests is most likely to be abnormal? (Q845956)

A. Bleeding Time (BT)

B. Clotting Time (CT)

C. Prothrombin Time (PT)

D. Activated Partial Thromboplastin Time (aPTT)

Correct Answer: A. Bleeding Time (BT)

Explanation: Based on the clinical presentation, the most likely diagnosis is von Willebrand Disease (vWD) , which is the most common inherited bleeding disorder. The patient's symptoms like mucocutaneous bleeding (nosebleeds, heavy periods, easy bruising) and prolonged bleeding after minor cuts, point toward a defect in primary hemostasis (platelet plug formation) rather than the coagulation cascade. Symptoms: Epistaxis, menorrhagia, and easy bruising are classic signs of platelet or vessel wall dysfunction. Pathophysiology: In vWD, there is a deficiency or dysfunction of von Willebrand Factor (vWF). vWF is essential for: Platelet Adhesion: It acts as a bridge between platelets and the damaged subendothelium. Factor VIII Stabilization: It protects Factor VIII from rapid degradation in the blood. Bleeding Time (BT): Prolonged when platelet number or function is reduced → best screening test for primary hemostasis defect. Clotting Time (CT) (Option B) : Measures overall clot formation (intrinsic + extrinsic); normal in isolated platelet defects. Normal CT: 8-15 mins. Prothrombin Time (PT) (Option C): Prolonged only in extrinsic pathway disorders (factor VII deficiency, warfarin therapy). Normal PT: 11-16 secs. Activated Partial Thromboplastin Time (aPTT) (Option D): Prolonged in intrinsic pathway defects (hemophilia A/B, heparin therapy). Normal aPTT: 25-30 secs.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 663

www.ncbi.nlm.nih.gov/books/NBK265/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q18: A 2-week-old male infant is brought to the pediatrician by his parents because of prolonged bleeding from the umbilical stump. The parents report that the bleeding started soon after the umbilical cord fell off and has not stopped despite applying pressure. Laboratory tests show normal Prothrombin Time (PT), Activated Partial Thromboplastin Time (aPTT), and platelet count. Which of the following deficiencies is most likely causing the prolonged bleeding? (Q845955)

A. Factor VIII

B. Factor XIII

C. Factor IV

D. Factor IX

Correct Answer: B. Factor XIII

Explanation: Factor XIII is crucial for maintaining clot stability and promoting fibrin polymer cross-linking, ensuring effective hemostasis. Its deficiency can lead to prolonged bleeding from the umbilical stump in neonates, as seen in this case. Other symptoms include severe menstrual bleeding, hemarthrosis, repeated early pregnancy loss, and delayed postoperative bleeding. Unlike other factors, Factor XIII deficiency does not affect BT, CT, PT, aPTT, or platelet count. Diagnosis is confirmed with a urea clot solubility test, in which the clot dissolves if Factor XIII is deficient. Factor VIII deficiency (Option A): Hemophilia A, or Factor VIII deficiency is an X-linked disorder, characterized by elevated aPTT and causes deep tissue and joint bleeding. Von Willebrand factor (vWF) protects Factor VIII from degradation, and its deficiency can lead to reduced Factor VIII levels, resulting in a condition called pseudohemophilia. Factor IV deficiency (Option C): Factor IV (calcium) is essential for the coagulation cascade, activating Factor X in intrinsic and extrinsic pathways. However, calcium deficiency is extremely rare and not associated with umbilical stump bleeding; it typically causes widespread bleeding. Factor IX deficiency (Option D): Factor IX deficiency (Hemophilia B or Christmas disease) is an X-linked recessive disorder affecting the intrinsic pathway, causing elevated aPTT with normal PT. Like Hemophilia A, it primarily leads to deep tissue and joint bleeding.

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 667-669

www.ncbi.nlm.nih.gov/books/NBK557467/

↑ *Back to this question in Part A*

@Neet_pg_bot

Q19: A 30-year-old woman presents with excessive bleeding following a tooth extraction. She reports a history of recurrent nosebleeds and easy bruising since childhood. Lab tests show prolonged activated partial thromboplastin time (aPTT) and normal prothrombin time (PT). Further testing reveals decreased levels of a clotting factor's activity. Which of the following is not an intrinsic factor? (Q845954)

A. Factor XII

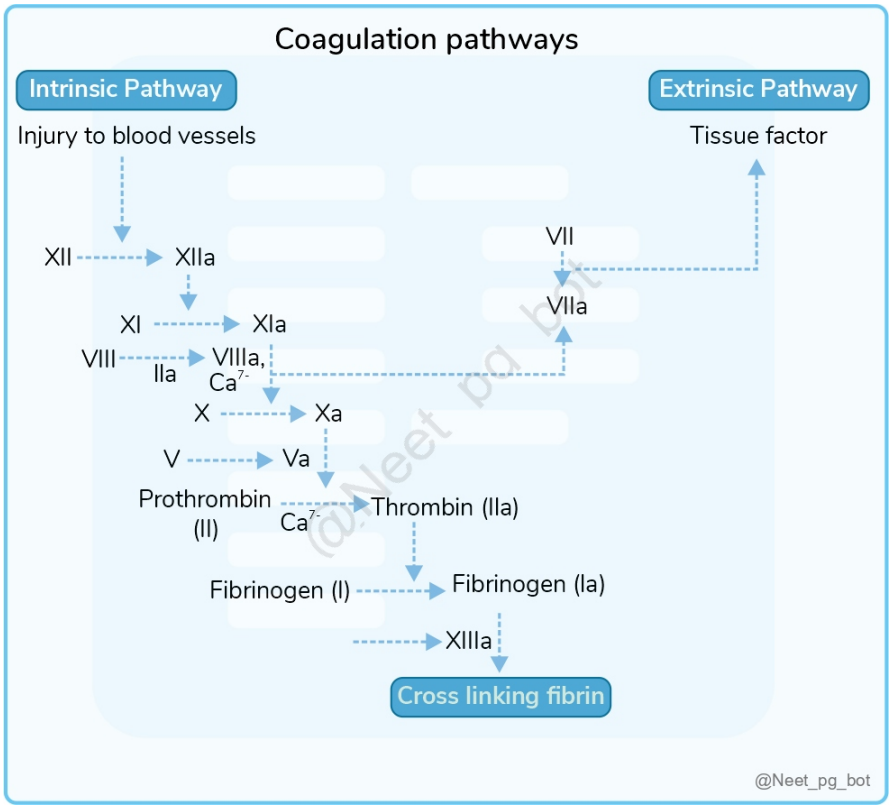
B. Factor VII

C. Factor XI

D. Factor IX

Correct Answer: B. Factor VII

Explanation: Factor VII is an extrinsic factor. Clotting cascade: Extrinsic factors Intrinsic factors Common pathway factors 3 (tissue factor), 7 12, 11, 9 (Options A, C , D), 8 10, 5, 2, 1, 13



References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 121

↑ *Back to this question in Part A*

@Neet_pg_bot

Q20: A 55-year-old male patient presents with a history of recurrent episodes of uncontrolled bleeding from minor injuries and easy bruising. Lab investigations reveal prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). Considering a potential vitamin K deficiency, which specific clotting factors should be evaluated to confirm the diagnosis in this patient? (Q845953)

A. Tissue thromboplastinLabile factor

B. Labile factor

C. Hageman factor

D. Stable factor

Correct Answer: D. Stable factor

Explanation: In the context of a potential vitamin K deficiency, clotting factors synthesized in the liver and dependent on vitamin K should be evaluated. Factors II (Prothrombin), VII (Stable factor), IX (Christmas factor), X (Stuart-Prower factor), and Protein C depend on vitamin K for synthesis in the liver. Vitamin K deficiency leads to reduced carboxylation of glutamate residues on clotting factors impairing blood clotting. Factors III (Tissue thromboplastin), V (Labile factor), and XII (Hageman factor) are not vitamin K-dependent factors (Options A, B, and C)

References:

Robbins and Cotran, Pathological Basis of Disease, 10th Edition, Page 122.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q21: A 32-year-old woman presents with easy bruising, heavy menstrual bleeding, and prolonged bleeding after cuts and dental extraction. Lab tests show normal platelet counts but impaired platelet function. Which of the following substances, primarily released from alpha granules, might be deficient in this patient's platelets? (Q845952)

A. Serotonin

B. Epinephrine

C. ADP

D. P-selectin

Correct Answer: D. P-selectin

Explanation: P-selectin, primarily released from platelet alpha granules, plays a crucial role in platelet aggregation and adhesion. Its deficiency leads to easy bruising and prolonged bleeding. Alpha and delta granules in platelets and their contents: Alpha granules Delta/Dense granules P- selectin (Option D) PF4 (platelet factor 4) PDGF (platelet-derived growth factor) Factor V, VIII Fibrinogen (Mnemonic: all P things and all Factors) ADP (Option C) ATP Serotonin (Option A) Serum calcium Epinephrine (Option B)

@Neet_pg_bot

Q22: A 22 y/o woman arrives at the clinic complaining of heavy menstrual flow and recurrent nosebleeds. Upon physical inspection, her arms and legs have several minor bruises. Coagulation studies show high BT, APTT, and normal PT. She is diagnosed with von Willibrand disease. Which type of vWD shows a decrease in binding between VWF and Gp 1b/9? (Q845951)

A. Type 1

B. Type 2a

C. Type 2b

D. Type 3

Correct Answer: B. Type 2a

Explanation: Von Willebrand disease is the most common inherited bleeding disorder. Clinically and molecularly, von Willebrand disease is heterogeneous, below are 3 identified kinds, each with a variety of phenotypes; vWD type 1 (Option A) vWD Type 2 vWD Type 3 (Option D) Autosomal dominant. The most common type. Mild to moderate vWF deficiency. Quantitative defect. point substitutions prevent the vWF protein from maturing or cause it to leave the plasma quickly Autosomal dominant. Qualitative defect. Types: 2A, 2B, 2M, 2N 2A (Most common) - Decrease in binding between vWF and Gp1b/9 (Option B) missense mutations cause faulty multimer formation → the most active forms of vWF, i.e. large- and intermediate-sized multimers are absent. 2B - Increase in binding between vWF and Gp1b/9 (Option C) 2M - VWF dependant platelet adhesion is decreased. There is impairment of VWF binding to platelets. Type 2M VWD typically has mild to moderate mucocutaneous bleeding 2N - There is marked decline in the binding affinity for factor VIII. The level of factor VIII is lower when compared to the VWF:Ag. This led to misdiagnosis as haemophilia A Autosomal recessive . Quantitative defect. produced by frameshift mutations or deletions affecting both alleles (autosomal recessive), which produce little or no vWF. Factor VIII levels are also lowered because vWF stabilizes factor VIII in the blood, and the resulting bleeding condition is severe.

↑ *Back to this question in Part A*

Q23: A 30-year-old woman is diagnosed with von Willebrand Disease (vWD) after presenting with frequent nosebleeds and prolonged bleeding after minor cuts. Laboratory tests reveal a defect in the von Willebrand factor (vWF). Which of the following is also involved in the pathogenesis of this condition? (Q845950)

A. gp1b-IX

B. gpIIb-IIIa

C. Factor IX

D. Factor XIII

Correct Answer: A. gp1b-IX

■ *Listen to Audio 1*

Explanation: Gp1b-IX is a membrane complex in platelets that facilitates binding to the von Willebrand Factor, which is defective/deficient in von Willebrand disease. vWF is produced by endothelial cells (Weibel–Palade bodies) and megakaryocytes (α-granules of platelets). vWF stabilizes factor VIII in circulation, so its deficiency causes both platelet adhesion defect and a secondary factor VIII deficiency (hence bleeding resembles both platelet-type and hemophilia-like features). Defective platelet adhesion occurs because vWF mediates binding between platelets (GpIb receptor) and subendothelial collagen. gpIIb-IIIa (Option B): This glycoprotein complex is crucial for platelet aggregation, the final step in primary hemostasis. It binds fibrinogen and von Willebrand factor (vWF), aiding in the formation of platelet plugs. However, defects in gpIIb-IIIa are not associated with von Willebrand Disease (vWD). Factor IX (Option C): Factor IX (or Christmas factor) is a vitamin K-dependent clotting factor, part of the intrinsic clotting pathway. Factor IX deficiency is known as Hemophilia B, an X-linked recessive disorder. Factor XIII (Option D) stabilises fibrin by cross-linking and deficiency leads to severe bleeding.

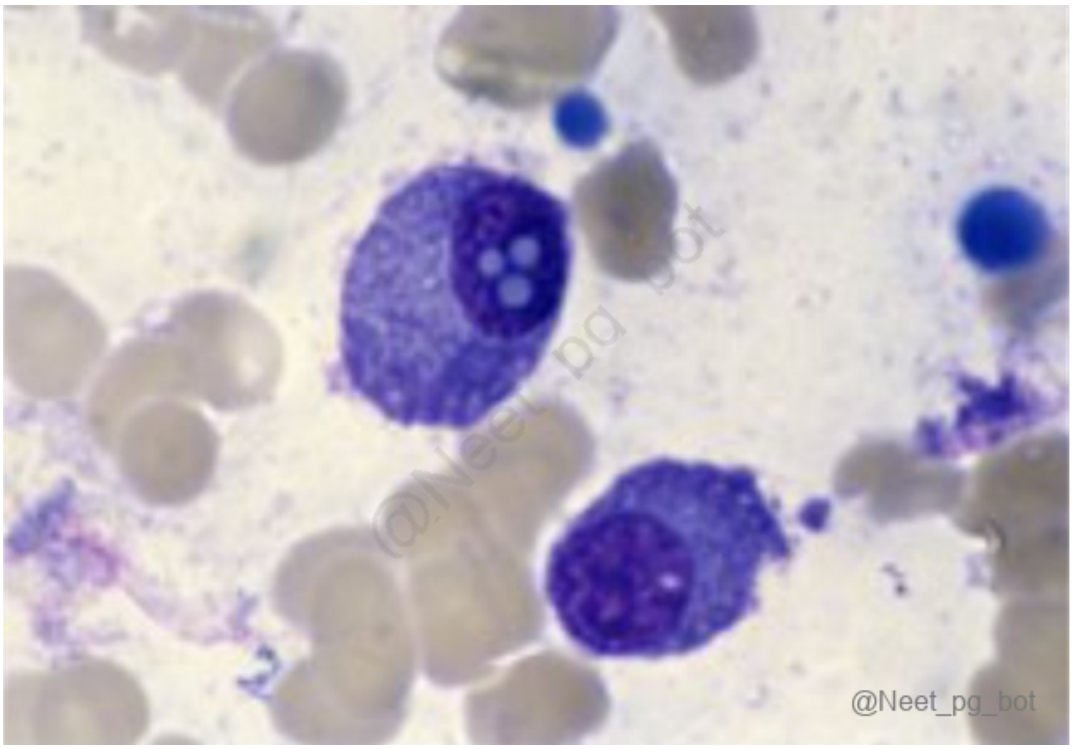
Q1: A patient presents with a tingling sensation in both legs, polyuria, and weight loss. Based on the given bone marrow aspirate findings, what is the most likely diagnosis? (Q844224)

A. Multiple myeloma with renal failure

B. SACD with vitamin B12 deficiency

C. SACD with diabetes

D. Waldenstrom's Macroglobulinemia



Correct Answer: A. Multiple myeloma with renal failure

Explanation: Correct Option A - Multiple myeloma with renal failure: The bone marrow aspirate shows intranuclear inclusions known as Dutcher's bodies, which are characteristic of multiple myeloma. Multiple myeloma often presents with renal failure, polyuria (due to hypercalcemia), and tingling sensations (due to amyloid deposition or hypercalcemia-related neuropathy). Incorrect Options: Options B, C, and D do not show Dutcher bodies on bone marrow biopsy.

@Neet_pg_bot

Q2: Most common cause of inherited coagulopathy is: (Q853370)

A. Factor V Leiden mutation

B. Antithrombin III deficiency

C. Protein C deficiency

D. Protein S deficiency

Correct Answer: A. Factor V Leiden mutation

Explanation: Factor V Leiden mutation is the most common cause of inherited coagulopathy among the given options. Hypercoagulability It refers to an increased tendency of the blood to clot, usually due to changes in coagulation factors. Types: Primary disorders (genetic) Secondary disorders (acquired) Among inherited causes, point mutations in the factor V and prothrombin genes are the most common. Primary disorders (Genetic) Secondary disorders (Acquired) Common Factor V mutation A single-nucleotide mutation (autosomal dominant inheritance) in the factor V gene makes factor V resistant to cleavage and inactivation by protein C. Prothrombin mutation A single nucleotide change (G20210A) in the 3′-untranslated region of the prothrombin gene is linked to hypercoagulability. Rare Antithrombin III deficiency (Option B) Protein C deficiency (Option C) Protein S deficiency (Option D) Very rare Fibrinolysis defects Homozygous homocystinuria (deficiency of cystathionine β-synthetase) Strong Risk Factors for Thrombosis Prolonged bed rest or immobilization Myocardial infarction Atrial fibrillation Tissue injury (surgery, fracture, burn) Cancer Prosthetic cardiac valves Disseminated intravascular coagulation Heparin-induced thrombocytopenia Antiphospholipid antibody syndrome Other Risk Factors for Thrombosis Cardiomyopathy Nephrotic syndrome Hyperestrogenic states (pregnancy and postpartum) Oral contraceptive use Sickle cell anemia Smoking

@Neet_pg_bot

Q3: Which of the following diseases are correctly associated with their respective inclusion bodies? (Q853377)

A. Rabies - Lewy bodies

B. Parkinson’s disease - Dutcher bodies

C. Multiple myeloma - Negri bodies

D. Malakoplakia - Michaelis Gutmann bodies

Correct Answer: D. Malakoplakia - Michaelis Gutmann bodies

Explanation: Michaelis Gutmann bodies are seen in Malakoplakia. Disease Inclusion bodies Rabies Negri bodies are cytoplasmic, round to oval, eosinophilic inclusions found in pyramidal neurons of the hippocampus and Purkinje cells of the cerebellum , sites usually devoid of inflammation. Parkinson’s disease Lewy bodies These are single or multiple, cytoplasmic, eosinophilic, round to elongated inclusions that often have a dense core surrounded by a pale halo. They are composed of fine filaments, densely packed in the core but loose at the rim; these filaments are composed of α-synuclein. Multiple myeloma The globular inclusions are referred to as Russell bodies (if cytoplasmic) or Dutcher bodies (if nuclear). Malakoplakia Michaelis Gutmann bodies: Laminated mineralized concretions resulting from calcium deposition in enlarged lysosomes.

Q4: Vacutainer used in serum electrolyte estimation: (Q853367)

A. Green

B. Lavender

C. Yellow

D. Grey

Correct Answer: A. Green

Explanation: The green-top vacutainer contains lithium heparin, which is routinely used for plasma electrolyte estimation because: Heparin prevents clotting without altering electrolyte levels. Plasma electrolytes remain stable and can be analyzed immediately. Types of Vacutainers Colour Anti-coagulants Uses Purple/Lavender (Option B ruled out) EDTA (Ca2+ chelating anticoagulant) CBC, Peripheral Smear, ESR, HbA1c. Light Blue Citrate (Ca2+ chelating anticoagulant) ESR, PT (Prothrombin Time), APTT (Activated Partial Thromboplastin Time), and INR

(International Normalized Ratio). Red No anti-coagulant is added. Serum studies (blood chemistry, serology, and blood bank testing). Yellow (Option C ruled out) Clot activator/Gel separator Serum tests, such as hormone tests, chemistry panels, and serological tests Grey (Option D ruled out) Sodium Fluoride Blood glucose. Green Heparin ABG, Osmotic fragility, flow cytometry, Serum electrolytes, immunophenotyping.

Q5: Anticoagulant used in the test tube for estimating HbA1c? (Q853366)

A. Warfarin

B. Sodium Fluoride

C. EDTA

D. Heparin

Correct Answer: C. EDTA

Explanation: EDTA (purple/lavender vacutainer) is the anticoagulant for estimating HbA1c. Vacutainers types Colour Anti-coagulants Uses Purple/Lavender EDTA (Ca2+ chelating anticoagulant) (Option C) CBC, Peripheral Smear, ESR, HbA1c. Light Blue Citrate (Ca2+ chelating anticoagulant). ESR, PT (Prothrombin Time), APTT (Activated Partial Thromboplastin Time), and INR (International Normalized Ratio) Red No anti-coagulant is added Serum studies (blood chemistry, serology, and blood bank testing) Yellow Clot activator/Gel separator Serum tests, such as hormone tests, chemistry panels, and serological tests (LFT, RFT, serum electrolytes) Grey Sodium Fluoride (Option B) Blood Glucose Green Heparin (Option D) ABG, Osmotic fragility, flow cytometry, immunophenotyping Warfarin (Option A) is not an anticoagulant in any vacutainer.

@Neet_pg_bot

Q6: A child is brought to the emergency department with a large lesion on his forearm. As a surgery resident, you decide to excise the lesion in the emergency operation theatre. Which of the following investigations will test the entire coagulation pathway? (Q856915)

A. Activated partial thromboplastin time

B. Prothrombin time

C. Thromboelastography

D. Bleeding time

Correct Answer: C. Thromboelastography

Explanation: Thromboelastography (TEG) is a coagulation test that evaluates the entire coagulation pathway, including both the intrinsic and extrinsic pathways and fibrinolysis. It offers a comprehensive assessment of clot formation, clot strength, and clot breakdown. Thromboelastography (TEG) is a diagnostic tool used to evaluate coagulation profiles and guide management with transfusions and hemostatic therapies. Studies show that TEG can reduce blood product usage by up to 40%, decrease postoperative length of stay, and lower the risk of reoperation. TEG measures the viscoelastic properties of blood as clotting occurs. The resulting data is plotted on a graph with time on the x-axis and amplitude (clot strength) on the y-axis. Key values include: Reaction time (R): The time it takes for the clot strength to reach an amplitude of 2 mm. Kinetics (K): The time from R to when the amplitude reaches 20 mm. α-angle: The angle formed by a line from R to the point where K intersects with the 20 mm amplitude mark. Maximum amplitude (MA): The highest amplitude reached. Lysis at 30 minutes (Ly30): The per cent decrease in amplitude 30 minutes after MA (or 60 minutes in some cases). Inference: A prolonged R time may indicate coagulation factor deficiency or anticoagulation. A decreased α-angle can result from hypofibrinogenemia Low MA can be due to thrombocytopenia or platelet dysfunction. Increased Ly30 indicates hyperfibrinolysis, often seen in severe trauma or with thrombolytic therapy. Based on the TEG findings, targeted blood products can be administered to normalize coagulation. For example: Fresh frozen plasma for prolonged R time Cryoprecipitate for decreased α-angle Platelets for decreased MA Tranexamic acid or aminocaproic acid for increased Ly30 Incorrect Options: Activated Partial Thromboplastin Time (aPTT) (Option A) primarily evaluates the intrinsic pathway of the coagulation cascade. Prothrombin Time (PT) (Option B) mainly assesses the extrinsic pathway of the coagulation cascade. Bleeding Time (Option D) measures the duration for bleeding to cease following a standardized skin incision. It primarily evaluates platelet function and primary hemostasis.

@Neet_pg_bot

Q7: What is the commonest cause of a hypercoagulable state? (Q857441)

A. Antithrombin III deficiency

B. Protein C deficiency

C. Factor V Leiden mutation

D. G20210A prothrombin gene mutation

Correct Answer: C. Factor V Leiden mutation

Explanation: The most common inherited cause of a hypercoagulable state (predisposing to thrombosis) is the Factor V Leiden mutation . Mutation: Factor V becomes resistant to cleavage and inactivation by protein C, disrupting the antithrombotic pathway. Inheritance: Autosomal dominant. Primary causes of Hypercoagulable states Common causes Factor V mutation (Factor V Leiden) Prothrombin mutation (G20210A) - It is comparatively less common than Factor V mutation (Option D ruled out) Elevated factor levels (VIII, IX, XI, or fibrinogen) Rare causes Antithrombin III deficiency (Option A ruled out) Protein C deficiency (Option B ruled out) Protein S deficiency Very rare causes Fibrinolysis Defects Homozygous Homocystinuria Secondary causes of Hypercoagulable states Major risk factors Myocardial infarction Atrial fibrillation Tissue injury (surgery, fracture, burn) Cancer Prosthetic cardiac valves DIC Heparin-induced thrombocytopenia Prolonged rest or immobilisation Additional risk factors for thrombosis Cardiomyopathy Nephrotic syndrome Hyperestrogenic states (pregnancy and postpartum) Oral contraceptive use Sickle cell anemia Smoking

@Neet_pg_bot

Q8: How does Total plasma exchange help in the management of TTP (Q857426)

A. TPE removes the Von Willebrand factor

B. TPE removes the Antiplatelet antibodies

C. TPE removes Anti ADAMTS13 autoantibodies and thereby increases the ADAMTS protease activity

D. TPE replenishes the coagulation factor

Correct Answer: C. TPE removes Anti ADAMTS13 autoantibodies and thereby increases the ADAMTS protease activity

Explanation: Total plasma exchange (TPE) is a key treatment for thrombotic thrombocytopenic purpura (TTP); it removes the autoantibodies against ADAMTS13. (Option B ruled out) ADAMTS13 is a protease that cleaves von Willebrand factor, preventing the formation of large, thrombogenic von Willebrand factor multimers. (Option A ruled out) This helps restore normal ADAMTS13 activity and reduces the microvascular clotting that characterizes TTP. Treatment of TTP Plasma exchange (PEX) with high-dose corticosteroid therapy. It is the mainstay of treatment in TTP. Corticosteroids operate by decreasing the activity of the reticuloendothelial system as well as decreasing autoantibody production. Both the ultra-large VWF multimers and the ADAMTS13 autoantibodies are effectively removed from circulation by plasma exchange therapy. The recommended volume of exchange is one estimated plasma volume (usually 40 mL/kg of body weight) with each treatment. The recommended dose for corticosteroids is 1 mg/kg per day of prednisolone. Rituximab An anti-CD20 monoclonal antibody was found to help treat TTP refractory to PEX. It targets B-lymphocytes and has a good response rate in refractory and relapsed TTP. Caplacizumab It has a high potential for TTP. It is a humanized monoclonal antibody fragment (a bivalent, variable-domain-only fragment) that attacks the A1 section of VWF and prevents platelet adhesion. Others

Splenectomy, Vincristine, Cyclosporine and Cyclophosphamide. TPE replenishes the coagulation factor (Option D) : TPE does not replenish coagulation factors; instead, it removes harmful substances like autoantibodies against ADAMTS13 in TTP, where clotting issues stem from defective vWF cleavage, not coagulation factor deficiencies.

@Neet_pg_bot

Q9: Which of the following is not seen in a delayed hemolytic transfusion reaction? (Q840056)

A. Raised LDH

B. Raised indirect bilirubin

C. No improvement in Hb despite transfusion

D. Cola-colored urine after 2 hrs

Correct Answer: D. Cola-colored urine after 2 hrs

Explanation: Correct Option D - Cola-colored urine after 2 hrs Cola-colored urine is not a typical presentation in delayed hemolytic transfusion reactions. Instead, urine color typically ranges from red to brown during hemolysis. Additionally, delayed reactions typically occur after 2-3 days or even a few weeks. Incorrect Options: Options A, B & C: Raised LDH, Raised indirect bilirubin, and No improvement in Hb despite transfusion are all features of delayed hemolytic transfusion reactions.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: In a trauma patient with an unknown blood group who is unstable and requires urgent blood transfusion, which type of blood should be transfused? (Q840032)

A. A positive

B. AB positive

C. O positive

D. O negative

Correct Answer: D. O negative

Explanation: O-negative red blood cells are called the universal donor for RBC transfusion. O blood group has no A or B antigens, and negative Rh (D) antigen avoids Rh sensitization in Rh-negative recipients. This is critical in trauma or emergency situations when there is no time to determine blood group. Allows rapid transfusion while minimizing risk of acute hemolytic transfusion reactions. After stabilizing the patient and determining the blood group, group-specific blood should be transfused. Incorrect Options: Option A) A positive: May cause hemolytic reaction if the patient is type B or O. Option B) AB positive: Contains A and B antigens; unsafe for most unknown recipients. Option C) O positive: Safe for Rh-positive patients, but can sensitize Rh-negative recipients.

@Neet_pg_bot

Q11: Which of the following is used in the treatment of Hemophilia B? (Q840031)

A. Factor 9

B. Cryoprecipitate

C. Factor 8

D. Tranexamic acid

Correct Answer: A. Factor 9

Explanation: Hemophilia B is caused by Factor IX deficiency (Christmas disease). Replacement therapy with Factor IX concentrate restores the intrinsic coagulation pathway and stops bleeding. It can be given prophylactically or during bleeding episodes or surgery. Incorrect Answers: Option B) Cryoprecipitate: Rich in Factor VIII, fibrinogen, and vWF, but contains minimal Factor IX. Not effective for Hemophilia B. Option C) Factor VIII: Used in Hemophilia A (Factor VIII deficiency). Does not correct Factor IX deficiency. Option D) Tranexamic acid : Antifibrinolytic; stabilizes formed clots. Supportive only, does not replace missing Factor IX.

@Neet_pg_bot

Q12: Match the following blood products with their shelf lives. a. 1-Granulocytes A- 5 days b. 2- PRBC B- 24 hours c. 3- SDP C- 42 days d. 4- CRYO D- 1 year (Q840026)

A. 1-A, 2-C, 3D, 4-B

B. 1-B, 2-D, 3-A, 4-C

C. 1-C, 2-A, 3-B, 4-D

D. 1-B, 2-C, 3-A, 4-D

Correct Answer: D. 1-B, 2-C, 3-A, 4-D

Explanation: Correct Option D - 1-B, 2-C, 3-A, 4-D: Granulocyte concentrate : They have a very short shelf life of 24 hours. PRBC (Packed Red Blood Cells) : Packed Red Blood cells have a shelf life of 35 to 42 days, depending on the anti-coagulant used: 21 days (ACD/CPD), 35 days (CPDA) and 42 days (SAGM). SDP (Single Donor Platelets) : Single Donor Platelets have a shelf life of 5 days, CRYO (Cryoprecipitate) : Cryoprecipitate has a shelf life of 1 year. Incorrect Options: Options A, B, and C are incorrectly matched.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: A young boy presents with joint swelling after a fall. Lab investigations show normal PT and raised aPTT. What is the most likely diagnosis? (Q866666)

A. Von Willebrand Disease

B. Hemophilia

C. Iron Deficiency Anaemia (IDA)

D. Platelet function disorder

Correct Answer: B. Hemophilia

Explanation: This presentation matches haemophilia because: Joint swelling after trauma → suggests hemarthrosis, which is typical of coagulation factor deficiencies, especially haemophilia. Normal PT → extrinsic pathway is intact. Prolonged aPTT → intrinsic pathway defect (Factors VIII, IX, XI). Haemophilia A = Factor VIII deficiency; Haemophilia B = Factor IX deficiency. Incorrect Options: Von Willebrand Disease (Option A): usually has prolonged aPTT (due to low factor VIII) and mucocutaneous bleeding (epistaxis, menorrhagia), not deep joint bleeds as the main feature. Iron Deficiency Anaemia (IDA) (Option C) : causes pallor and fatigue, not

isolated coagulation abnormalities. Platelet function disorder (Option D): causes mucosal bleeding and petechiae, not hemarthrosis; PT and aPTT are usually normal.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q14: Which of the following is the most common inherited bleeding disorder? (Q865368)

A. Von Willebrand Disease

B. Disseminated Intravascular Coagulation

C. Factor V Deficiency

D. Hemophilia

Correct Answer: A. Von Willebrand Disease

Explanation: Von Willebrand Disease (VWD) is the most common inherited bleeding disorder. Types: vWD type 1 vWD Type 2 vWD Type 3 Autosomal dominant. The most common type. Mild to moderate vWF deficiency. Quantitative defect. point substitutions prevent the vWF protein from maturing or cause it to leave the plasma quickly Autosomal dominant. Qualitative defect. Types: 2A, 2B, 2M, 2N 2A (Most common) - Decrease in binding between vWF and Gp1b/9 missense mutations cause faulty multimer formation → the most active forms of vWF, i.e. large- and intermediate-sized multimers are absent. 2B - Increase in binding between vWF and Gp1b/9 2M - VWF dependant platelet adhesion is decreased. There is impairment of VWF binding to platelets. Type 2M VWD typically has mild to moderate mucocutaneous bleeding 2N - There is marked decline in the binding affinity for factor VIII. The level of factor VIII is lower when compared to the VWF:Ag. This led to misdiagnosis as haemophilia A Autosomal recessive . Quantitative defect. produced by frameshift mutations or deletions affecting both alleles (autosomal recessive), which produce little or no vWF. Factor VIII levels are also lowered because vWF stabilizes factor VIII in the blood, and the resulting bleeding condition is severe. Disseminated Intravascular Coagulation (DIC) (Option B) is an acquired (not inherited), secondary condition due to systemic activation of the clotting cascade (e.g., in sepsis, trauma, malignancy). Factor V Deficiency (Option C) is a rare inherited bleeding disorder, also known as parahemophilia. Far less common than vWD. Hemophilia (A or B) (Option D) is an inherited X-linked recessive disorder involving Factor VIII (A) or Factor IX (B) deficiency. More common in males but still less prevalent than von Willebrand disease.

Textbook of Robbin and Cotran’s Pathological Basis of Diseases, 10th Edition, Page 668.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: Which of the following clotting factor deficiencies will not affect clotting in vivo? (Q856490)

A. Factor VII

B. Factor V

C. Factor XII

D. Factor IX

Correct Answer: C. Factor XII

Explanation: Factor XII deficiency (Hageman factor) does not significantly affect clotting in vivo, as it primarily participates in the intrinsic pathway and is involved in the activation of the fibrinolytic system and the contact activation of the clotting cascade. Factor XII does not notably impair normal clotting, as other factors and pathways can compensate for its lack. In contrast, Factor VII, Factor V, and Factor IX deficiencies significantly impact the clotting cascade and lead to bleeding disorders. Factor VII (Option A) is a critical component of the extrinsic pathway of coagulation. Deficiency can lead to bleeding disorders, as it directly impacts the initiation of the clotting cascade in vivo. Factor V (Option B) is essential for the common pathway of coagulation, acting as a cofactor for Factor Xa in the conversion of prothrombin to thrombin. Its deficiency results in impaired clotting and increases the risk of bleeding. Factor IX (Option D) is involved in the intrinsic pathway of coagulation. Deficiency causes Hemophilia B, leading to impaired clot formation and increased bleeding risk in vivo.

@Neet_pg_bot

Q16: Leiden mutation is of factor: (Q856167)

A. V

B. VIII

C. I

D. X

Correct Answer: A. V

Explanation: The Leiden mutation is a genetic alteration in Factor V , a protein essential for blood clotting. It has the autosomal dominant type of inheritance. The mutation makes factor V resistant to inactivation by protein C, disrupting an antithrombotic pathway and increasing the risk of thrombosis. Factor VIII (Option B) plays a key role in the intrinsic pathway of coagulation, where it activates Factor X to Xa, which then helps in the conversion of prothrombin to thrombin, leading to the formation of a blood clot. It is not associated with the Leiden mutation. Factor I (Option C) , also known as fibrinogen, is the precursor to fibrin, which forms the structural framework of a blood clot. When bleeding occurs, fibrinogen is converted to fibrin by the enzyme thrombin during the final steps of the coagulation cascade. It is not associated with the Leiden mutation. Factor X (Option D) , also known as the Stuart-Prower factor, is a key enzyme in the blood clotting process. It is activated to Factor Xa and plays a crucial role in converting prothrombin to thrombin, ultimately leading to the formation of a blood clot. It is not associated with the Leiden mutation.

Robbins & Cotran Pathological Basis of Diseases, 10th Edition, Page 127.

↑ *Back to this question in Part A*

@Neet_pg_bot

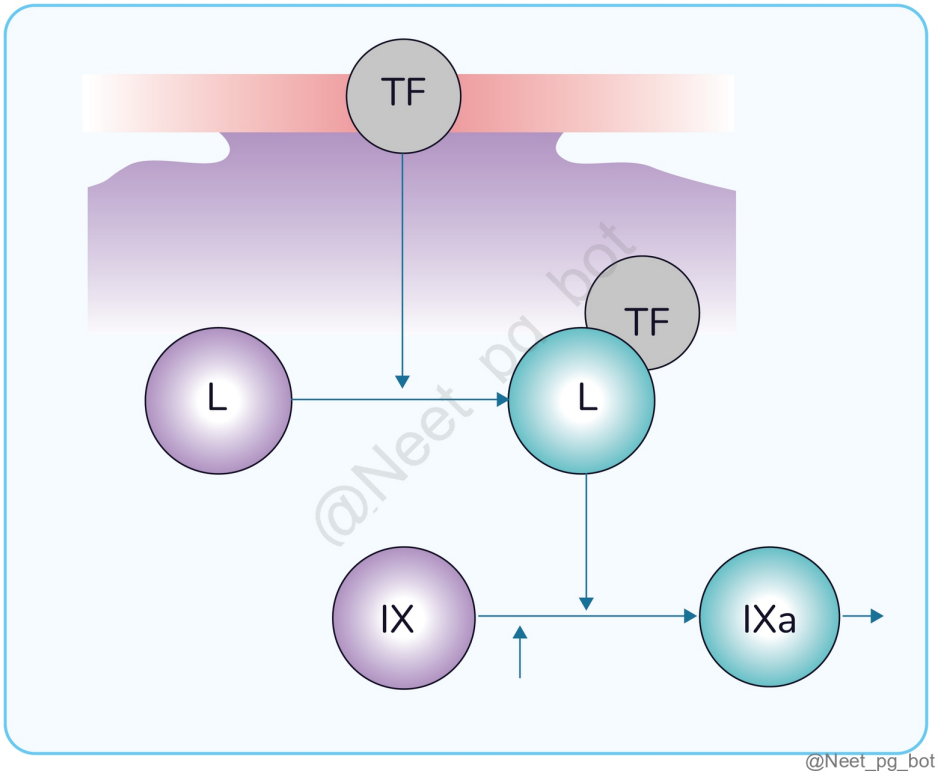
Q17: Below is an image of the coagulation cascade activation following closed endothelial injury. Identify the factor ‘L’, which combines with tissue factor to activate factor IX. (Q856684)

A. Factor XII

B. Factor VII

C. Factor VIII

D. vWF



Correct Answer: B. Factor VII

Explanation: Factor VII (Proconvertin) combines with tissue factor to activate factor IX in the Coagulation Cascade following closed endothelial injury. When tissue factor is exposed due to endothelial injury, it forms a complex with Factor VII. This complex activates Factor IX by cleaving it to Factor IXa, which then participates in the coagulation cascade. Factor XII (Hageman factor) (Option A) is involved in the initiation of the intrinsic pathway of the coagulation cascade. It is not directly responsible for activating factor IX in response to closed endothelial injury. Factor VIII (antihemophilic factor A) (Option C) plays a crucial role in the intrinsic pathway of the coagulation cascade. However, it is not involved in the direct activation of factor IX in response to closed endothelial injury. vWF (von Willebrand factor) (Option D) is a glycoprotein that plays a vital role in platelet adhesion and aggregation. It is not directly involved in activating factor IX in the coagulation cascade following closed endothelial injury.

@Neet_pg_bot

Q18: Stellate granuloma is found in: (Q857169)

A. Cat scratch disease

B. Leprosy

C. Coccidomycosis

D. Histoplasmosis

Correct Answer: A. Cat scratch disease

Explanation: Stellate granulomas are irregular star-shaped granulomas commonly found in Cat Scratch Disease (CSD) , caused by Bartonella henselae . Causative agent: Bartonella henselae (transmitted via cat scratches/bites). Histology: Stellate-shaped granulomas with central necrosis and neutrophilic infiltrate. Symptoms: Painful lymphadenopathy (axillary, cervical) with fever. Resolves spontaneously in immunocompetent individuals. Leprosy (Option B) granulomas contain foamy macrophages (Virchow cells) and Langhans giant cells, not stellate granulomas. Coccidiomycosis (Option C) forms caseating granulomas , not stellate granulomas. Histoplasmosis (Option D) forms well-defined granulomas with caseation commonly found in the lungs .

@Neet_pg_bot

Q19: Which of the following shows maximum amplitude on thromboelastography? (Q856011)

A. Platelets

B. Intrinsic

C. Extrinsic

D. von Willebrand Disease (vWD)

Correct Answer: A. Platelets

Explanation: Thromboelastography (TEG) measures the viscoelastic properties of blood as it clots. The maximum amplitude (MA) on TEG reflects the strength of the clot, which is primarily determined by the number and function of platelets and the fibrinogen concentration. The platelets contribute most significantly to the clot's strength and the MA value. Thromboelastography (TEG) is a diagnostic tool used to evaluate coagulation profiles and guide management with transfusions and hemostatic therapies. Studies show that TEG can reduce blood product usage by up to 40%, decrease postoperative length of stay, and lower the risk of reoperation. TEG measures the viscoelastic properties of blood as clotting occurs. The resulting data is plotted on a graph with time on the x-axis and amplitude (clot strength) on the y-axis. Key values include: Reaction time (R): The time it takes for the clot strength to reach an amplitude of 2 mm. Kinetics (K): The time from R to when the amplitude reaches 20 mm. α-angle: The angle formed by a line from R to the point where K intersects with the 20 mm amplitude mark. Maximum amplitude (MA): The highest amplitude reached. Lysis at 30 minutes (Ly30): The per cent decrease in amplitude 30 minutes after MA (or 60 minutes in some cases). Inference: A prolonged R time may indicate coagulation factor deficiency or anticoagulation. A decreased α-angle can result from hypofibrinogenemia Low MA can be due to thrombocytopenia or platelet dysfunction. Increased Ly30 indicates hyperfibrinolysis, often seen in severe trauma or with thrombolytic therapy. Based on the TEG findings, targeted blood products can be administered to normalize coagulation. For example: Fresh frozen plasma for prolonged R time Cryoprecipitate for decreased α-angle Platelets for decreased MA Tranexamic acid or aminocaproic acid for increased Ly30.

@Neet_pg_bot

Q20: A young patient presents with a large retroperitoneal hemorrhage and a history of intermittent knee swelling during strenuous exercise. There is no history of mucosal bleeding. Which of the following deficiencies is responsible for this condition ? (Q855429)

A. Factors VIII and IX

B. GP1b/IX

C. Von Willebrand factor

D. Lupus anticoagulant

Correct Answer: A. Factors VIII and IX

Explanation: The clinical picture suggests hemarthroses (knee swelling after exertion) and deep soft tissue bleeding (retroperitoneal hemorrhage), classic for hemophilia. Hemophilia A is due to factor VIII deficiency, and Hemophilia B is due to factor IX deficiency. These are X-linked recessive disorders, typically presenting in males, without mucosal bleeding. Unlike platelet disorders or von Willebrand disease, hemophilia mainly causes joint and muscle bleeding. Large retroperitoneal hemorrhage in a young male strongly points toward severe factor VIII or IX deficiency. Incorrect Options: Option B) GP1b/IX – Deficiency causes Bernard-Soulier syndrome, characterized by mucosal bleeding and thrombocytopenia, not deep muscle/joint bleeds. Option C) Von

Willebrand factor – Deficiency causes mucocutaneous bleeding (nosebleeds, menorrhagia), not typically hemarthroses. Option D) Lupus anticoagulant – Causes thrombosis, not bleeding.

@Neet_pg_bot

Q21: A 26-year-old female with a bleeding disorder following autosomal dominant inheritance. She gave the history of her father and sister having the same bleeding disorders. What is the most likely disorder? (Q854692)

A. Von Willebrand disease

B. Hemophilia A

C. Christmas disease

D. Factor X deficiency

Correct Answer: A. Von Willebrand disease

Explanation: Von Willebrand disease (VWD) is the most common inherited bleeding disorder caused by defective or deficient von Willebrand factor (vWF) . It follows an autosomal dominant inheritance pattern , affecting both males and females, with a 50% chance of passing the disorder to offspring. Von Willebrand disease is clinically and molecularly heterogeneous, with three identified types, each exhibiting a variety of phenotypes. vWD type 1 vWD Type 2 vWD Type 3 Autosomal dominant. The most common type. Mild to moderate vWF deficiency. Quantitative defect. Point substitutions prevent the vWF protein from maturing or cause it to leave the plasma quickly. Autosomal dominant. Qualitative defect. Types: 2A, 2B, 2M, 2N 2A (Most common) - Decrease in binding between vWF and Gp1b/9 Missense mutations cause faulty multimer formation → the most active forms of vWF, i.e. large- and intermediate-sized multimers are absent. 2B - Increase in binding between vWF and Gp1b/9 2M - VWF-dependent platelet adhesion is decreased. VWF binding to platelets is impaired. Type 2M VWD typically has mild to moderate mucocutaneous bleeding 2N - There is a marked decline in the binding affinity for factor VIII. The level of factor VIII is lower when compared to the VWF: Ag. This led to misdiagnosis as haemophilia A. Autosomal recessive . Quantitative defect. Produced by frameshift mutations or deletions affecting both alleles (autosomal recessive), which produce little or no vWF. Factor VIII levels are also lowered because vWF stabilizes factor VIII in the blood, and the resulting bleeding condition is severe. Hemophilia A (Option B) is an X-linked recessive disorder that mainly affects males, with females being carriers. This makes it an unlikely diagnosis for this patient, who has a family history involving females. Christmas disease (Option C) is an X-linked recessive disorder; hence, this condition is primarily seen in males, and it is less likely to be the cause of an autosomal dominant inheritance pattern. Factor X deficiency (Option D) is a rare bleeding disorder that can be inherited in autosomal recessive patterns, which causes the clotting process to take longer than normal.

@Neet_pg_bot

Q22: Which of the following statements about Von Willebrand's disease is incorrect? (Q843976)

A. Type 2 von Willebrand disease is associated with a moderate bleeding tendency.

B. Type 3 von Willebrand disease is associated with a complete absence of von Willebrand factor.

C. Type 1 von Willebrand disease presents with severe bleeding since childhood.

D. Type 2 von Willebrand disease includes subtypes with varying defects in the von Willebrand factor.

Correct Answer: C. Type 1 von Willebrand disease presents with severe bleeding since childhood.

Explanation: Type 1 vWD is the most common type and involves a partial quantitative deficiency of vWF. It typically produces mild to moderate bleeding symptoms. Patients often remain asymptomatic until later childhood or adulthood. Severe bleeding from early childhood is not characteristic of Type 1. Such severe presentations are more typical of Type 3 vWD. Incorrect Options: Option A) Type 2 vWD is associated with a moderate bleeding tendency: True. Type 2 involves qualitative defects that cause moderate bleeding. Option B) Type 3 vWD is associated with a complete absence of vWF: True. Type 3 is the most severe form with near-total absence of vWF. Option D) Type 2 vWD includes subtypes with varying vWF defects: True. Subtypes 2A, 2B, 2M, and 2N each show specific qualitative abnormalities.

@Neet_pg_bot

Q23: A patient underwent ileal resection and subsequently developed anemia along with peripheral neuropathy and features of SACD. Laboratory findings show hemoglobin (Hb) of 9 g/dL and mean corpuscular volume (MCV) of 110 fL. What is the most likely cause of his anemia? (Q866386)

A. Iron deficiency anemia

B. Vitamin B12 deficiency

C. Folic acid deficiency

D. Sideroblastic anemia

Correct Answer: B. Vitamin B12 deficiency

Explanation: Ileal resection can lead to vitamin B12 deficiency, as the terminal ileum is the primary site for absorption of the vitamin B12–intrinsic factor complex; this deficiency commonly results in macrocytic anemia, reflected by an elevated MCV of 110 fL. Terminal ileum : Site of vitamin B12 absorption (B12–intrinsic factor complex). Ileal resection → impaired B12 absorption → Vitamin B12 deficiency. Vitamin B12 deficiency : Causes macrocytic (megaloblastic) anemia → MCV > 100 fL. May present with neurological symptoms (e.g., paresthesia, ataxia). Lab findings : ↓ Hemoglobin ↑ MCV (e.g., 110 fL) ↑ LDH, ↑ indirect bilirubin, ↓ reticulocyte count Incorrect Options: Iron deficiency anemia (Option A) is unlikely because it typically causes microcytic anemia (low MCV), not macrocytic anemia. Folic acid deficiency (Option C) causes macrocytic anemia, but folate is absorbed in the jejunum, not the ileum, making it less likely after ileal resection. Sideroblastic anemia (Option D) usually presents with microcytic or dimorphic anemia, and it's not related to ileal absorption.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q24: Bernard-Soulier syndrome is caused by a defect in which of the following platelet glycoproteins? (Q866676)

A. GpIIb/IIIa

B. GpIb/IX complex

C. GpIa/IIa

D. GpIV

Correct Answer: B. GpIb/IX complex

Explanation: Bernard-Soulier syndrome is caused by a defect in the GpIb/IX complex on platelets. GpIb/IX complex is the receptor for von Willebrand factor (vWF) → mediates platelet adhesion to subendothelial collagen after vascular injury. In Bernard–Soulier syndrome, this adhesion step is impaired → defective platelet plug formation. Labs/Findings: Normal or low platelet count Prolonged bleeding time Giant platelets on peripheral smear Normal platelet aggregation with ADP, collagen, epinephrine, but absent aggregation with ristocetin (not corrected by adding normal plasma, unlike vWD). Incorrect Options: GpIIb/IIIa (Option A) : Function: Binds fibrinogen → platelet aggregation . Defect causes Glanzmann thrombasthenia , not BSS. Lab: Normal platelet count, defective aggregation with all agonists except ristocetin. GpIa/IIa (Option C): Function: Binds collagen

(supports platelet adhesion). Defects are rare and cause mild bleeding disorders, not the classic BSS picture. GpIV (Option D): Also called CD36; role in platelet adhesion and scavenger receptor function.

Q1: A pathologist is reviewing the chromosomal locations of blood group antigens. When considering the Rh blood group system, including the Rh antigen, which of the following chromosomes is involved? (Q845924)

A. Chr. 1

B. Chr. 9

C. Chr. 19

D. Chr. 13

Correct Answer: A. Chr. 1

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The Rh antigen is denoted by the C, D, and E antigens , and these are located on chromosome 1 (Option A) . The ABO antigens are present on chromosome 9 . (Option B) All antigens and all blood groups are derived from a common precursor - H antigen or H substance , which is present on chromosome 19. (Option C)

@Neet_pg_bot

Q2: A 32-year-old male requires a blood transfusion after a severe bike accident. He is known to have the Bombay phenotype. Before the transfusion, his blood sample is sent to the laboratory for compatibility testing. Based on his blood group, which of the

following statements is incorrect? (Q845926)

A. Lack of H, A and B antigens on RBCs

B. Lack of H, A and B substances in saliva

C. Lack of antigens of several blood group systems

D. H, A and B antibodies will always be present in the serum

Correct Answer: C. Lack of antigens of several blood group systems

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: People with the Bombay phenotype lack H, A, and B antigens on the red blood cells. (Option A ruled out) "Oh" phenotype denotes Bombay blood group. The antigens are absent in all body secretions including saliva. (Option B ruled out) As the antigens are not expressed, the serum will always present the H, A, and B antibodies. (Option D ruled out) Antigens from blood group systems other than ABO system (e.g., Rh, MNS, etc.) are still present on the RBC (Option C) This person can receive blood only from another Bombay blood group donor.

Wintrobe’s Clinical Hematology, 12th Edition, Pages 635, 636

↑ *Back to this question in Part A*

@Neet_pg_bot

Q3: A 23-year-old individual is scheduled to donate blood for a local blood drive. To ensure the safety of the blood supply, the donor's blood will be screened for various infectious diseases. Among the following options, which one is typically not included in the routine screening for donated blood? (Q845928)

A. Malaria

B. Hepatitis B

C. HIV

D. Dengue fever

Correct Answer: D. Dengue fever

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Dengue is a viral illness spread by Aedes mosquitoes, and routine blood donor screening isn't done since it's mainly mosquito-borne, not transfusi In India, the following five diseases are screened before blood transfusion: HIV-1 & 2 (Option C) . HBV (Option B) . HCV. Malaria (Option A) . Syphilis. The following infections can be transmitted by blood transfusion. Viral Bacterial Parasites Others Hepatitis (A, B, C, G). HIV (I & II). HTLV (I & II). CMV. EBV. Parvovirus B19. Syphilis Malaria Babesiosis Trypanosoma cruzi Creutzfeldt-Jakob disease

@Neet_pg_bot

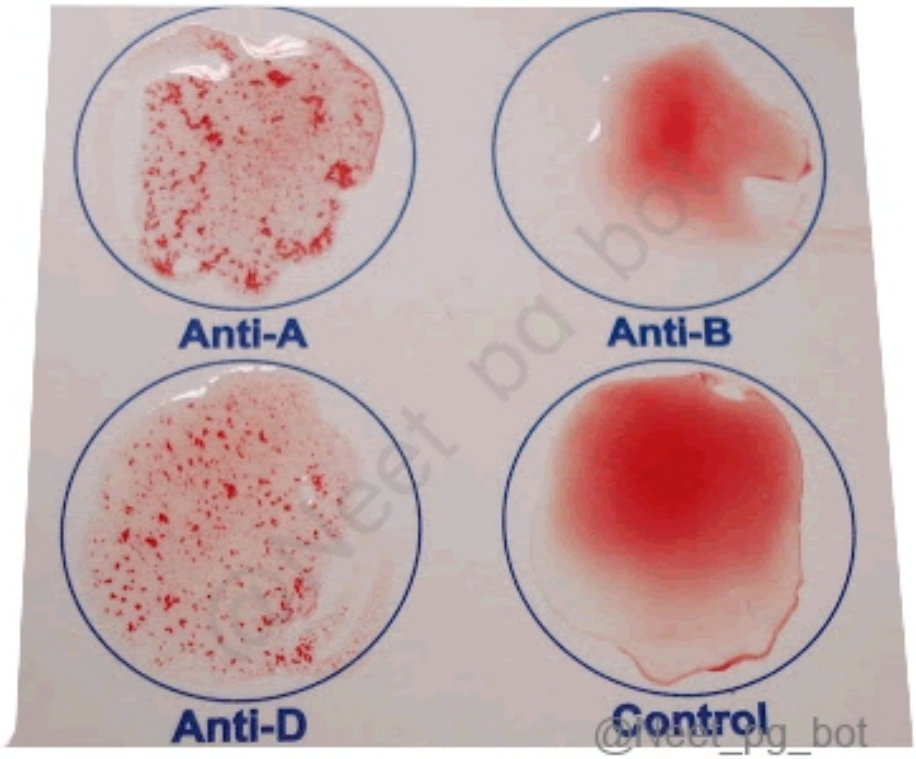
Q5: Based on the agglutination test shown below, what is the blood group? (Q845931)

A. B Positive

B. B negative

C. A positive

D. AB positive



Correct Answer: C. A positive

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The image shows a slide agglutination test to determine a person's blood group. It shows clotting with anti-A and anti-D , indicating the person has an A (+ve) blood group. During agglutination test for blood group determination, a control (only blood) is always added first to confirm proper sampling and ensure the blood hasn’t clotted. A drop of antibody is then added to the blood sample, and if antigen–antibody reaction causes agglutination (clumping), the site of agglutination indicates the blood group. Interpretation of results:

@Neet_pg_bot

Q6: Match the following: Blood Products Shelf Life A Packed Red Blood Cells (PRBCs) in CPD-A i 1 year B Fresh Frozen Plasma (FFP) ii 35 days C Platelets iii 42 days D PRBC in SAGM iv 5 days (Q845935)

A. A-iii, B-i, C-iv, D-ii

B. A-i, B-iii, C-iv, D-ii

C. A-ii, B-i, C-iv, D-iii

D. A-ii, B-iii, C-i, D-iv

Correct Answer: C. A-ii, B-i, C-iv, D-iii

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The blood products and their corresponding shelf life are: Blood Products Shelf Life Storage temperature Packed Red Blood Cells (PRBCs) in CPD-A 35 days / 5 weeks 1-6 °C Fresh Frozen Plasma (FFP) 1 year -30°C or colder Platelets 5 days 20–24°C (with continuous agitation) PRBC in SAGM 42 days / 6 weeks 1–6°C Cryoprecipitate 2 years –30°C

Harmening, D. M. (2012). Modern Blood Banking & Transfusion Practices (6th ed.).

http://nbtc.naco.gov.in/assets/resources/training/8.pdf

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A unit of packed red blood cells is issued from the blood bank for transfusion to a patient in the emergency department. Due to delays in setting up the IV line, the staff asks how long the unit can safely remain out of refrigeration before the transfusion must be completed.What is the maximum allowable time for transfusing this RBC unit after removal from cold storage? (Q845936)

A. 1 hour

B. 4 hour

C. 8 hour

D. 24 hour

Correct Answer: B. 4 hour

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The recommended time frame for administering a unit of red blood cells (RBCs) once it has been removed from cold storage is within 4 hours. The unit must be removed from the refrigeration and the temperature must be brought up to the room temperature before transfusion Once a unit of RBCs is removed from the refrigerator, it should be transfused as soon as possible, ideally starting within 30 minutes. The entire unit should be infused within 4 hours as hemolysis occurs after 4 hours which can lead to metabolic abnormalities like hyperkalemia. Duration times for transfusion of blood and blood products: Blood product Start time End time Whole blood/PRBC Within 30 minutes of removing it from the refrigerator ≤ 4 hours Discard if this period is exceeded Platelets Immediately Within 30 minutes FFP Immediately Within 30 minutes Cryoprecipitate Immediately Within 30 minutes

References:

Harmening, D. M. (2012). Modern Blood Banking & Transfusion Practices (6th ed.)

↑ *Back to this question in Part A*

@Neet_pg_bot

Q8: Which of the following is the most common complication of blood transfusion? (Q845938)

A. TRALI

B. TACO

C. Delayed Hemolytic Reaction

D. Febrile Non-hemolytic reaction

Correct Answer: D. Febrile Non-hemolytic reaction

Explanation: Febrile non-hemolytic transfusion reactions (FNHTRs) are the most common complication of blood transfusions. These reactions typically occur when the recipient's immune system responds to the transfused blood product's white blood cells or cytokines. FNHTRs are characterised by fever and chills during or shortly after a transfusion. TRALI (Transfusion-related acute lung injury) (Option A) is a severe transfusion reaction causing acute non-cardiogenic pulmonary edema within 6 hours due to donor antibodies or bioactive substances. TACO (Transfusion-associated circulatory overload) (Option B) results from rapid or excessive transfusion, causing circulatory overload and pulmonary edema from raised pulmonary pressure. Delayed hemolytic reactions (Option C) arise days to weeks post-transfusion, causing mild fever, jaundice, and gradual hemoglobin drop.

References:

Harmening, D. M. (2012). Modern Blood Banking & Transfusion Practices (6th ed.).

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following is defined as a massive blood transfusion? (Q845939)

A. Replacement of whole blood volume within 12 hours

B. Replacement of whole blood volume within 48 hours

C. Replacement of whole blood volume within 24 hours

D. Replacement of whole blood volume within 4 hours

Correct Answer: C. Replacement of whole blood volume within 24 hours

Explanation: Massive blood transfusion replaces a patient's total blood volume within 24 hours. This is usually around 10 units of red blood cells (RBCs) in adults. Massive transfusion is defined as: Transfusion of ≥1 blood volume (~10 units PRBC) in 24 hours ≥4 units PRBC in 1 hour with ongoing need >50% blood volume replaced within 3 hours Indications of Massive Transfusion: Trauma - Polytrauma, road traffic accidents Obstetric hemorrhage - PPH, placenta previa, abruption Surgical bleeding GI bleeding - Variceal bleed, peptic ulcer Coagulopathy - DIC, liver failure Balanced transfusion approach (Damage control resuscitation): PRBC, Fresh frozen plasma and Platelets in typical ratio of 1 : 1 : 1. Complications of Massive Blood Transfusion: Hematological Complications: Dilutional thrombocytopenia Dilutional coagulopathy Disseminated intravascular coagulation Metabolic Complications: Hypocalcemia - Citrate in blood binds Ca^{2}■ Hyperkalemia - Potassium leaks from stored RBCs Metabolic alkalosis - Citrate is converted into bicarbonate Metabolic acidosis - Poor perfusion, shock Temperature-related: Hypothermia - Cold stored blood (2–6°C) Respiratory Complications: Transfusion-related acute lung injury Transfusion-associated circulatory overload Immunological Complications: Acute hemolytic transfusion reaction - ABO incompatibility Febrile non-hemolytic reaction - Cytokine-mediated Allergic reactions - Urticaria, anaphylaxis

References:

Harmening, D. M. (2012). Modern Blood Banking & Transfusion Practices (6th ed.).

↑ *Back to this question in Part A*

@Neet_pg_bot

Q10: All of the following are complications of massive blood transfusion except? (Q845941)

A. Metabolic Alkalosis

B. Metabolic Acidosis

C. Hyperkalemia

D. Hypocalcemia

Correct Answer: B. Metabolic Acidosis

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Metabolic acidosis can occur in the setting of shock and hypoperfusion rather than directly from the transfusion itself, so it is not likely seen in massive blood transfusion. In massive blood transfusion, the anticoagulant citrate is transfused along with blood. Citrate stimulates bicarbonate production, leading to metabolic alkalosis (Option A) . It also chelates calcium, causing hypocalcemia (Option D) . In stored blood, red

cell breakdown releases potassium, resulting in hyperkalemia (Option C) .

References:

Harmening, D. M. (2012). Modern Blood Banking & Transfusion Practices (6th ed.).

↑ *Back to this question in Part A*

@Neet_pg_bot

Q11: Which of the following is a characteristic feature of Transfusion-Related Acute Lung Injury (TRALI)? (Q845942)

A. Non-cardiogenic pulmonary edema within 6 hours of transfusion

B. Cardiogenic pulmonary edema within 24 hours of transfusion

C. Acute onset of fever and chills without respiratory symptoms

D. Gradual onset of jaundice and anemia several days after transfusion

Correct Answer: A. Non-cardiogenic pulmonary edema within 6 hours of transfusion

Explanation: TRALI is characterised by acute onset of respiratory distress and non-cardiogenic pulmonary edema occurring within 6 hours of a blood transfusion. It is caused by an immune reaction to donor antibodies or bioactive substances in the transfused blood. Characteristics: Onset: TRALI typically occurs within 6 hours of transfusion. Symptoms: Sudden onset of dyspnea (shortness of breath). Hypoxemia (low blood oxygen levels) Fever. Hypotension. Bilateral pulmonary infiltrates on a chest X-ray, indicating fluid accumulation in the lungs without cardiac cause. TACO is a transfusion reaction with respiratory distress and cardiogenic pulmonary edema within 24 hours due to circulatory fluid overload. (Option B) . Febrile non-hemolytic transfusion reactions present with acute fever and chills without respiratory distress. (Option C) Delayed hemolytic transfusion reactions present days to weeks later with gradual jaundice and anemia. (Option D) Note: Multigravida women develop anti-HLA antibodies during pregnancy due to exposure to fetal antigens. If such plasma is transfused, the antibodies react with recipient leukocytes and will lead to TRALI. Hence blood banks prefer male plasma donors and screen female donors for HLA antibodies. Thalassemia patients are at increased risk of immune-mediated reactions including TRALI, since they receive repeated transfusions and hence an increased exposure to donor antibodies

« Back to Folder Directory

[20_Blood Banking and Transfusion Medicine] 081 Previous Year Questions — Quick Jump

Q1 (p. 3136) *Q2 (p. 3137)* *Q3 (p. 3138)* *Q4 (p. 3139)* *Q5 (p. 3139)* *Q6 (p. 3140)*

Q1: A 28-year-old woman with a known history of beta-thalassemia undergoes a blood transfusion. During the transfusion, she develops symptoms of anxiety, hypotension, and fever. What is the next appropriate step in the management of this patient? (Q860282)

A. Stop the blood transfusion and restart after stabilization

B. Continue the blood transfusion and perform an ECG

C. Investigate for clerical errors in the blood transfusion process

D. Administer corticosteroids and monitor vital signs

Correct Answer: A. Stop the blood transfusion and restart after stabilization

Explanation: In a woman with beta-thalassemia experiencing anxiety, hypotension, and fever during transfusion, the immediate step is to stop the transfusion and ensure stabilization. Transfusion Reactions: It refers to an adverse response to blood components, which can be Immunologically mediated (via WBC) Related to infections. It can either be immediate or delayed. Aspect Immediate Transfusion Reactions Delayed Transfusion Reactions Onset Time Within hours of transfusion Days to weeks after transfusion Cause Immunologic reactions, hemolytic or non-hemolytic Immune-mediated, often involving minor antigen sensitization Presentation Fever, chills, Dyspnea (TRALI, TACO), Acute respiratory distress (TRALI), Pulmonary oedema (TACO), hypothermia, electrolyte abnormalities, coagulopathy, acid-base disorders and hyperkalemia Fever, jaundice, Gradual decline in haemoglobin levels (hemolysis) Severity Can range from mild to life-threatening Generally less severe than immediate reactions Examples Febrile non-hemolytic reaction (FNHTR) Transfusion-related acute lung injury (TRALI) Transfusion-associated circulatory overload (TACO) Delayed hemolytic reaction Management Stop the blood transfusion. Supportive care. Three samples are to be collected Blood 1st sample: For BG/CM (blood grouping - cross matching) (EDTA vial) 2nd sample: Biochemical test for hemolysis (plain red vial) Urine Test for hemoglobinuria (hemolysis). Continue the blood transfusion and perform an ECG (Option B) : Continuing the transfusion could worsen the reaction. The first step in managing a suspected transfusion reaction is stopping the transfusion. Investigate for clerical errors in the blood transfusion process (Option C) : While clerical errors (e.g., blood type mismatch) are important to rule out, the immediate priority is to stop the transfusion and stabilize the patient before investigating further. Administer corticosteroids and monitor vital signs (Option D) : Corticosteroids may be used in certain reactions (such as allergic reactions), but the first step should be stopping the transfusion

and addressing any immediate complications (e.g., hypotension, fever). Corticosteroids are not the first-line treatment for most transfusion reactions.

@Neet_pg_bot

Q2: Blood transfusion requires screening of donor blood for all of the following infections except: (Q855917)

A. Hepatitis C virus

B. Dengue virus

C. HIV virus

D. Hepatitis B virus

Correct Answer: B. Dengue virus

Explanation: Dengue fever is a viral illness transmitted by Aedes mosquitoes . Unlike some other diseases listed, routine screening for dengue in donated blood is not typically performed. This is because mosquitoes primarily transmit dengue rather than through blood transfusions. Screening for transfusion-transmitted infections: The following infections can be transmitted by blood transfusion. Viral Bacterial Parasites Others Hepatitis (A, B, C, G) HIV (I & II) HTLV (I & II) CMV EBV Parvovirus B19 Syphilis Malaria Babesiosis Trypanosoma cruzi Creutzfeldt- Jakob disease Plasma processing methods have been shown to inactivate most recognized infectious organisms, except for non-lipid-enveloped viruses and prions. All clinically relevant blood components transmit prion disease following a single blood transfusion. Malaria can also be transmitted by most blood components (red cells, platelets, white-cell concentrates, cryoprecipitates, and frozen red cells after thawing and washing). Transmission from single-donor FFP has not been reported. In India, the following five diseases are screened: HBV (Option D) HCV (Option A) HIV (Option C) Malaria Syphilis Screening for the diseases mentioned above is mandatory , and transfusing unscreened blood is a medical offence.

@Neet_pg_bot

Q3: A patient has been brought with severe bleeding to your ER. His blood group is unknown. Fresh frozen plasma from which of the following blood groups can be given? (Q855120)

A. O

B. AB

C. B

D. A

Correct Answer: B. AB

Explanation: In the given scenario where the blood group is unknown, fresh frozen plasma from blood group AB can be safely administered to the patient. Blood group AB individuals are considered universal plasma donors because their plasma lacks both A and B antibodies, making it compatible with recipients of any ABO blood type without causing an ABO incompatibility reaction. The differences between Rh Blood Group and ABO Blood Group: Properties ABO system Rh system Blood groups A, B, AB, and O Rh-positive & negative Genetic loci On chromosome 9 On chromosome 1 Ag and Ab Group Antigen Antibody C, c, D, E, & e antigens. ‘d’ indicates the absence of D. Most important: Anti-D antibody. O H Anti-A & anti-B A A Anti-B B B Anti-A AB A & B None Antigens also seen on/in Endothelial & epithelial cells, plasma, saliva, and semen (not seen in CSF) No other cells Type of Ab IgM (naturally occurring). IgG (does not occur naturally). Clinical significance Anti-A & anti-B can cause severe intravascular haemolysis after incompatible transfusion. ABO-matching is required before the transplantation of solid organs. Rh -ve individuals make anti-D Ab if: Transfused with Rh +ve blood. Rh -ve pregnant women are exposed to Rh +ve fetal RBCs that have crossed the placenta.

Q4: Which of the following can be prevented by transfusing irradiated RBCs? (Q856715)

A. Graft versus host disease

B. HLA alloimmunization

C. Immunomodulation

D. Nonhemolytic Febrile Transfusion Reactions

Correct Answer: A. Graft versus host disease

Explanation: Transfusion of irradiated red blood cells (RBCs) can prevent graft versus host disease (GVHD). Steps for Production of Red Blood Cell Concentrates (RBCC) from Whole Blood 1 Whole Blood Collection Blood is drawn into sterile bags with anticoagulants to prevent clotting. Each unit contains 450-500 mL. (First 20-30 ml is discarded due to skin flora contamination) 2 Slow Speed Centrifugation (Soft Spin) Separates Red Blood Cell Concentrate (RBCC) at the bottom and Platelet-Rich Plasma (PRP) at the top, with the buffy coat (white blood cells) in between. 3 RBCC Processing and Additive Solutions After removing plasma and buffy coat, additive solutions like SAGM (Saline, Adenine, Glucose, Mannitol) or CPD are added to preserve cell viability and extend shelf life. 4 Leukoreduction/ Deleucocytation Achieved by filtering RBCC to remove >99.9% of white blood cells. Purpose: Nonhemolytic Febrile Transfusion Reactions (NHFTRs) . (Option D ruled out) Alloimmunization and platelet transfusion refractoriness. (Option B ruled out) Transfusion-transmitted infections, such as cytomegalovirus (CMV). Immunomodulation risks from transfusions (Option C ruled out) Post-reduction leukocyte content: <1–5 x 10■ leukocytes/unit. 5 Irradiation (Optional) RBCC is irradiated with X-rays or gamma rays (25–35 Gy). Purpose: Prevents graft-versus-host disease (GVHD) by inactivating donor lymphocytes. (Option A) Use: RBCC must be transfused within 24 hours post-irradiation. 6 Plasma Reduction (Optional) Plasma proteins are removed to prevent allergic or anaphylactic reactions. Purpose: Useful for patients with a history of allergic transfusion reactions, reducing post-transfusion anaphylaxis risk. 7 Cryopreservation (Optional) RBCC is cryopreserved at -80°C, mainly for rare blood types. Purpose: Extends shelf life up to 30 years, increasing availability of rare blood groups.

@Neet_pg_bot

Q5: A 24-year-old man, after being involved in a road traffic accident (RTA), was brought to the casualty 6 hours later. His B.P. was 90/60 mm Hg, heart rate was

110/min, and SpO2 was 92%. A blood transfusion was administered. A few hours later, the patient becomes febrile and tachypneic and starts bleeding from the IV and NG tube sites. His SpO2 levels begin to drop. What is the likely cause? (Q856483)

A. Transfusion reaction

B. Acute adrenal crisis

C. Fat embolism

D. Hemorrhagic shock

Correct Answer: A. Transfusion reaction

Explanation: The patient's fever, tachypnea, bleeding from IV and NG tube sites, and declining SpO2 after transfusion suggest an acute transfusion reaction, likely due to an immune response causing hemolysis, shock, and DIC. Types of Transfusion reactions Aspect Immediate Transfusion Reactions Delayed Transfusion Reactions Onset Within hours of transfusion Days to weeks after transfusion Cause Immunologic reactions, hemolytic or non-hemolytic Immune-mediated, often involving minor antigen sensitization Presentation Fever, chills, dyspnea (TRALI, TACO), Acute respiratory distress (TRALI), Pulmonary oedema (TACO), hypothermia, electrolyte abnormalities, coagulopathy , acid-base disorders and hyperkalemia. Fever, jaundice, gradual decline in haemoglobin levels (hemolysis). Severity Can range from mild to life-threatening. Generally less severe than immediate reactions. Examples Febrile non-hemolytic reaction (FNHTR) Transfusion-related acute lung injury (TRALI) Transfusion-associated circulatory overload (TACO) Delayed hemolytic reaction Management Stop transfusion and manage symptoms. Supportive care (e.g., antipyretics, oxygen). Monitor for worsening anaemia and hemolysis. Consider further transfusion support if indicated.

Q19 (p. 3176)	*Q20 (p. 3177)*				

Q1: A patient who presents with a painful, progressively enlarging growth from her left upper tibia is suspected to have chondrosarcoma and subjected to a biopsy and examination. The report states, “presence of osteoclast-type giant cells with intralesional bone formation”. Which of the following types of chondrosarcoma does this patient have? (Q845700)

A. Conventional

B. Mesenchymal

C. Clear cell

D. Dedifferentiated

Correct Answer: C. Clear cell

Explanation: The presence of osteoclast-type giant cells with intralesional bone formation is seen in clear-cell chondrosarcoma. Chondrosarcoma: Chondrosarcomas are malignant cartilage tumors, often with IDH1/IDH2 mutations, mainly affecting males over 40 usually arising in the axial skeleton (pelvis, shoulder, ribs) Clear cell and mesenchymal types occur in younger patients. Characteristic popcorn-like calcifications appear in the cartilage matrix, and histologically they are classified into 4 types: Conventional (Option A): Neoplastic cartilage invades marrow and surrounds bony trabeculae. Dedifferentiated (Option D): Low-grade chondrosarcoma can have a high-grade, non-cartilage-producing component. Clear-cell (Option C): Contains large malignant chondrocytes with clear cytoplasm, many osteoclast-like giant cells, and intralesional bone formation. Mesenchymal (Option B): Composed of islands of hyaline cartilage amid primitive small round cells.

@Neet_pg_bot

Q3: A 55-year-old male, presents with a sudden onset of severe pain, redness, and swelling in his right big toe. The right big toe is red, swollen, and extremely tender to touch. There is no fever or other systemic symptoms. He enjoys red meat and seafood, and he drinks alcholol regularly. All of the following are true about his diagnosis except? (Q845728)

A. Deposition of monosodium urate crystals in joints.

B. Thiazide diuretics can precipitate attacks.

C. Rhomboid-shaped, weakly positively birefringent under polarised light confirms the diagnosis.

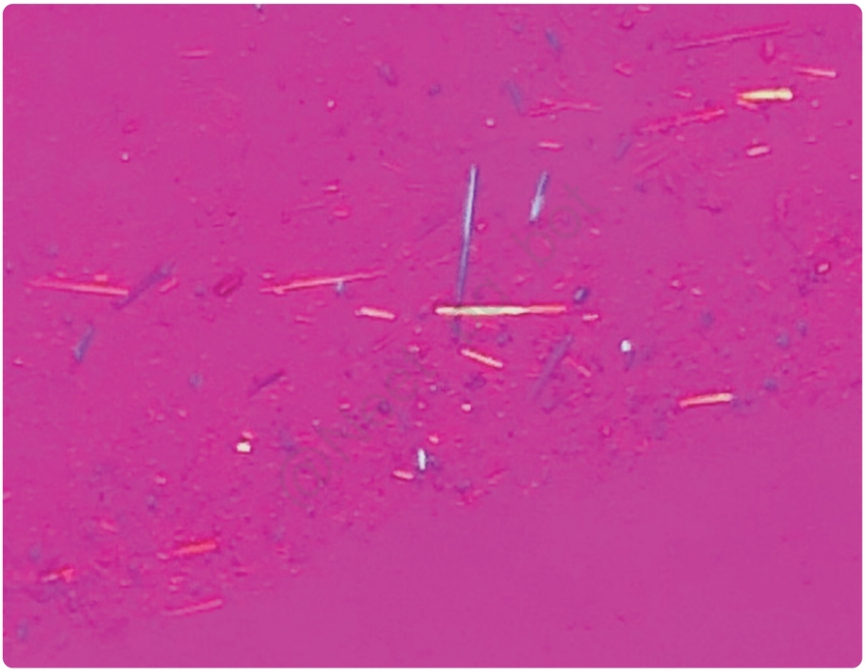
D. Elevated uric acid levels.

Correct Answer: C. Rhomboid-shaped, weakly positively birefringent under polarised light confirms the diagnosis.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Correct Option: C) Rhomboid-shaped, weakly positively birefringent under polarised light confirms the diagnosis. Explanaiton: The patient's presentation is suggestive of acute gout. Feature Gout Pseudogout Aetiology Deposition of monosodium urate (MSU) crystals in the joint. (Option A) Deposition of calcium pyrophosphate dihydrate (CPPD) crystals Commonly Affected Joints First metatarsophalangeal joint (big toe), ankles, knees Knees, wrists, hips, shoulders, elbows Crystal Characteristics Needle-shaped, negatively birefringent under polarised light Rhomboid-shaped, weakly positively birefringent under polarised light (Option 3) Serum Findings Elevated uric acid levels (Option D) Often, normal calcium and phosphorus levels Risk Factors High purine diet, alcohol consumption, obesity, diuretics (thiazides & loop diuretics) (Option B) , genetic predisposition Age, joint trauma, familial predisposition, metabolic disorders (e.g., hyperparathyroidism, hemochromatosis) Acute Attack Presentation Sudden, severe pain, redness, swelling, and warmth in the affected joint Sudden, severe pain, redness, swelling, and warmth in the affected joint



@Neet_pg_bot

Q4: All of the following are true about rhabdomyosarcoma except? (Q845726)

A. It is the most common soft tissue sarcoma in children.

B. Positive IHC staining for desmin and myogenin.

C. It commonly presents in the extremities of children and adolescents.

D. It has a benign clinical course and rarely metastasizes.

Correct Answer: D. It has a benign clinical course and rarely metastasizes.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Rhabdomyosarcoma is also known as Sarcoma botryoids (Bunch of grapes)/Embryonal RMS It is a malignant tumour arising from skeletal muscle progenitors. It is the most common soft tissue sarcoma in children and adolescents (Option 1). It commonly presents in the extremities (Option 3). The tumours are often large, soft, and infiltrative, with areas of necrosis and haemorrhage. Microscopy: Small, round to spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm , sometimes with a myxoid stroma are also seen. IHC Positive Markers: Desmin , myogenin , MyoD1 , and muscle-specific actin (Option 2). Rhabdomyosarcoma has an aggressive clinical course and can metastasise, particularly to the lungs, bone marrow, and lymph nodes. Common locations and symptoms: Head and Neck: Often presents as a painless lump, but can cause nasal congestion, ear discharge, or headaches. Orbit (Eye): Causes rapid bulging of the eye (proptosis), swelling, or double vision. Genitourinary: May cause hematuria, difficulty urinating, or a vaginal/scrotal mass. Extremities: Typically appears as a rapidly enlarging, firm, and sometimes painful mass on the arms or legs. Main subtypes: ■■■■■■■ Embryonal (ERMS): The most common type, usually affecting children under age 5. It often occurs in the head, neck, or pelvic organs Generally has a favorable prognosis . Alveolar (ARMS): More aggressive and common in teens/young adults. It often affects the trunk or limbs Frequently linked to specific gene fusions (PAX/FOXO1). Spindle Cell/Sclerosing: A rarer variant that can occur in both children (often paratesticular) and adults. Pleomorphic: Primarily affects adults over age 50 and is highly aggressive. Microscopic examination: Cambium layer (dense cellular layer) Strap cells (RMS)/Tennis racket appearance Tennis Racket: The image below shows alveolar rhabdomyosarcoma.

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Page1212

↑ *Back to this question in Part A*

@Neet_pg_bot

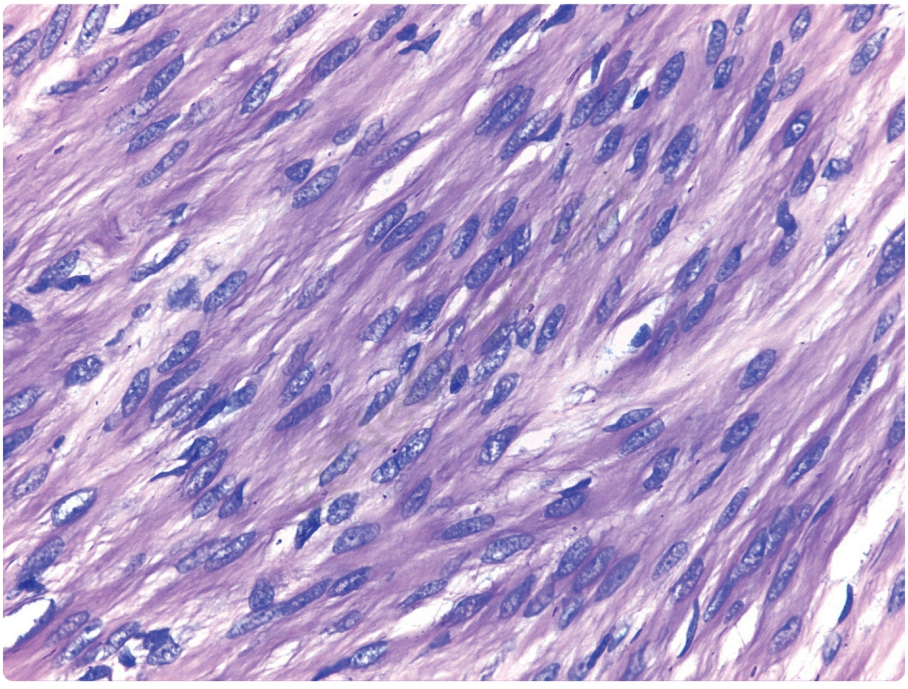
Q5: A 38-year-old female presents with a 6-month history of heavy menstrual bleeding and a sensation of pelvic pressure. She reports that her periods have become increasingly heavy. There is no significant past medical history, and she is not currently on any medication.Ultrasound reveals a heterogeneous, hypoechoic mass within the uterus. A histology image is given below. What is the most likely diagnosis? (Q845719)

A. Adenomyosis

B. Leiomyosarcoma

C. Endometrial carcinoma

D. Leiomyoma



@Neet_pg_bot

Correct Answer: D. Leiomyoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Leiomyoma, also known as a uterine fibroid , is a benign smooth muscle tumour that commonly occurs in the uterus. These tumors are composed of well-differentiated smooth muscle cells and are the most common benign tumours in women of reproductive age. Symptoms: Menorrhagia, pelvic pressure, and potential reproductive issues like infertility or miscarriage. Genetic Factors: Mutations in MED12 gene. Physical Exam: Presents as a firm, enlarged, irregularly shaped, non-tender uterus . Hormonal Influence: Their growth is highly influenced by estrogen and progesterone ; they typically regress after menopause. Leiomyomas have low mitotic activity. Degeneration: In pregnancy, fibroids may undergo Red (Carneous) Degeneration due to rapid growth outstripping blood supply, leading to acute pain. On biopsy: Spindle-shaped cells with blunt-ended nuclei (classical cigar-shaped nuclear appearance) are seen Cigar-shaped nuclei confirms a smooth muscle origin and can be seen in: Normal smooth muscle Benign smooth muscle tumors (leiomyoma) Malignant smooth muscle tumors (leiomyosarcoma) Distinction from Leiomyosarcoma: Unlike many other cancers, leiomyosarcomas typically arise de novo and not from a pre-existing benign fibroid. Malignancy is suspected if there is rapid post-menopausal growth or high mitotic figures on histology. Types of fibroids: Type Location High-Yield Clinical Points Submucosal Beneath the endometrium (protrudes into the uterine cavity). Most symptomatic: Associated with heavy/prolonged menstrual bleeding (menorrhagia) and infertility. Intramural Within the muscular wall (myometrium) of the uterus. Most common: Causes uterine enlargement and can lead to heavy bleeding or pelvic pressure. Subserosal Beneath the serosa (outer surface of the uterus). Pressure symptoms: Often asymptomatic regarding bleeding, but can cause frequent urination (bladder pressure) or constipation (rectal pressure). {{caption_text}} Adenomyosis (Option A): Typically presents with a uniformly enlarged, boggy uterus. Histologically shows endometrial glands and stroma within the myometrium, not just smooth muscle cells. Leiomyosarcoma (Option B): Histologically shows significant atypia, high mitotic rate, and areas of necrosis. Most important diagnostic criterion for leiomyosarcoma is the mitotic count and for diagnosis, we must see more than 10 mitoses per 10 high-power fields . Endometrial carcinoma (Option C): Typically presents with abnormal uterine bleeding, especially postmenopausal bleeding. Histology shows malignant endometrial glandular cells, not smooth muscle cells.

↑ *Back to this question in Part A*

@Neet_pg_bot

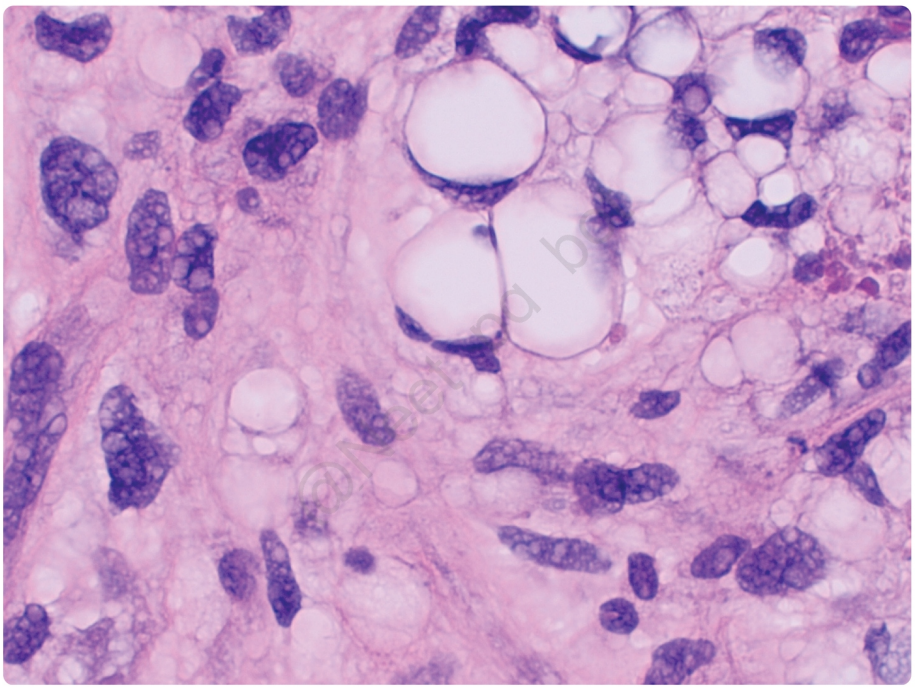
Q6: A 65-year-old male presented with an enlarging mass in his left thigh for the last three months. Physical examination revealed a non-tender, palpable mass with indistinct borders. He has a prior history of mass excision in the same location. A biopsy of the lesion is obtained. Based on the presentation, which of the following is the most likely diagnosis? (Q845711)

A. Lipoma

B. Liposarcoma

C. Leiomyosarcoma

D. Rhabdomyosarcoma

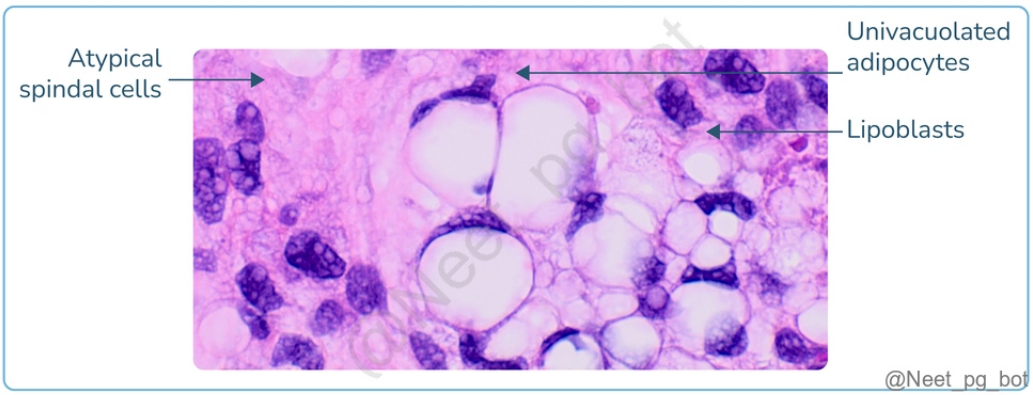


@Neet_pg_bot

Correct Answer: B. Liposarcoma

- *Listen (English)*
- *Listen (Hindi)*

Explanation: Liposarcoma: Malignant adipose tissue tumour. Most common adult sarcoma. Typically occur in the sixth and seventh decades. Develop in proximal extremities and retroperitoneum. Biopsy: The nucleus is very prominent and is indented to the corner by fatty vacuoles (lipoblasts). Subtype Genetic Feature Histological Hallmark Well-Differentiated MDM2 amplification (12q15) Looks like fat but has atypical stromal cells with enlarged nuclei. Myxoid t(12;16) (FUS-DDIT3) "Chicken-wire" capillary pattern and a myxoid (mucoid) matrix. Pleomorphic Complex karyotype High-grade, bizarre multinucleated giant cells; very aggressive. Lipoma (Option A): Lipoma is the benign soft tissue tumor of fat in adults and, upon biopsy, reveals clear cells (mature fat cells) with peripheral nuclei. Typically presents as a soft, mobile, painless mass in the subcutaneous tissue (back, neck, or proximal extremities). Gross Appearance: Well-circumscribed, encapsulated, bright yellow "greasy" mass. Histology: Consists of clusters of mature adipocytes that are indistinguishable from normal fat. They lack cellular atypia or increased mitotic activity. Genetics: Most common chromosomal abnormality involves 12q13-15 rearrangements. Leiomyosarcoma (Option C): Leiomyosarcomas are malignant, painless, firm masses arising from smooth muscle. These tumours are composed of eosinophilic spindle cells with blunt-ended, cigar shaped nuclei. Rhabdomyosarcoma (Option D): Fibrosarcoma is a malignant tumour of fibroblasts with a "herringbone" architecture.



Atypical spindal cells
Univacuolated adipocytes
Lipoblasts

↑ *Back to this question in Part A*

@Neet_pg_bot

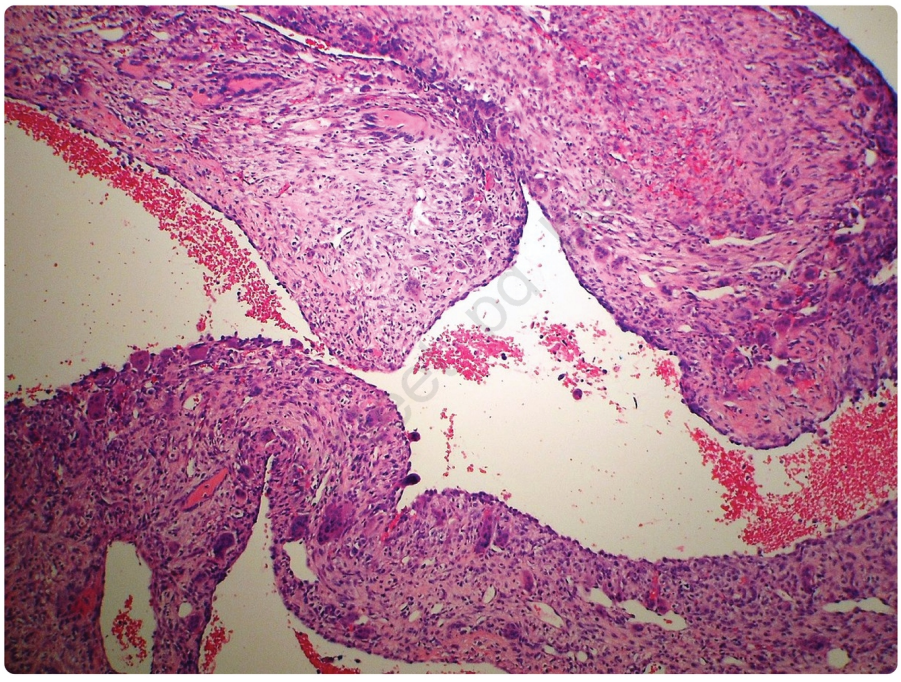
Q7: A 17-year-old female presents with worsening pain in her right tibia over the past few months. On examination, there is tenderness and swelling over the proximal right tibia. Biopsy results show blood-filled cystic spaces lined by fibrous septa containing giant cells. All the following statements are true regarding this condition except? (Q845708)

A. Characterised by uniloculated blood-filled spaces with eggshell appearance on x-ray.

B. Often aggressively growing and are frequently discovered in vertebral bodies.

C. Majority cases are found associated with USP6 gene involvement in chromosome 17

D. Nearly one third patients have a distinctive basophilic metaplastic matrix known as blue bone

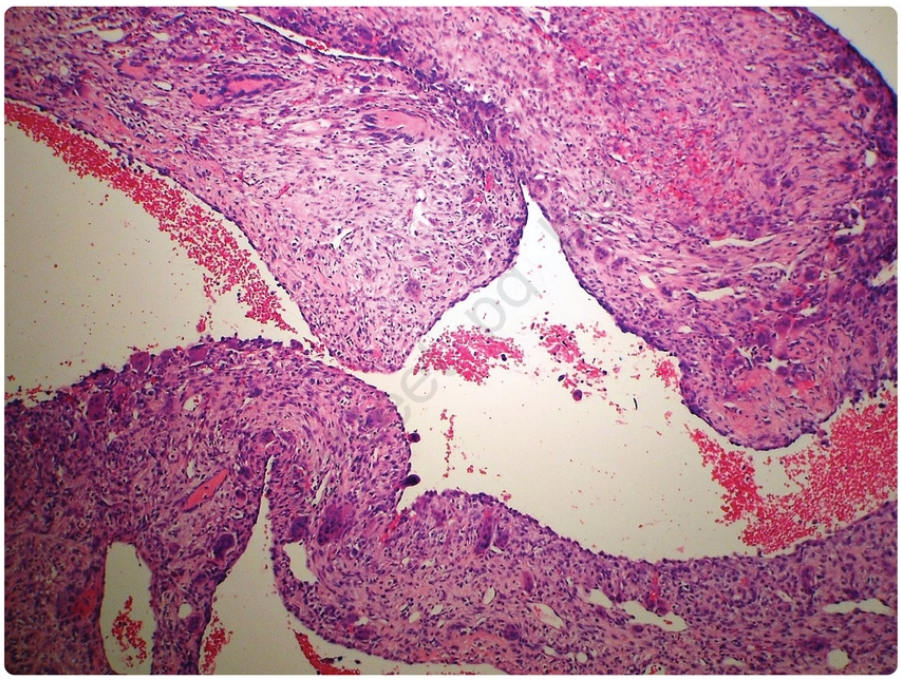


@Neet_pg_bot

Correct Answer: A. Characterised by uniloculated blood-filled spaces with eggshell appearance on x-ray.

Explanation: Aneurysmal Bone Cyst (ABC): Affects all age groups, with most cases in adolescence. Characterised by multiloculated blood-filled spaces (Option 1). Location: Femur, tibia, and posterior vertebral body (Option 2).

Genetics : Chromosome 17p13 rearrangements result in fusion of the USP6 coding region in 70% cases. (Option 3) Highly expressed osteoblast genes like CDH11. Biopsy: Blood-filled cystic spaces separated by thin, tan-white septa made up of spindle cells , osteoclast-like giant cells. Approximately one-third cases contain densely calcified, basophilic metaplastic matrix called blue bone (Option 4).



@Neet_pg_bot

References:

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1194-1195

↑ *Back to this question in Part A*

@Neet_pg_bot

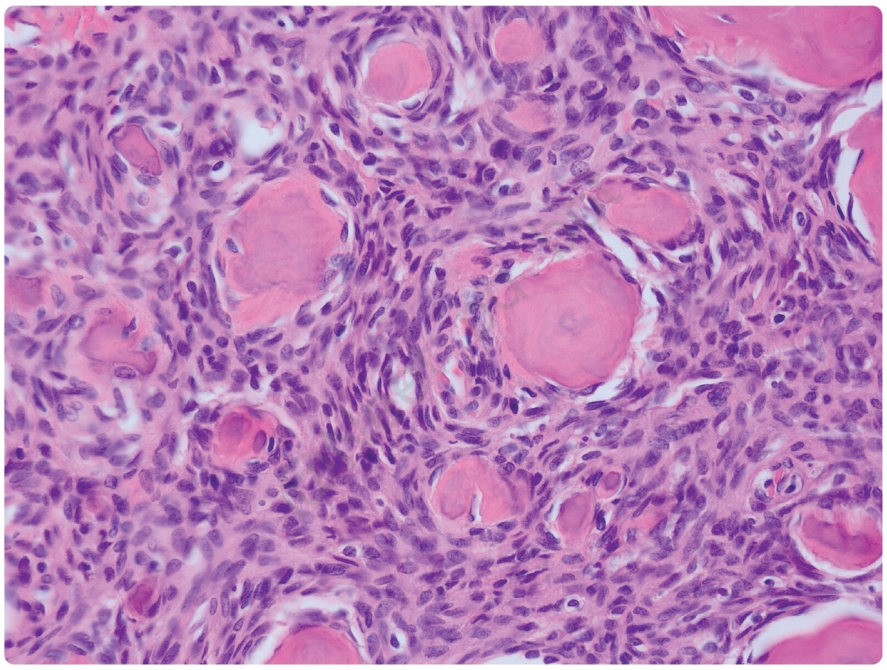
Q8: A 14-year-old male presents with left knee pain for several months. Physical examination reveals tenderness and X-ray demonstrates metaphyseal lesion of the distal femur. A biopsy image of the lesion is shown. What is the most likely diagnosis? (Q845706)

A. Chondrosarcoma

B. Ewing sarcoma

C. Non-ossifying fibroma

D. Giant cell tumor of bone



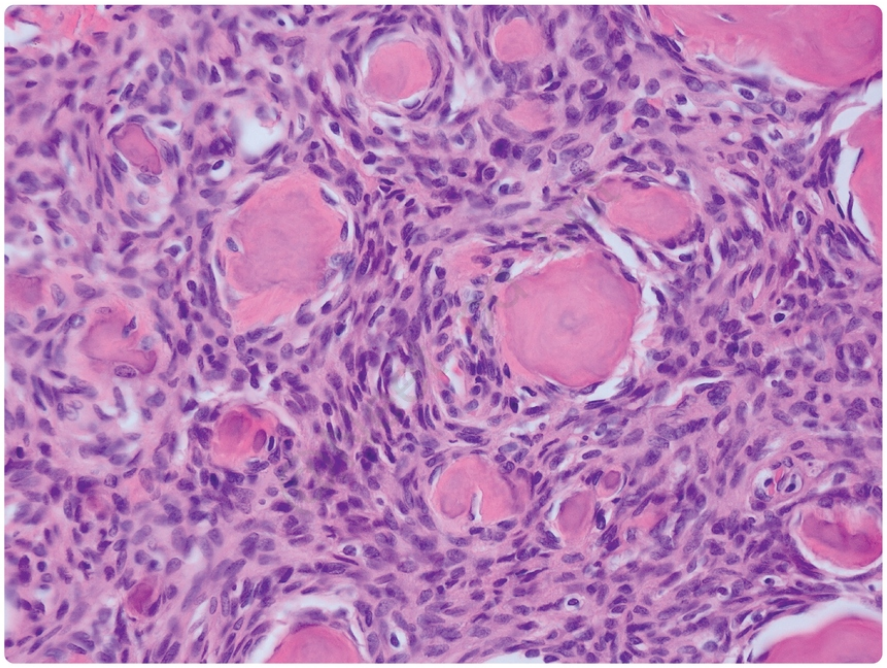
@Neet_pg_bot

Correct Answer: C. Non-ossifying fibroma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: A non-ossifying fibroma is the most likely diagnosis. A biopsy finding suggestive of a storiform pattern made by benign spindle cells with scattered osteoclast-type giant cells. Non-Ossifying Fibroma: Developmental defect in which fibrous connective tissue replaces bone. It is a cartilagenous tumor that is commonly seen in children and adolescents. Arise eccentrically in the metaphysis of the distal femur and proximal tibia. Bony trabeculae that appear pink are seen on biopsy, and these trabeculae are lined by osteoblasts , a pattern referred to as osteoblastic rimming . Giant cell tumor of bone (Option D): It arises in the epiphysis rather than the metaphysis. Giant cells are seen on biopsy. Ewing sarcoma (Option B): It classically occurs in the diaphysis . Small round blue cells are seen on biopsy. Chondrosarcoma (Option A): It is a cartilaginous tumor. So histology reveals bluish cartilage matrix and cells showing chondrocytic differentiation .



@Neet_pg_bot

References:

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Page1192-1195

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: Which of the following statements are true regarding fibrous dysplasia? It is a malignant tumour with components of normal bone unable to differentiate into mature structures Associated with CSF 1 R gene mutation and soft tissue myxoma. Typically occurs in older individuals causing bones to become weak and easily fractured. Histopathological examination shows woven bone trabeculae with disorganised growth plates. Females commonly presents with precocious puberty and irregular dark skin lesions. (Q845705)

A. 1, 3 and 4

B. 2, 3 and 5

C. 3, 4 and 5

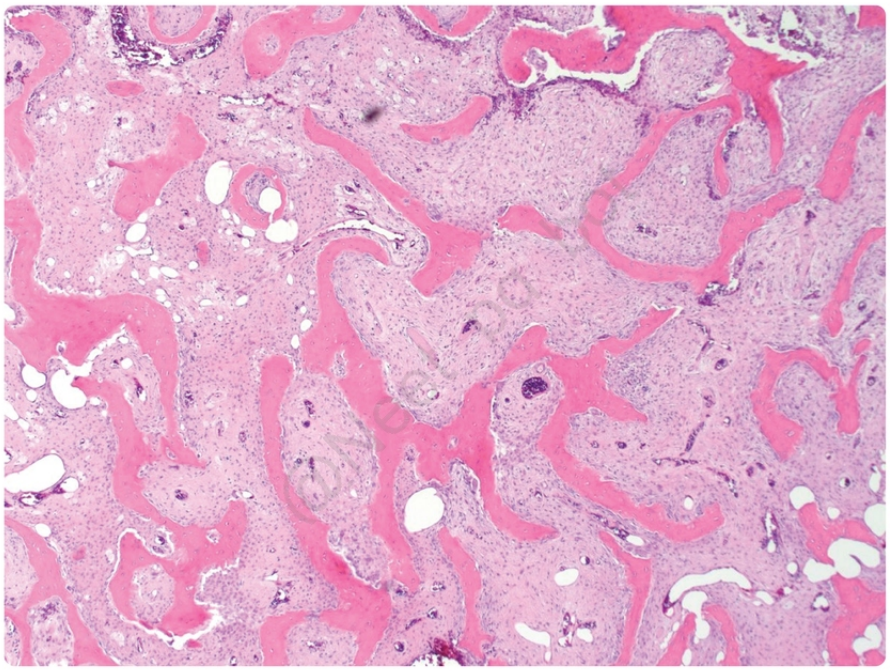
D. 4 and 5

Correct Answer: D. 4 and 5

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Fibrous Dysplasia: It is a benign childhood tumour caused by GNAS1 mutations, characterised by immature normal bone components and disorganised growth plates, linked to McCune- Albright syndrome. (Statement 1 and 3 ruled out) McCuneAlbright Syndrome: Commonly presented as precocious sexual development, mainly in girls. (Statement 5) Polyostotic disease associated with café-au-lait skin pigmentations and endocrine abnormalities. Café-au-lait macules: dark large macules with irregular serpiginous borders on the same side of the body as the bone lesions. Microscopy: Curvilinear trabeculae of woven bone that lack conspicuous osteoblastic rimming in a background of fibrous tissue (Chinese letter pattern). (Statement 4) Statement 2: CSF 1 R gene mutation is seen in giant cell tumor of tendon sheath, but not in fibrous dysplasia.



References:

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1195-1197

↑ *Back to this question in Part A*

@Neet_pg_bot

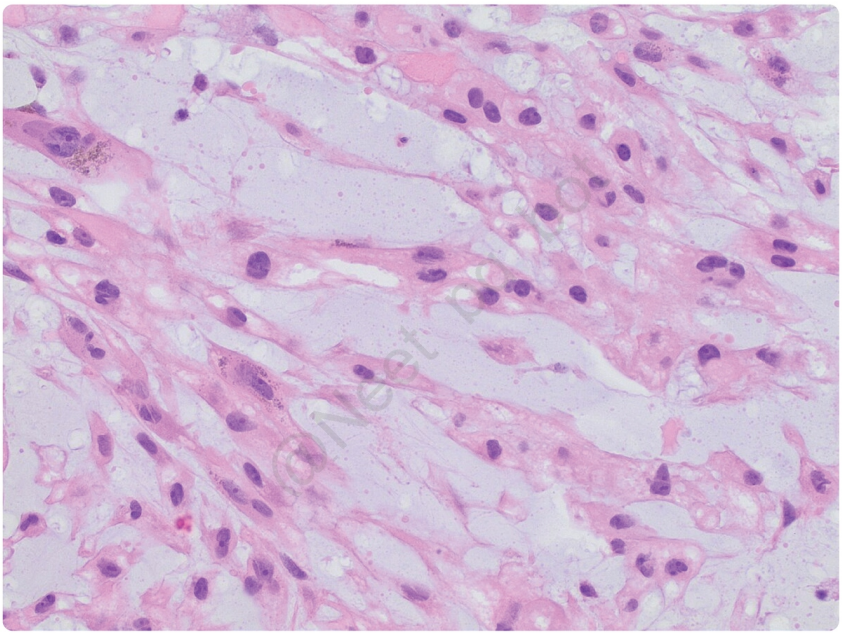
Q10: A 58-year-old male presents with worsening lower back pain and difficulty walking for the last few months. Molecular analysis revealed brachyury gene expression. A biopsy image of the lesion is shown. What is the most likely diagnosis? (Q845702)

A. Chordoma

B. Enchondroma

C. Ewing sarcoma

D. Chondrosarcoma



@Neet_pg_bot

Correct Answer: A. Chordoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical vignette of lower back pain, brachyury gene expression, and biopsy showing Physaliferous cells is suggestive of chordoma. Chordoma: It is a low-grade, slow-growing but locally invasive and locally aggressive tumour. They arise from the remnants of the notochord and occur along the midline spinal axis between the clivus and the sacrum , anterior to the spinal cord. Genetics: Brachyury gene mutation Morphology: Microscopy: Physaliferous cells (cells with bubbly or vacuolated appearance), abundant eosinophilic cytoplasm, cords of epithelioid cells, vacuoles, and extracellular myxoid matrix. Enchondroma (Option B) are benign cartilaginous tumors that typically occur in the small bones of the hands and feet , not the axial skeleton. They are

usually asymptomatic unless they cause a pathologic fracture. Histology: They consist of mature hyaline cartilage and do not express the brachyury gene . Ewing Sarcoma (Option C): This is a high-grade malignant tumor primarily seen in children and adolescents (typically ages 10–20), not 58-year-olds. Histology: It is characterized by sheets of Small Round Blue Cells . Molecular: It is defined by the t(11;22) translocation involving the EWS-FLI1 gene, not brachyury. Chondrosarcoma (Option D): While chondrosarcomas can occur in the axial skeleton of older adults, they lack the specific brachyury expression found in chordomas. Histology: They show malignant chondrocytes within a chondroid (cartilaginous) matrix , often with multiple cells per lacuna and nuclear pleomorphism. They do not contain physaliphorous cells.

@Neet_pg_bot

Q12: Which of the following is incorrect about enchondromas? (Q845647)

A. Maffucci syndrome can also co-exist with brain glioma.

B. Mutations in isocitrate dehydrogenase enzyme genes are common.

C. Histology shows hyaline cartilage encased by reactive bone.

D. Ollier's disease presents as solitary juxta-cortical enchondromas.

Correct Answer: D. Ollier's disease presents as solitary juxta-cortical enchondromas.

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Chondroma is a benign tumour of hyaline cartilage that occurs in bones of endochondral origin. Enchondromas: Tumours can arise within the medullary cavity, Juxtacortical chondromas: Tumors arising on the bone surface. Both Maffucci syndrome and Ollier’s disease are characterised by multiple enchondromas (not solitary). (Option D) Option A: Maffucci syndrome can be distinguished from Ollier’s disease by the presence of other neoplasms like spindle cell hemangioma, brain glioma, etc. Option B: Mutations in the IDH1 & IDH2 genes which code for isocitrate dehydrogenase enzyme are seen commonly in enchondromas. Option C: Radiograph shows a characteristic nodule of hyaline cartilage encased by reactive bone , which can also be confirmed by histopathological examination, as shown in the image. Benign Cartilage

@Neet_pg_bot

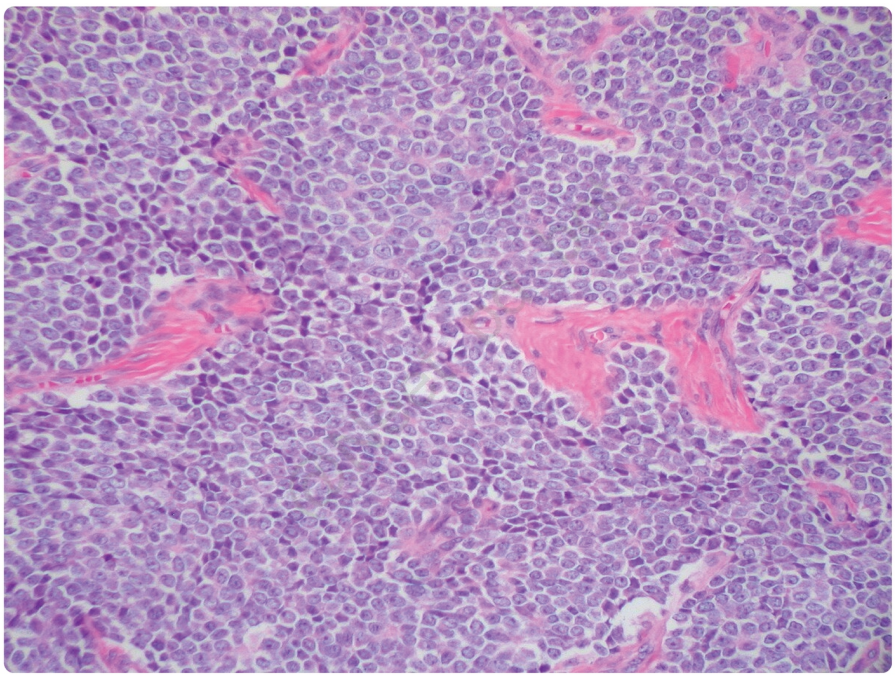
Q13: A 14-year-old boy presents with a swelling on his left tibia. An X-ray of the leg shows a destructive process with indistinct borders and an onion-skin pattern of the periosteal bone. A biopsy was performed, as shown in the image below. Identify the true statements regarding this condition. It is a malignant tumour characterised by primitive round cells with obvious differentiation. It affects boys more than girls. More than 90% of the cases are caused due to t(11;22)(q24;q12) mutation. The presence of rounded cell clusters with a central fibrillary core indicates neuroectodermal differentiation. Chemotherapy-induced necrosis is a negative prognostic indicator. (Q845646)

A. 1, 2, 3

B. 2, 3, 4

C. 1, 3

D. 3, 4, 5



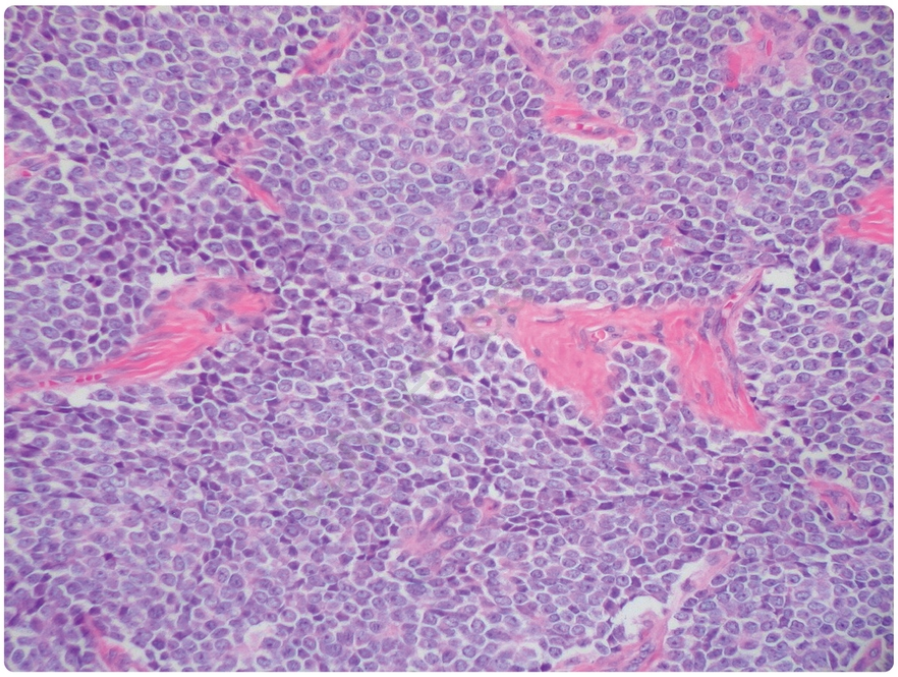
@Neet_pg_bot

Correct Answer: B. 2, 3, 4

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The given clinical scenario suggests Ewing's sarcoma. The correct statements regarding this condition are 2, 3, 4. Ewing's sarcoma: It is a malignant bone tumour characterised by primitive round cells without obvious differentiation. (Statement 1) Approximately 80% of patients are younger than 20 years of age. Males are affected more often than Females. (Statement 2) It usually arises in the diaphysis of long tubular bones, especially the femur and in the flat bones of the pelvis and presents as a painful, enlarging mass. The most common mutation (>90% of the cases) is t(11;22)(q24;q12). (Statement 3) Morphology: It comprises sheets of uniform, small, round cells with scant cytoplasm that may be clear due to abundant glycogen. Homer-Wright rosettes (pseudorosettes) are rounded cell clusters with a central fibrillary core, their presence indicates neuroectodermal differentiation. (Statement 4) Specific markers: CD99+ (MIC2) positive. Chemotherapy-induced necrosis is a positive prognostic indicator. (Statement 5)



@Neet_pg_bot

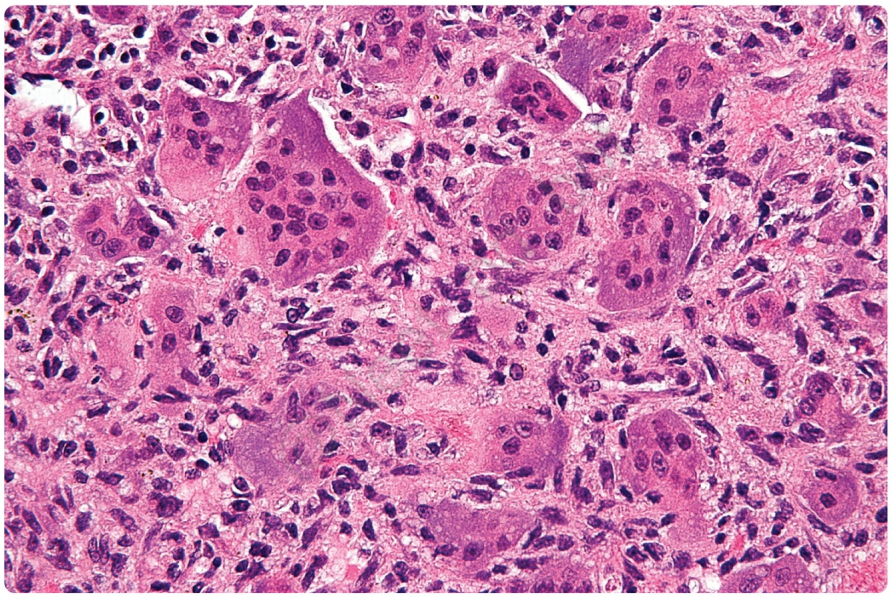
Q14: Histopathological examination of a lesion arising from the right distal femur is given as the image below with such characteristic cells. Which of the following is the most probable diagnosis? (Q845645)

A. Osteoclastoma

B. Chondrosarcoma

C. Osteochondroma

D. Ewing's sarcoma



@Neet_pg_bot

Correct Answer: A. Osteoclastoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The histopathological image shows numerous multinucleated giant cells , along with mononuclear cells scattered in the background in a bone lesion, suggesting osteoclastoma/giant cell tumour. Giant cell tumour (Osteoclastoma): It is a benign but locally aggressive tumour characterised by numerous multinucleated osteoclast-type giant cells. The neoplastic component is made up of the mononuclear cells , while the multinucleated giant cells are only a reactionary or secondary component . Giant cell tumours develop within the epiphysis and may extend into the metaphysis. Mostly located near the knee, involving the distal femur or proximal tibia. Although rare, they can metastasize to the lungs , but typically regress spontaneously and are rarely fatal. Morphology: Grossly, the tumours are large , red-brown masses that frequently undergo cystic degeneration. Chondrosarcoma (Option B): S hows malignant cartilage, which is recognised by the presence of multiple cartilage cells within a single lacuna, Osteochondroma (Option C): It classically shows both bone (osteo) and

cartilage components together. Ewing’s sarcoma (Option D): This belongs to the group of small round blue cell tumors . On histology, we would see sheets of small blue cells and the characteristic Homer Wright pseudorosettes , none of which are seen here.

Robbins and Cotran Pathologic Basis of Disease 10th Edition, Page 1193

↑ *Back to this question in Part A*

@Neet_pg_bot

Q15: A patient presented with a hard mass over the right tibia, and subsequent imaging revealed the presence of sessile growth in the bone. Biopsy is done later, which shows the presence of “cartilage cap” over the lesion. What is the most likely diagnosis? (Q845604)

A. Osteochondroma

B. Chondroblastoma

C. Enchondroma

D. Chondrosarcoma

Correct Answer: A. Osteochondroma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation is suggestive of osteochondroma, characterised by the presence of cartilage cap over the lesion and sessile growth in the bone, which means the lesion has both bone and cartilage elements together. Osteochondroma (Exostosis): Osteochondroma is one of the most common benign bone tumors , also called exosurface. It looks like a mushroom-like growth coming out of the bone and is in exact continuity with the underlying bone . In osteochondroma, the tumor's medulla is continuous with the bone medulla (inner part) and its cortex with the bone cortex (outer part), but it is covered by a cartilage cap, which distinguishes it and gives it the name osteochondroma. Histology: It resembles a disorganized growth plate , and they undergo enchondral ossification , with the newly formed bone making up the inner portion of the head and stalk.

Robbins and Cotran Pathologic Basis of Diseases, 10th Edition, Pages 1189-1190

↑ *Back to this question in Part A*

@Neet_pg_bot

Q16: A 15-year-old male presents with persistent knee pain and swelling of two months duration. The pain is persistent, severe at night and not relieved by NSAIDs.

On examination there is a firm, tender mass around distal femur. X-ray shows destructive lesion with sunburst pattern and lifting of the perisoteum. A biopsy was performed, and it showed pleomorphism, large hyperchromatic nuclei, and bizarre giant cells producing unmineralised osteoid. What is the most likely diagnosis? (Q845601)

A. Osteoid osteoma

B. Osteoblastoma

C. Osteosarcoma

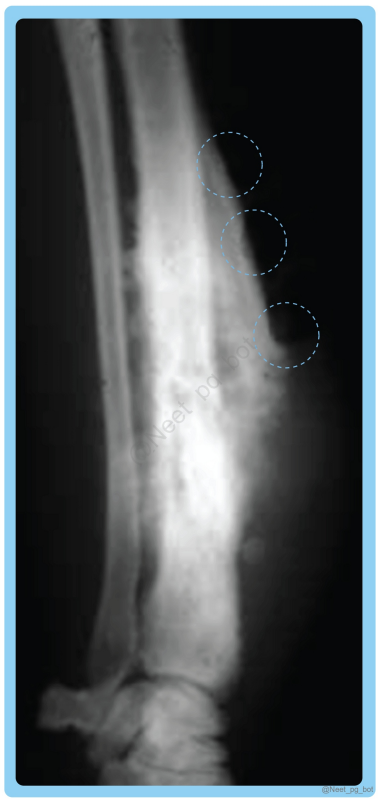
D. Osteoclastoma

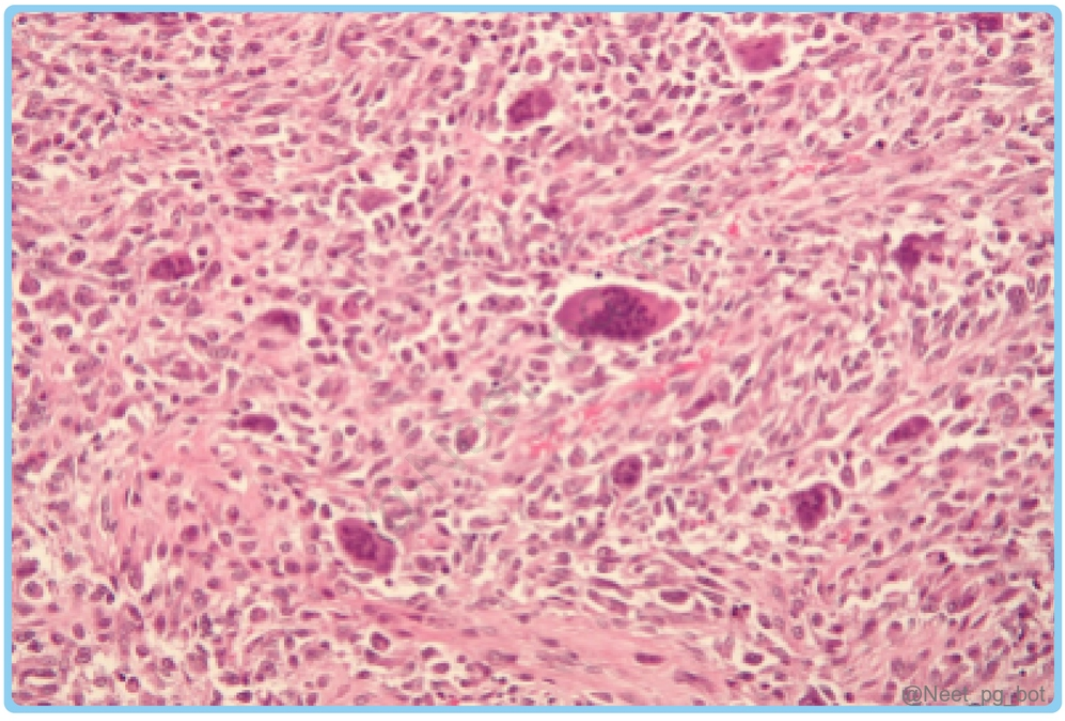
Correct Answer: C. Osteosarcoma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The clinical presentation is suggestive of osteosarcoma, characterised by presence of pleomorphism, large hyperchromatic nuclei, and bizarre giant cells producing unmineralised osteoid Osteosarcoma : It is the most common primary malignant tumour of bone . Tumours usually arise in the metaphyseal region of the long bones (distal femur or proximal tibia). Genetic associations: RB gene (most common) TP53. CDKN2A (also known as INK4a). MDM2 and CDK4. Morphology: Osteosarcomas are bulky, gritty, grey-white tumours that often contain haemorrhage and cystic degeneration. Histology demonstrate pleomorphism , large hyperchromatic nuclei , bizarre tumour giant cells , and abundant mitoses. Extensive necrosis and intravascular invasion are also common. Diagnosis of osteosarcoma requires the presence of malignant tumour cells producing unmineralised osteoid or mineralised bone. Osteoid Osteoma (Option A): Small benign tumor. Severe night pain , but typically relieved by NSAIDs. Histology: woven bone and osteoblasts , but no marked pleomorphism or malignant features . No unmineralised osteoid with atypia Osteoblastoma (Option B): Benign , larger than osteoid osteoma. May cause chronic pain, less responsive to NSAIDs than osteoid osteoma. Histology: Similar to osteoid osteoma but larger, more vascular, no marked pleomorphism or malignant osteoid production Osteoclastoma (Option D):(Giant Cell Tumor): Typically occurs in young adults. Involves epiphysis of long bones, not metaphysis. Histology: multinucleated giant cells, but no malignant osteoid, and no pleomorphic malignant osteoblasts





References:

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 1188, 1189

↑ *Back to this question in Part A*

Q17: A 25-year-old male presents with persistent pain in his right leg that worsens at night and is partially relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). Imaging is given below. Based on the clinical presentation and imaging findings, which of the following is incorrect regarding this condition? (Q845596)

A. It has a predilection for the appendicular skeleton.

B. It is less than 2 cm in diameter.

C. It commonly affects the axial skeleton

D. Pain is relieved on taking aspirin

Correct Answer: C. It commonly affects the axial skeleton

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The imaging shows a small, well-defined bone tumor, and the clinical presentation is consistent with osteoid osteoma , which is characterized by nocturnal pain. These are rarely found in the axial skeleton , with a much higher predilection for the appendicular skeleton (limbs). On X-ray, sclerotic bone at the periphery is seen in

both osteoid osteoma and osteoblastoma. The center of the lesion contains a nidus made of woven or spongy bone, surrounded by cortical bone that appears white on the X-ray. Features Osteoid Osteoma Osteoblastoma Size Less than 2 cm More than 2 cm Site Femur or Tibia (Appendicular skeleton) Spine (Axial skeleton) Pain Nocturnal pain Dull pain On treatment Relieved about taking aspirin Not relieved on taking aspirin Imaging The image below shows the histological features of osteoid osteoma, including spongy (woven) bone with dilated blood vessels.

Robins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1188

↑ *Back to this question in Part A*

Q18: All of the following are associated with Gardner’s syndrome except? (Q845577)

A. Multiple osteoma

B. Colon polyps with risk of malignancy

C. Enchondroma

D. Supernumerary teeth

Correct Answer: C. Enchondroma

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Gardner syndrome is an autosomal dominant phenotypic variant of familial adenomatous polyposis(FAP) , along with various extraintestinal manifestations. The patient has more than 100 polyps in the intestine (High risk of malignancy) Several extraintestinal manifestations are also seen, like: Skin – S ebaceous cysts . Below the skin (fibrous tissue) – Fibromas (Fibrous tumors) Below the fibrous tissue (bones) – Multiple osteomas (Bony tumors) , which are classically seen in the head and neck region of the bones . Spernumerary teeth . Familial Adenomatous Polyposis (FAP): It is an Autosomal dominant hereditary colorectal cancer. Genetic pathogenesis: APC gene: chr 5q21 Rare: NER gene defect 100% risk of cancer, usually >100 polyps (minimum) Types of FAP: 1. Classical FAP: This is the standard form of the disease caused by a germline mutation in the APC (Adenomatous Polyposis Coli) gene located on chromosome 5q21 . Clinical Presentation: Polyps typically begin to appear in the second or third decade of life. Leads to Congenital hypertrophy of RPE (Retinal Pigment Epithelium) The "100" Rule: A diagnosis usually requires the presence of at least 100 polyps in the large intestine. Pathophysiology: The APC gene is a tumor suppressor that regulates the Wnt signaling pathway . Mutation leads to the accumulation of β-catenin, which translocates to the nucleus and activates genes promoting cell proliferation. Management: Total proctocolectomy is generally recommended by age 20. 2. Gardner Syndrome: This variant combines the intestinal features of FAP with specific extracolonic manifestations. It is caused by the same APC mutation but with different phenotypic expression. Key Triad: Colonic Polyposis: >100 polyps in the large intestine. Osteomas: Benign bony growths, most commonly found in the mandible, skull, or long bones. Soft Tissue Tumors: Includes Desmoid tumors (aggressive fibromatosis), epidermoid cysts, and fibromas. Dental Abnormalities: Often presents with impacted or supernumerary (extra) teeth. 3. Turcot Syndrome: This variant involves the association of intestinal polyposis with Central Nervous System (CNS) tumors . It is often referred to as the "Brain-Turcot" association. A diagnosis usually requires the presence of at least 100 polyps in the large intestine. FAP-Associated Turcot: Specifically associated with Medulloblastoma . This is linked to the APC gene mutation. HNPCC (Lynch)-Associated Turcot: More commonly associated with Glioblastoma multiforme . This is linked to DNA mismatch repair gene mutations. 4. Attenuated FAP (AFAP): A milder version of the syndrome where the onset of polyps and cancer is delayed. Pore Count: Patients typically develop fewer than 100 polyps (average 30). Location: Polyps are more likely to be located in the proximal (right) colon . Cancer Risk: While delayed, the lifetime risk of colorectal cancer is still significantly high (~70%). 5. MUTYH-Associated Polyposis (MAP): While clinically similar to FAP, this variant has a different inheritance pattern and genetic cause.

Inheritance: Autosomal Recessive (unlike the dominant FAP). Gene: Mutation in the MUTYH gene, which is involved in base excision repair. Presentation: Typically presents with 10 to a few hundred polyps in the 40s or 50s. Variant Gene Polyp Number Age of Polyps CRC Risk/Age Extracolonic Features Classic FAP APC (5q) >100 10-15 yrs ~100% by 40 Gardner : osteomas, desmoids, dental anomalies, CHRPE Turcot : medulloblastoma Attenuated FAP (AFAP) APC (5' or 3' ends) 10-100 (R) colon > L 20-30 yrs 70% by 80 (delayed) Fewer/milder extracolonic MUTYH-associated polyposis (MAP) MUTYH (biallelic) 10-1000 20-40 yrs 80% lifetime Similar to AFAP; recessively inherited Gardner Syndrome APC (specific codons) >100 Same as classic Same as classic Osteomas (mandible), desmoid tumors (APC 1445), epidermoid cysts , supernumerary teeth Turcot Syndrome (Type 2) APC >100 Same as classic Same as classic Medulloblastoma (vs Type 1 = MMR genes + GBM)

@Neet_pg_bot

Q20: A 6-year-old boy presents with a history of frequent fractures, bone pain, and difficulty walking. On examination, he has short stature and cranial nerve palsies. The radiograph is revealed below. Which of the following is the most likely diagnosis? (Q845575)

A. Osteogenesis imperfecta

B. Osteopetrosis

C. Rickets

D. Paget disease of the bone

Correct Answer: B. Osteopetrosis

- *Listen (English)*
- *Listen (Hindi)*

Explanation: The clinical presentation and radiography showing generalised sclerosis and a bone-within-bone appearance is suggestive of osteopetrosis. Osteopetrosis/Marble bone disease: Osteopetrosis is a defect in the osteoclasts . Because the osteoclasts are not functioning properly, bone remodelling and bone resorption are impaired. As a result, the patient ends up with brittle bones , which gives rise to this bone-in-bone appearance . It has multiple inheritance patterns , including autosomal dominant, autosomal recessive, and X-linked disorders . Morphologically, affected bones lack internal medullary canal leading to frequent features Osteogenesis imperfecta (Option A): Often called "Brittle Bone Disease" This is a genetic disorder where the "blueprint" for bone is flawed from the start. Cause: A mutation (usually in the COL1A1 or COL1A2 genes) that affects Type I collagen . Key Features: Frequent Fractures: Bones can break with minimal impact or even no trauma at all. Blue Sclera: The whites of the eyes appear blue because the underlying veins show through the abnormally thin collagen. Hearing Loss: Small bones in the ear (ossicles) can fracture or develop abnormally. Rickets (Option C): It is a childhood disease characterized by soft, weak bones. Cause: A severe deficiency in Vitamin D (Most common) , Calcium, or Phosphate . Without these, the bone cannot "mineralize" (harden). In adults, this same process is called Osteomalacia . Key Features: Bowed Legs: Since the bones are soft, they bend under the weight of the growing child. Rachitic Rosary: Visible bumps on the rib cage where bone meets cartilage. Growth Delays: Significant impact on height and dental development. Paget disease of the bone (Option D): Cause: The normal bone remodeling process goes out of control. Old bone is broken down too fast, and new bone is laid down too quickly and haphazardly. It is very uncommon at a young age and typically occurs in older individuals Key Features: Disorganized Structure: The new bone is large and thick, but mechanically weak and "shaggy." Bone Pain & Deformity: Commonly affects the skull, pelvis, and spine. If the skull enlarges, it can compress nerves,

leading to headaches or hearing loss. Increased Vascularity: The affected area often feels warm because of increased blood flow to the overactive bone.. It is also considered a pre-malignant condition with an increased risk of osteosarcoma.

[21_Bone Disorders] 083 Previous Year Questions — Quick Jump

Q1 (p. 3180) *Q2 (p. 3181)* *Q3 (p. 3183)* *Q4 (p. 3186)* *Q5 (p. 3189)*

Q1: Which HLA is associated with Reiter syndrome? (Q860540)

A. HLA-DR3

B. HLA-B27

C. HLA-DQ8

D. HLA- DR4

Correct Answer: B. HLA-B27

Explanation: Reiter Syndrome (also known as Reactive Arthritis) is associated with HLA-B27. It is defined by the triad of: Arthritis Nongonococcal urethritis or cervicitis Conjunctivitis Etiology: It occurs days to weeks after genitourinary (Chlamydia) or gastrointestinal (Shigella, Salmonella, Yersinia, Campylobacter, and Clostrdioides difficile) infections. HIV-positive patients may also be affected. Clinical features: Onset: Acute Enthesitis, oligoarthritis and/or spinal inflammation. Lower limb joints and entheses are predominantly affected. Systemic disturbances like fever and weight loss. Achilles insertional enthesitis/tendonitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis can develop. Low back pain and stiffness (due to enthesitis and osteitis) Sacroiliitis Extra-articular features: Circinate balanitis: Starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern. Keratoderma blennorrhagica: Begins as discrete waxy, yellow-brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques on the palms and soles of the feet. Pustular psoriasis Nail dystrophy with subungual hyperkeratosis Mouth ulcers Conjunctivitis Uveitis HLA-DR3 (Option A) is associated with autoimmune diseases such as Systemic Lupus Erythematosus (SLE), Type 1 diabetes, and Graves' disease, but it is not linked to Reiter's Syndrome (Reactive Arthritis), which is specifically associated with HLA-B27. HLA-DQ8 (Option C) is associated with Celiac disease and some autoimmune disorders, such as Type 1 diabetes, but it is not linked to Reiter's Syndrome. HLA-DR4 (Option D) is associated with autoimmune conditions such as Rheumatoid Arthritis (RA) and Type 1 diabetes.

↑ *Back to this question in Part A*

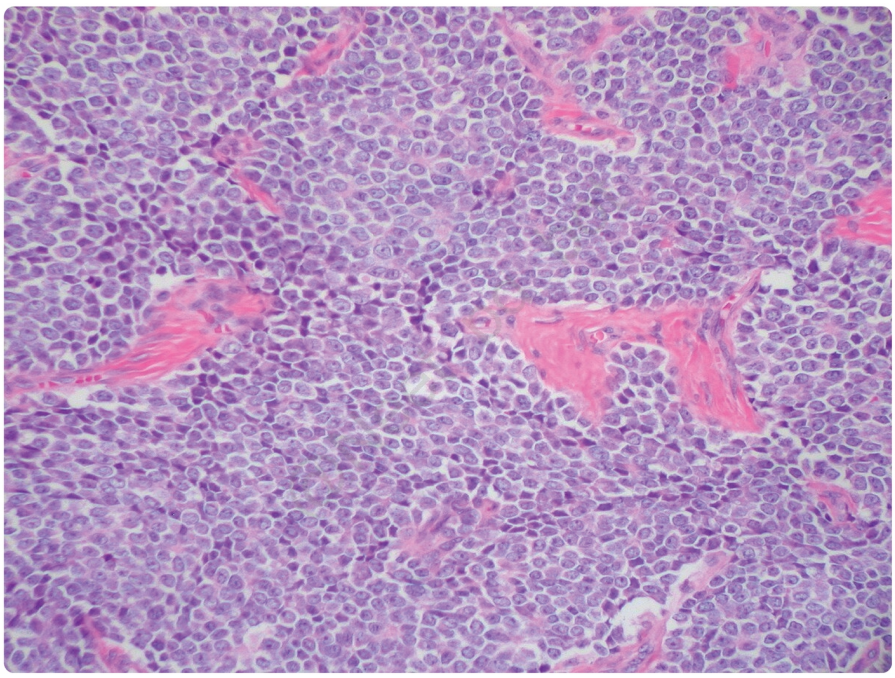
Q2: A 15-year-old boy presents with swelling in the upper diaphyseal part of the tibia. X-ray of the swelling showed a periosteal reaction. A histopathological image of the biopsy is given below. Immunohistochemistry was positive for synaptophysin and MIC2. What is the likely diagnosis? (Q855073)

A. Osteosarcoma

B. Ewing sarcoma

C. Metastatic neuroblastoma

D. Osteoclastoma



@Neet_pg_bot

Correct Answer: B. Ewing sarcoma

Explanation: The clinical scenario, along with the image showing small, round, uniform cells and positive immunohistochemistry for synaptophysin and MIC2 (CD99) in the diaphysis of long bones like the tibia, is characteristic of Ewing sarcoma. Ewing's sarcoma: It is a malignant bone tumour characterized by primitive round cells without obvious differentiation . Approximately 80% of patients are younger than 20 years of age. Males are affected slightly more often than Females. It usually arises in the diaphysis of long tubular bones, especially the

femur and in the flat bones of the pelvis, and presents as a painful, enlarging mass. The most common mutation (>90% of the cases) is t(11;22)(q24;q12) . Morphology: The tumour is soft , tan-white , and frequently contains areas of haemorrhage and necrosis. It comprises sheets of uniform, small, round cells with scant cytoplasm that may be clear due to abundant glycogen. Homer-Wright rosettes (pseudorosettes) are rounded cell clusters with a central fibrillary core; their presence indicates neuroectodermal differentiation. Specific markers: CD99+ (MIC2) positive. Fibrous septae may also be present, but there is little stroma. Geographic necrosis may be prominent. {{caption_text}} Chemotherapy-induced necrosis is a positive prognostic indicator. Osteosarcoma (Option A) is a type of bone cancer originating from cells that produce new bone tissue. It often presents with pain and swelling in the affected bone, and X-rays may show a characteristic "sunburst" or "spiculated" appearance . Histologically, osteosarcoma is characterized by the production of osteoid, a bone-like substance formed by the tumour cells. Metastatic Neuroblastoma (Option C) is a cancer that develops from immature nerve cells and most commonly occurs in young children. It can originate in areas like the adrenal glands or nerve tissues in the neck, chest, or abdomen. While it may metastasize to the bone and cause lytic lesions, it is not typically associated with a periosteal reaction or positive immunohistochemistry for synaptophysin and MIC2. Osteoclastoma (Option D), also known as a giant cell tumour of bone , is a benign tumour that mainly affects young adults. It is characterized by multinucleated giant cells and osteoclast-like cells. X-rays usually show a lytic lesion with a "soap bubble" appearance. However, it is not typically associated with a periosteal reaction or positive immunohistochemical findings for synaptophysin and MIC2.

Robbins & Cotran Pathologic Basis of Disease, 10th Edition, Page 1192,1193

↑ *Back to this question in Part A*

@Neet_pg_bot

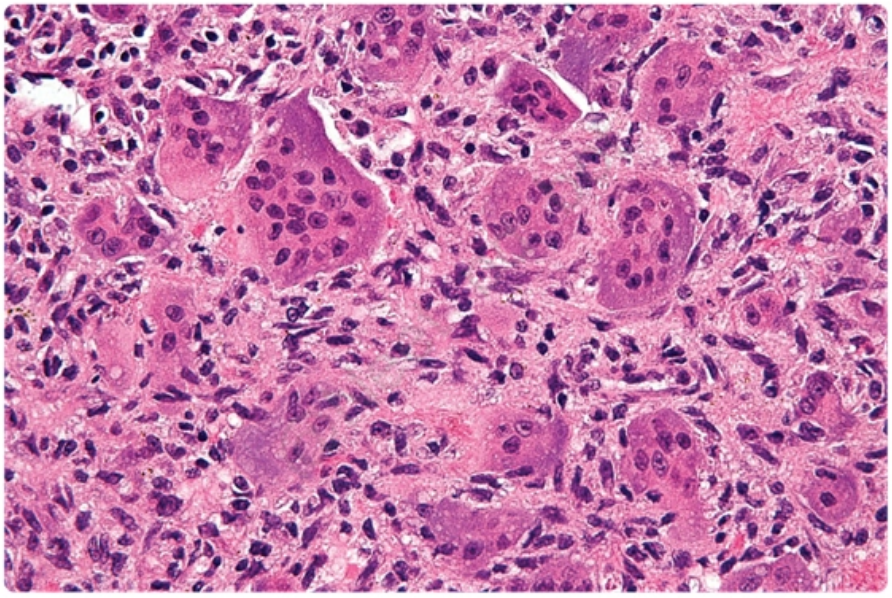
Q3: A 30-year-old woman has been experiencing left knee pain for one month. The knee is tender to touch, and an X-ray reveals a 5cm mass in the distal femoral epiphysis with a "soap bubble" appearance. Microscopy findings are provided below. What is the likely diagnosis? (Q857575)

A. Chondroblastoma

B. Osteoclastoma

C. Osteosarcoma

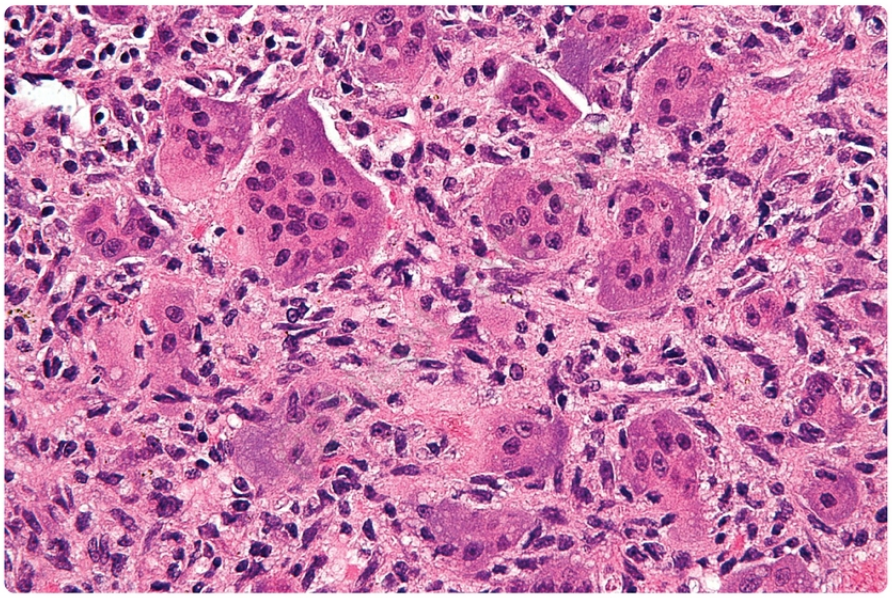
D. Osteochondroma



Correct Answer: B. Osteoclastoma

Explanation: The clinical presentation and histopathological image reveal numerous multinucleated giant cells within a bone lesion, which highly suggests Osteoclastoma (Giant cell tumour of bone). Giant cell tumour (Osteoclastoma): It is a benign but locally aggressive tumour, characterised by numerous multinucleated osteoclast-type giant cells. It occurs in the third to fifth decades of life. Pathogenesis: The neoplastic cells are primitive osteoblast precursors that express high levels of RANKL, promoting the proliferation of osteoclast precursors and their differentiation into mature osteoclasts. This increased activity of osteoclasts is responsible for the tumour being highly lytic and expansile due to uncontrolled bone resorption. Giant cell tumours develop within the epiphysis and may extend into the metaphysis. Mostly located near the knee, involving the distal femur or

proximal tibia. Although rare, they can metastasise to the lungs but typically regress spontaneously and are rarely fatal. Morphology: Grossly, the tumours are large , red-brown masses that frequently undergo cystic degeneration. Histologically, the tumours consist of uniform oval mononuclear tumour cells and abundant osteoclast-type giant cells with 100 or more nuclei. {{caption_text}} Chondroblastoma (Option A) is a benign, chondroid-producing tumour that usually arises in the epiphysis or apophysis of skeletally immature individuals. It is characterised by a sheet-like proliferation of chondroblasts and presents with pain, joint stiffness, and swelling. Chondroblastomas rarely show a soap bubble appearance on X-ray. {{caption_text}} Osteosarcoma (Option C) is a malignant bone tumour, typically found in the metaphysis of long bones. It is most common in children and young adults, particularly around sites of bone growth. It can present with bone pain, swelling, and fractures but does not typically exhibit the soap bubble appearance associated with giant cell tumours. {{caption_text}} Osteochondroma (Option D) is a benign bone tumour that forms on the surface of bones, usually near the growth plate. It comprises bone and cartilage and tends to stop growing after skeletal maturity. They do not present with a soap bubble appearance and are typically not located in the epiphysis. {{caption_text}}



@Neet_pg_bot

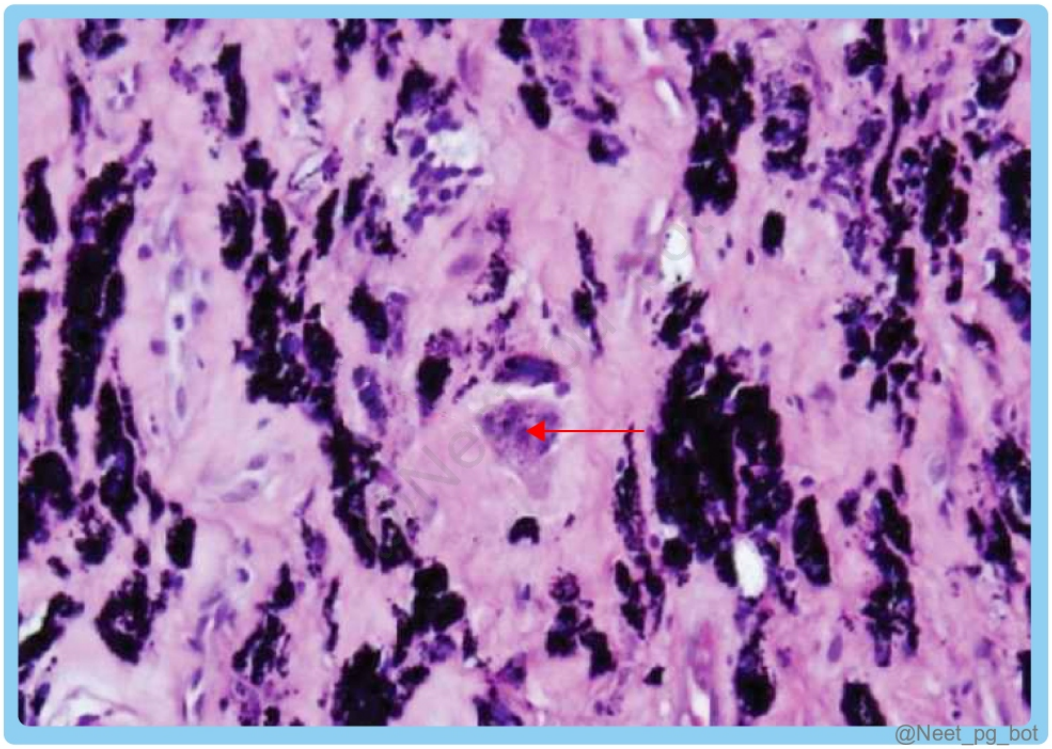
Q4: A woman who had undergone total knee replacement surgery comes back with complaints of knee pain and loosening of implants. The following histopathological slide was obtained, showing foreign body giant cells and the appearance highlighted in the image below. What is your diagnosis? (Q856891)

A. Ochronosis

B. Metallosis

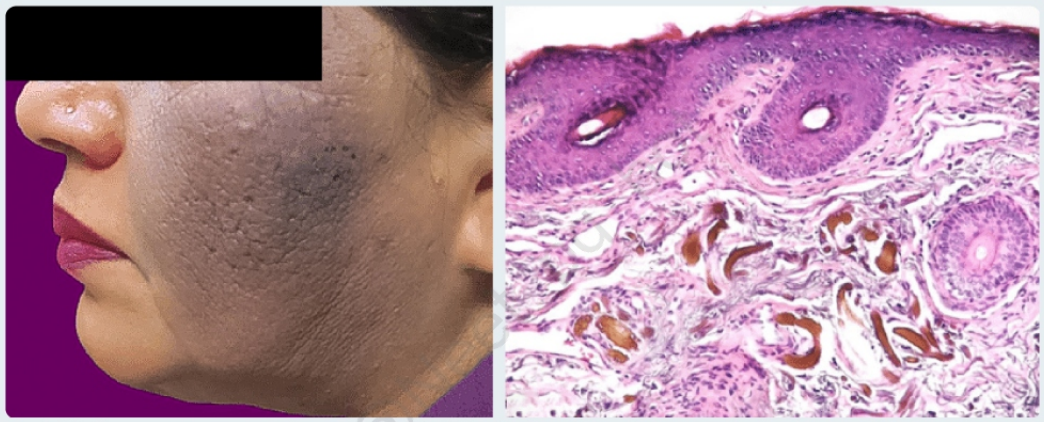
C. Malignant melanoma

D. Rosai-Dorfman disease



Correct Answer: B. Metallosis

Explanation: Metallosis refers to the accumulation of metal debris in tissues commonly associated with wear and corrosion of metal implants, such as those used in joint replacements. This causes inflammation, foreign body giant cells, and metallic debris, visible on histopathology. Metallosis: Definition: Aseptic fibrosis, local necrosis, and prosthetic loosening due to metal wear and corrosion in metal-on-metal (MoM) implants . Pathophysiology: Metallic debris (cobalt, chromium, titanium) triggers an inflammatory response , leading to foreign body giant cell reaction , cytokine release, and tissue necrosis . Systemic metal ion absorption may cause neuropathy, cardiomyopathy, and thyroid dysfunction . Clinical Features: Local : Chronic pain, swelling, pseudotumors, skin discolouration. Systemic : Neurological, cardiac, and endocrine toxicity. Diagnosis: Serum cobalt and chromium levels . MARS MRI (Metal Artifact Reduction Sequence) for pseudotumors. Histopathology : Pigmented macrophages, metal debris, necrosis. Management Regular monitoring of metal ion levels and symptoms. Revision surgery with non-metallic implants in symptomatic cases. Incorrect Options: Ochronosis (Option A) : A rare condition often associated with alkaptonuria, characterized by dark pigmentation in cartilage but not related to metal debris from implants. {{caption_text}} Malignant melanoma (Option C) is a type of skin cancer that arises from melanocytes. It typically presents as a pigmented skin lesion and does not cause the formation of foreign body giant cells or be associated with metal debris from joint replacements. {{caption_text}} Rosai-Dorfman disease (Option D) is a rare condition characterized by the accumulation of histiocytes (a type of white blood cell) in various organs, leading to lymphadenopathy and other systemic symptoms. It is not related to the inflammatory response caused by metal debris in metallosis. {{caption_text}}



(A) Exogenous ochronosis with itchy, tender, and darkened macules
(B) Skin biopsy showing elongated yellow-brown deposits ("banana-like") of acellular material in the superficial dermis with associated solar elastosis

@Neet_pg_bot

Q5: Which of the following conditions will have the least chance of a dry bone marrow aspiration? (Q856898)

A. Hairy cell leukemia

B. Acute myeloid leukemia (AML)

C. Myelodysplastic syndrome

D. Follicular lymphoma

Correct Answer: D. Follicular lymphoma

Explanation: Follicular lymphoma is less likely to result in a dry bone marrow aspiration compared to the other conditions. In follicular lymphoma, the bone marrow may be infiltrated with lymphoma cells but typically retains enough cellularity for a successful aspiration. Conditions that can lead to a dry bone marrow aspiration (Dry tap):

Metastatic carcinoma infiltration (17%) Chronic myeloid leukemia (CML) (15%) Myelofibrosis (14%) Hairy cell leukemia (10%) Acute leukemia (10%) Lymphomas, including Hodgkin's disease. {{caption_text}} Hairy Cell Leukemia (HCL) (Option A) , Acute Myeloid Leukemia (AML) (Option B) (e.g., AML with myelofibrosis), and Myelodysplastic Syndrome (MDS) (Option C) can all cause dry bone marrow aspiration due to bone marrow fibrosis, increased reticulin deposition or dense cellular infiltration .

Q13 (p. 3219)

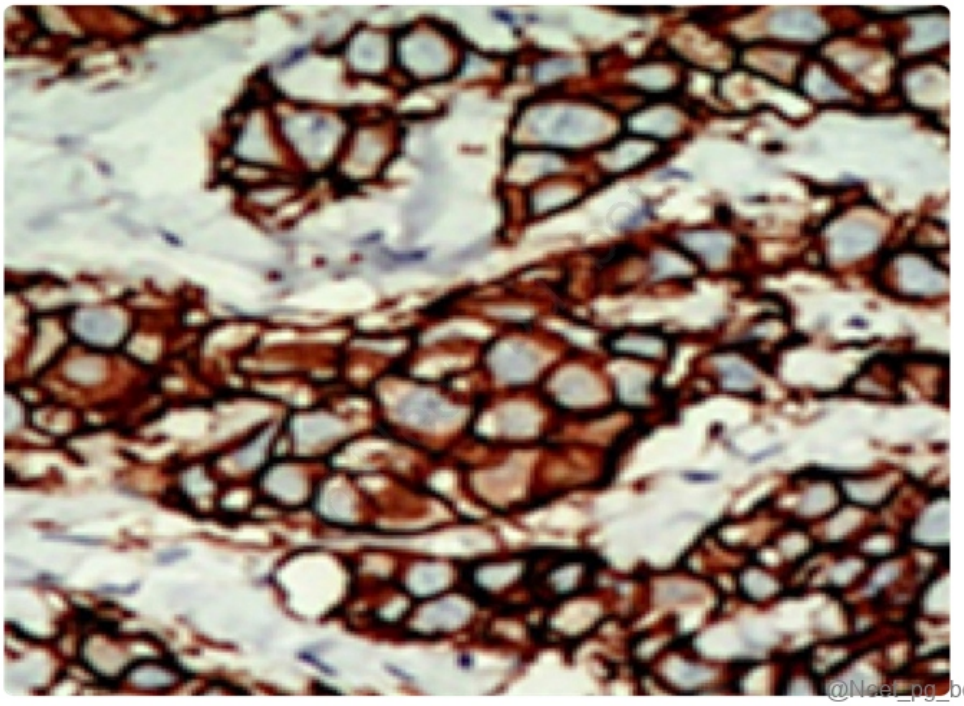
Q1: The image below represents the presence of HER2 neu cells in a patient with breast carcinoma. What agent is used to produce this characteristic discolouration? (Q854670)

A. FITC

B. Phycoerythrin

C. Cyanate dye

D. Diaminobenzidine



Correct Answer: D. Diaminobenzidine

Explanation: 3,3′-Diaminobenzidine (DAB) is a commonly used chromogen in immunohistochemistry (IHC) to detect HER2 overexpression in certain breast cancers. It serves as a substrate for a peroxidase enzyme coupled to a primary or secondary antibody. It is oxidised and converted to an insoluble polymer, precipitating as a dark brown pigment, which allows visualisation of the target molecule. FITC (Fluorescein Isothiocyanate) (Option A) is a fluorescent dye that is used in fluorescence microscopy to detect specific antigens but does not produce a brown colour. It would instead produce a green fluorescence. Phycoerythrin (Option B) is another fluorescent dye often used in flow cytometry and fluorescence microscopy but does not produce a brown colouration. It fluoresces red-orange and is used for labelling antibodies. Cyanate dye (Option C) is commonly used in fluorescence-based applications such as fluorescent labelling of biomolecules in biological and biochemical research. These dyes are known for their high sensitivity and photostability.

Q2: A phlebotomist is asked to collect blood samples for a patient undergoing multiple tests. Which of the following is the correct order of blood collection to avoid contamination of the samples based on the additives in the collection tubes? (Q854685)

A. Light blue → Lavender → Red → Grey

B. Grey → Red → Light blue → Lavender

C. Light blue → Red → Lavender → Grey

D. Red → Lavender → Grey → Light blue

Correct Answer: C. Light blue → Red → Lavender → Grey

Explanation: The correct order here is Light blue → Red → Lavender → Grey In blood collection, it's crucial to follow the correct order to prevent contamination between tubes with different additives. The correct order of drawing the blood in vacutainers is Blood culture → Light blue → Red or Yellow → Green → Lavender → Grey Vacutainer colour Additive Uses Blood culture Broth media (aerobic/anaerobic) For detecting bacterial and fungal infections Light blue {{caption_text}} Trisodium citrate For coagulation tests Red or Yellow {{caption_text}} {{caption_text}} No additive (Red) / Gel separator (Yellow) For serum collection (serology, chemistry) Green Heparin For plasma collection (chemistry tests) Lavender {{caption_text}} EDTA For haematology tests (e.g., CBC, blood smears) Pink EDTA For blood bank tests (e.g., crossmatch, blood type Grey {{caption_text}} Potassium Oxalate + Sodium Fluoride For glucose, lactate, and alcohol tests

@Neet_pg_bot

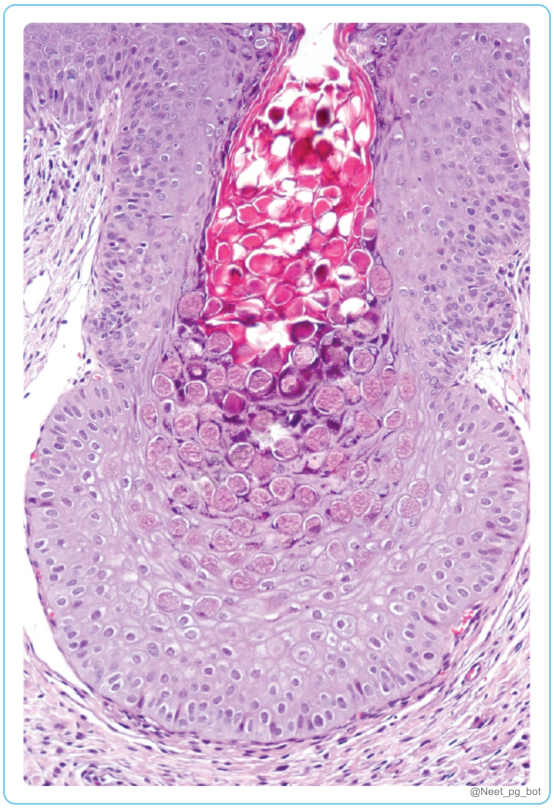
Q4: A child presents with multiple skin lesions over the inner thigh and genital areas. Initially, the lesions started as macules and later developed into nodules. Some of the nodules have a central umbilication. The histology of the lesion is shown below. What would be found on a biopsy? (Q855108)

A. Multinucleate giant cells (Tzanck cells)

B. Donovan bodies

C. Henderson-Patterson bodies

D. Koilocytes



Correct Answer: C. Henderson-Patterson bodies

Explanation: The given clinical scenario and image are diagnostic of Molluscum contagiosum lesions, which show intracytoplasmic inclusion bodies called Henderson-Patterson bodies /molluscum bodies. Molluscum Contagiosum: Caused by: Poxvirus (MCV-1 to MCV-4) MCV-1 is the most common. MCV-2 is often sexually transmitted. Common in: Children (2-12 years): Spread through direct contact or shared items (e.g., towels) Adults: Typically sexually transmitted, affecting genitals, lower abdomen, buttocks, and inner thighs Incubation period: Approximately 6 weeks Clinical Features: Pearly, dome-shaped papules (1-5 mm in diameter) with a dimpled centre. The central waxy core contains cytoplasmic viral inclusions. Common sites in children: Trunk, arms, and legs Common sites in adults: Genitals, lower abdomen, buttocks, and inner thighs Microscopic examination: Lesion characteristics: Cup-like, verrucous epidermal hyperplasia. Diagnostic structure : Molluscum body : Large (up to 35 µm), ellipsoid, homogeneous cytoplasmic inclusion. Found in the stratum granulosum and stratum corneum . Eosinophilic in the stratum granulosum. Pale blue hue in the stratum corneum. {{caption_text}} Multinucleate giant cells (Tzanck cells) (Option A) are typically seen in herpesvirus infections (like herpes simplex or varicella-zoster), not in molluscum contagiosum. They are large cells with multiple nuclei, and their presence is a hallmark of herpesvirus infections. {{caption_text}} Donovan bodies (Option B) are characteristic of granuloma inguinale , caused by Klebsiella granulomatis . The bodies are intracellular and appear in macrophages. They are unrelated to molluscum contagiosum. {{caption_text}} Koilocytes (Option D) are cells with a characteristic perinuclear halo and are associated with human papillomavirus (HPV) infections, such as warts. {{caption_text}}

Q5: Which of the following needles is commonly used for bone marrow biopsy? (Q855114)

A. Klima needle

B. Salah needle

C. Jamshidi needle

D. Islam needle

Correct Answer: C. Jamshidi needle

Explanation: The Jamshidi needle is the most widely used needle for bone marrow aspiration and biopsy. It has a hollow, beveled tip designed to obtain a core of bone marrow with minimal trauma. Common sites for biopsy using this needle are the posterior superior iliac spine and sternum (for aspiration only). It allows both aspiration of liquid marrow and core biopsy for histology in the same procedure. The needle is preferred for its ease of use, safety, and high-quality sample retrieval. {{caption_text}} Incorrect Options: Option A) Klima needle: Rarely used; mainly historical, not standard for marrow biopsy. Option B) Salah needle: Not a standard or recognized needle for bone marrow procedures. ■ Option D) Islam needle: Not used for bone marrow biopsy; no clinical standard. {{caption_text}}

@Neet_pg_bot

Q6: Which of the following oil red O stain is used? (Q855393)

A. Formalin fixation

B. Frozen section

C. Alcohol fixation

D. Glutaraldehyde fixation

Correct Answer: B. Frozen section

Explanation: Oil Red O stain is commonly used in frozen sections to detect the presence of lipids, particularly neutral lipids such as triglycerides. It is a lipophilic dye that selectively stains lipids within cells or tissues. It binds to the neutral lipid droplets and produces a bright red colour when examined under a microscope. {{caption_text}} This stain is particularly useful in identifying lipid accumulation in various tissues and organs, including adipose tissue, liver, muscle, and atherosclerotic plaques. Frozen sections are typically used for rapid intraoperative diagnosis or for research purposes. Formalin fixation (Option A) refers to the preservation of tissue samples using formaldehyde solutions, leading to the cross-linking of proteins and modification of lipid structures, which may interfere with the staining properties of Oil Red O. Alcohol fixation (Option C) involves the preservation of tissues using alcohol-based solutions, such as ethanol or methanol. It can also alter the structure of lipids, affecting the staining properties of Oil Red O. Glutaraldehyde fixation (Option D) is typically used for electron microscopy studies. It may lead to changes in lipid composition and affect the staining properties of Oil Red O.

@Neet_pg_bot

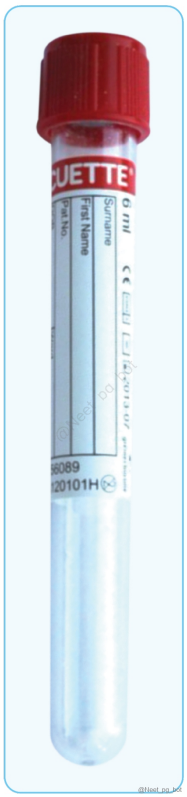
Q7: The vacutainer tube shown in the given image contains the following: (Q855434)

A. EDTA

B. Trisodium citrate

C. NAF - heparin

D. Clot activator



Correct Answer: D. Clot activator

Explanation: The vacutainer tube shown in the image contains a clot activator, which is a substance designed to accelerate the blood clotting process. It promotes quicker coagulation of the blood sample. This type of tube is typically used to collect serum samples for various laboratory tests. Colour Anti-coagulants Uses Purple/Lavender {{caption_text}} EDTA (Ca2+ chelating anticoagulant) (Option A ruled out) CBC, Peripheral Smear, ESR, HbA1c Light Blue {{caption_text}} Trisodium Citrate (Ca2+ chelating anticoagulant) (Option B ruled out) ESR, PT, aPTT Red {{caption_text}} No anti-coagulant is added. Clot activator without gel (Option D) Serum studies (Proteins, enzymes, hormones) Yellow {{caption_text}} Clot activator/Gel separator Serum studies (Proteins, enzymes, hormones) Grey {{caption_text}} Sodium Fluoride Blood Glucose Green {{caption_text}} Heparin (Option C ruled out) ABG, Osmotic fragility, flow cytometry, immunophenotyping

Q8: The following image shows an instrument used to estimate haemoglobin levels. What does it measure? (Q855893)

A. Alkaline hematin

B. Acid hematin

C. Oxyhemoglobin

D. Deoxyhemoglobin

@Neet_pg_bot

Correct Answer: B. Acid hematin

Explanation: The image depicts a device known as the Sahli hemoglobinometer, which is used to estimate haemoglobin levels in blood. The hemoglobinometer works by adding a dilute acid to a small sample of blood, causing the formation of acid hematin , a derivative of haemoglobin formed when haemoglobin reacts with an acid. This acid hematin is then compared to a standard colour chart to determine the haemoglobin concentration.

@Neet_pg_bot

Q9: Which of the following methods is iron in tissues stained? (Q855899)

A. Masson’s trichrome

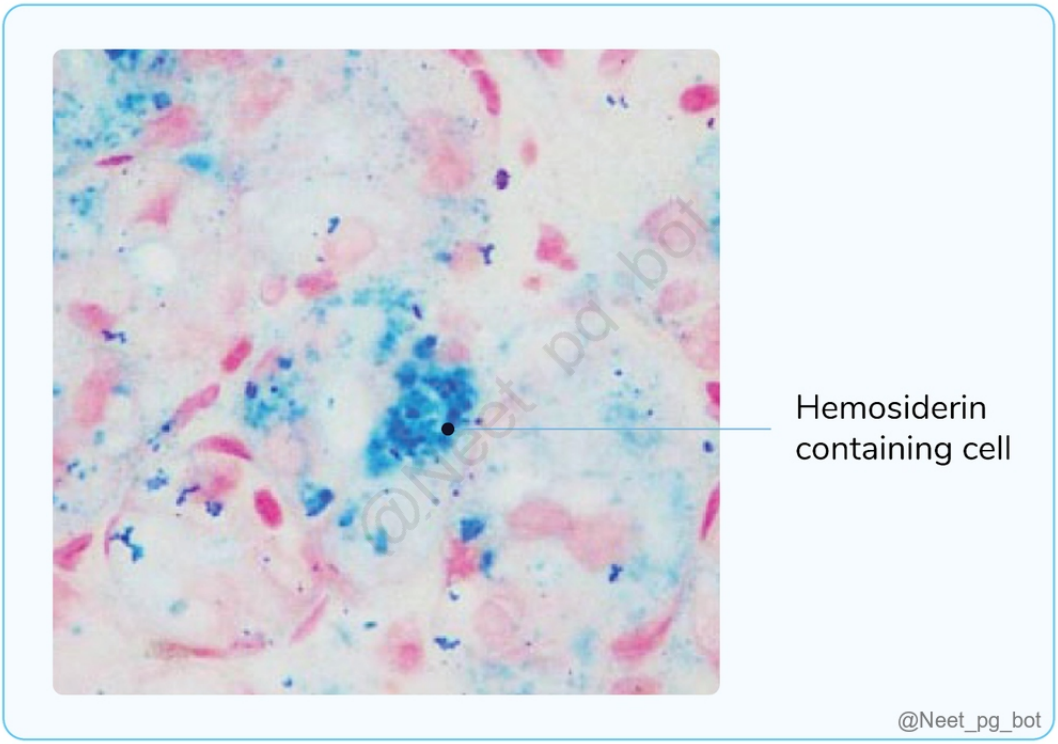
B. Prussian blue

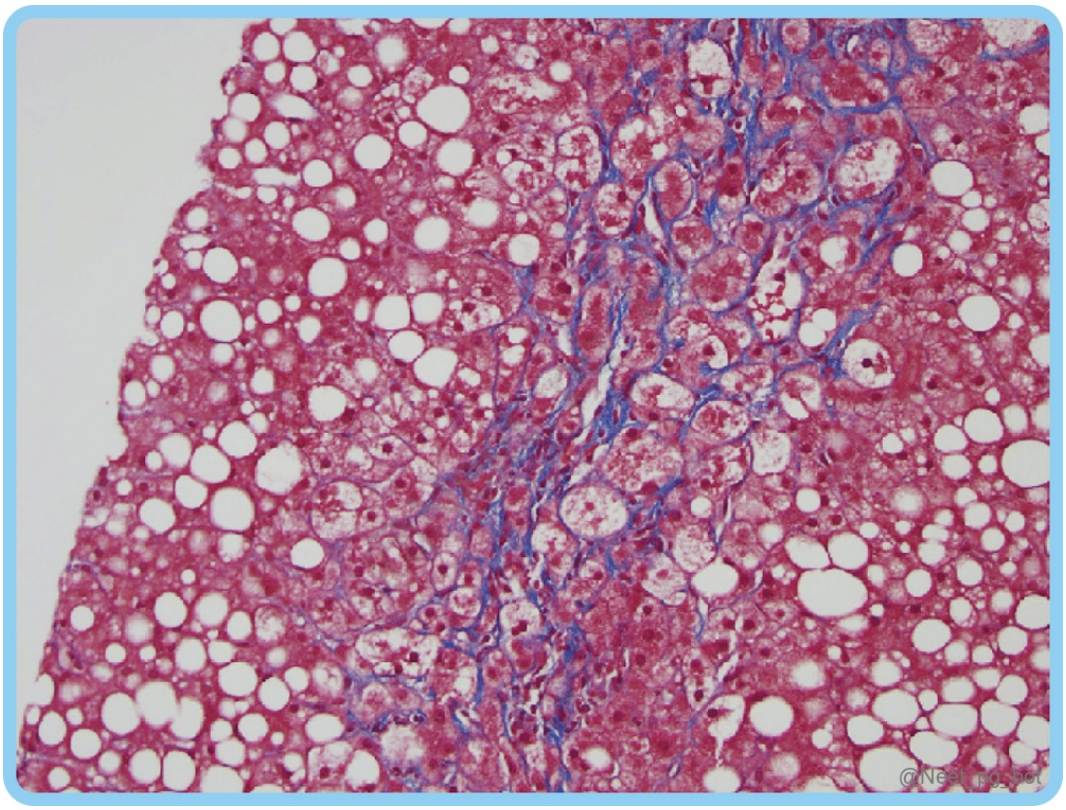
C. PAS

D. Fite-Faraco

Correct Answer: B. Prussian blue

Explanation: Iron in tissues is stained using Prussian blue. This staining technique relies on the reaction between Fe3+ ions and ferrocyanide ions to form an insoluble blue pigment. When tissue sections are treated with a solution of potassium ferrocyanide and hydrochloric acid, any iron present in the tissue reacts with the ferrocyanide, producing the blue pigment. This stain is specific for iron and is frequently employed to detect iron deposition in conditions like hemochromatosis and hemosiderosis. Prussian blue stain Iron {{caption_text}} Masson Trichrome Differentiate Collagen & muscle fibers {{caption_text}} Fite-Faraco stain Leprosy {{caption_text}} PAS stain Glycogen {{caption_text}}





@Neet_pg_bot

Q10: A woman presents with nodular lesions, 4-6 mm in size, on the inner thighs and peri-anal region. The lesions appear pale, and histopathological examination reveals multiple intracytoplasmic inclusion bodies consistent with Henderson-Patterson bodies. What is the most likely diagnosis? (Q855907)

A. Trichodysplasia spinulosa

B. Condyloma acuminata

C. Molluscum contagiosum

D. Donovanosis

Correct Answer: C. Molluscum contagiosum

Explanation: The patient's presentation of pale, nodular lesions on the inner thighs and peri-anal region, along with the presence of Henderson-Patterson bodies, is characteristic of Molluscum contagiosum . Henderson-Patterson bodies are eosinophilic inclusion bodies that are diagnostic for Molluscum contagiosum virus (MCV) infection. The virus primarily infects the skin, causing characteristic lesions that are typically described as pearl-like, dome-shaped, and umbilicated. The lesions are generally painless and self-limiting, though they can persist for months or even years. {{caption_text}} Molluscum Contagiosum: Caused by: Poxvirus (MCV-1 to MCV-4) MCV-1 is the most common. MCV-2 is often sexually transmitted. Common in: Children (2-12 years): Spread through direct contact or shared items (e.g., towels). Adults: Typically sexually transmitted, affecting genitals, lower abdomen, buttocks, and inner thighs. Incubation period: Approximately 6 weeks. Clinical Features: Pearly, dome-shaped papules with a dimpled centre. Papules are 1-5 mm in diameter. The central waxy core contains cytoplasmic viral inclusions. Common sites in children: Trunk, arms, and legs. Common sites in adults: Genitals, lower abdomen, buttocks, and inner thighs. Microscopic examination: Lesion Characteristics: Cup-like, verrucous epidermal hyperplasia. Diagnostic Structure : Molluscum body , a large (up to 35 µm), ellipsoid, homogeneous cytoplasmic inclusion. Found in the stratum granulosum and stratum corneum . Eosinophilic in the stratum granulosum. Pale blue hue in the stratum corneum. Trichodysplasia Spinulosa (Option A) is a viral infection that predominantly affects immunocompromised individuals, especially organ transplant recipients. It typically manifests as follicular papules and spiny nodules on the face, neck, and upper extremities. Histologically, it shows hyperkeratosis, follicular plugging, and hair shaft abnormalities. Condyloma acuminata (Option B) , or genital warts, is caused by the human papillomavirus (HPV) and is a sexually transmitted infection. These warts usually appear as flesh-coloured, cauliflower-like growths in the genital and perianal regions. Histologically, they are characterized by hyperkeratosis, acanthosis, and koilocytosis, where squamous cells exhibit a clear halo around the nucleus. {{caption_text}} Donovanosis (Option D), also called granuloma inguinale, is a bacterial infection caused by Klebsiella granulomatis . It presents as painless nodules or ulcers in the genital and perianal regions. Histologically, it shows granulomatous inflammation with Donovan bodies, which are large, rod-shaped, intracytoplasmic bacteria

@Neet_pg_bot

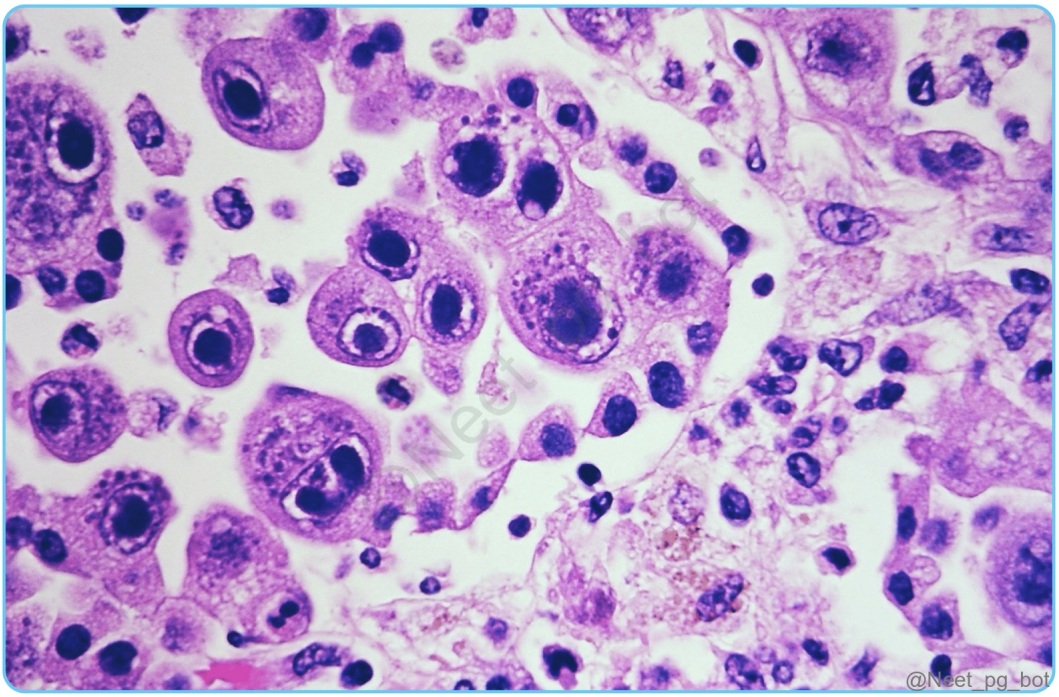
Q11: The given inclusion bodies are characteristic of which of the following organisms? (Q858119)

A. Human papillomavirus

B. Cytomegalovirus

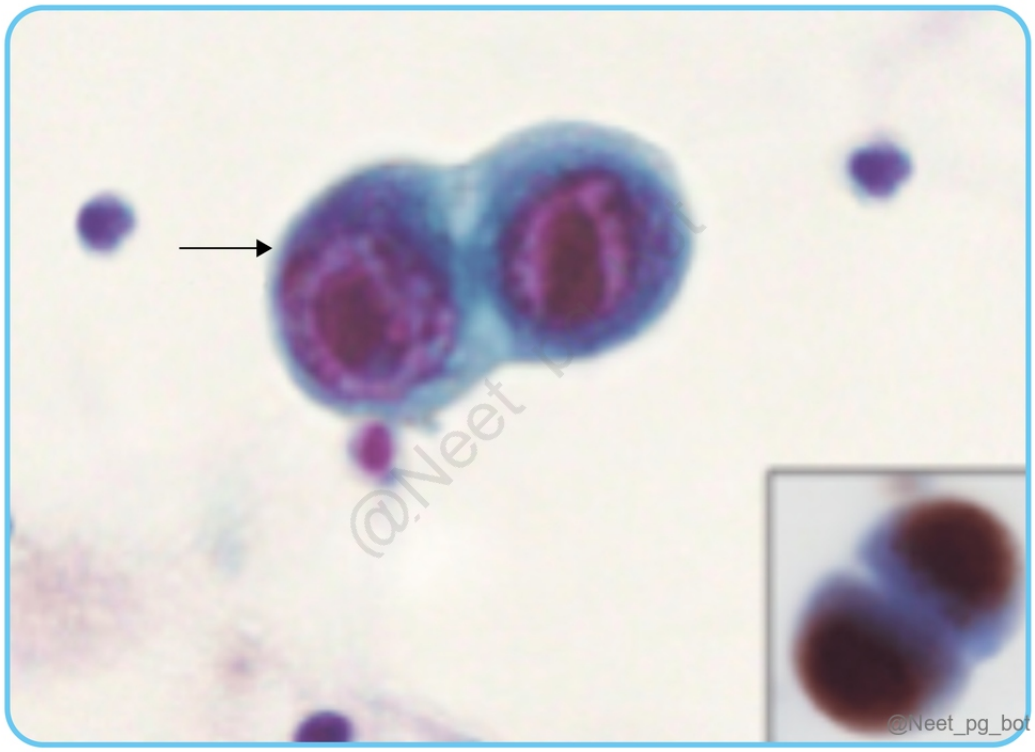
C. Epstein-Barr virus

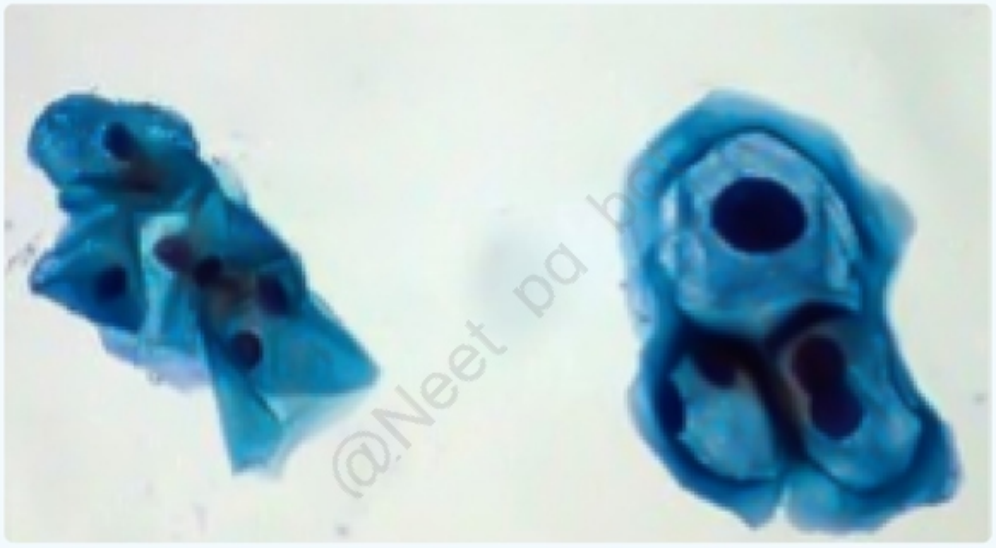
D. Herpes simplex virus



Correct Answer: B. Cytomegalovirus

Explanation: The presence of inclusion bodies, which gives the characteristic “Owl-eye appearance,” suggests Cytomegalovirus. CMV infection Modes of transmission Oral route, respiratory & body secretions (most common) Vertical transmission Sexual transmission Organ transplantation Blood transfusion Investigations Peripheral smear Owl’s eye appearance of inclusion bodies {{caption_text}} Virus isolation It is done by Human fibroblast cell line culture Shell vial culture Antigen detected PP65 Antibody detection It is done by ELISA, and the antibodies detected are CMV IgM antibodies. CMV IgG antibodies. Against PP150 and PP65. Against the PP52. PCR Used in detecting CMV DNA. Quantitative nucleic acid testing (QNAT) by PCR is the most sensitive and specific testing. Treatment Ganciclovir (drug of choice) Foscarnet (in Ganciclovir resistance) CMV immunoglobulins and Ganciclovir are given to bone marrow transplant patients. Incorrect Options: Human papillomavirus (Option A) is a sexually transmitted virus, including low-risk strains 6 & 11, causing benign genital warts, and high-risk strains 16 & 18 , linked to cervical carcinoma, vulvar intraepithelial neoplasia (VIN) and vulvar carcinoma. It is characterised by the presence of enlarged, hyperchromatic nuclei with perinuclear halos (koilocytes) in the superficial layers of the epithelium. {{caption_text}} Epstein-Barr virus (Option C) is primarily associated with infectious mononucleosis and certain lymphoproliferative disorders. It is characterised by ‘ Downey cells’, i.e. atypical lymphocytes (large, vacuolated) and Ballerina skirt appearance. {{caption_text}} Herpes simplex virus (Option D) causes vesicular lesions and is characterised by intranuclear inclusion bodies in infected cells. It is characterised by multinucleated giant cells with faceted nuclei and homogeneously stained 'ground-glass' chromatin (Tzanck cells) in the Tzanck smear and the formation of Lipschutz bodies (Cowdry type A). {{caption_text}}





Koilocytes showing perinuclear halo on pap smear

@Neet_pg_bot

Q12: CD markers can be detected by which of the following tests? (Q866390)

A. Cytogenetics

B. Next-generation sequencing

C. Flow cytometry

D. Karyotype

Correct Answer: C. Flow cytometry

Explanation: CD markers (Cluster of Differentiation) are surface proteins used to identify and classify immune cells, and they are typically detected using Flow Cytometry , which employs fluorescent-labeled antibodies. Principle : Detects physical and chemical characteristics of individual cells in a fluid stream using laser-based technology. Detects : CD markers (surface antigens) using fluorescent-labeled antibodies. Cell size, granularity, and fluorescence. Used in : Immunophenotyping (e.g., leukemia/lymphoma classification) Stem cell enumeration Monitoring HIV (CD4 count) Output : Dot plots or histograms showing expression of specific markers. Incorrect Options: Cytogenetics (Option A): Detects chromosomal abnormalities, not surface markers. Next-generation sequencing (NGS) (Option B): Detects gene mutations, not surface proteins. Karyotype (Option D): Analyzes chromosome structure and number, not proteins.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q13: In Pap smear cytology, which of the following is the most appropriate fixative used to preserve cellular details immediately after smearing? (Q866744)

A. 50% formaldehyde

B. 95% ethanol

C. 70% ethanol

D. 10% buffered formalin

Correct Answer: B. 95% ethanol

Explanation: 95% ethanol is the fixative used in a conventional pap smear. Fixatives are chemicals that preserve biological tissues by stabilizing cellular structures and preventing decay or degradation. The goal is to maintain the

tissue in a life-like state as much as possible for microscopic examination. Fixation helps maintain the tissue's integrity by preventing autolysis (self-digestion) and putrefaction (bacterial decay). Crosslinking Fixatives: These fixatives work by forming covalent bonds between the proteins and other cellular structures, effectively "locking" them in place. This preserves the tissue’s structural integrity. Formaldehyde: Most commonly used in the form of 10% neutral-buffered formalin. (Option D) Glutaraldehyde : Often used for electron microscopy due to its ability to preserve fine cellular structures. Osmium tetroxide : Used primarily for electron microscopy, particularly for preserving lipids and membranes. Precipitating Fixatives: These work by precipitating proteins and other cellular components, which makes them less soluble and helps preserve their structure. Methanol Ethanol Additive Fixatives: They chemically bind to tissue components, such as proteins or nucleic acids, and stabilise them. They are typically more gentle and produce better preservation of ultrastructure. Formaldehyde (Option A) Glutaraldehyde Non-Additive Fixatives: Alcohol Acetone Pap smear Site The transformation zone of the cervix, where the squamous epithelium (ectocervix) and columnar epithelium (endocervix) meet. This is the most common site for cervical cancer to develop. Instruments Ayre spatula collects cells from the ectocervix Cervical broom (also called a cytobrush) from the transition zone Endocervical brush from the endocervix Procedure Conventional Pap smear : Cells are collected with a spatula or brush, smeared onto a slide, and immediately fixed with a spray fixative or by immersing in 95% ethanol with/without ether Liquid-based cytology : Cells are collected and then rinsed into a liquid fixative vial. This is considered more sensitive than the conventional Pap smear as it provides a more uniform distribution of cells.

Q1: In which following layer of the epidermis would you most likely find the melanin-producing cells of the skin? (Q845865)

A. Stratum corneum

B. Stratum spinosum

C. Stratum granulosum

D. Stratum basale

Correct Answer: D. Stratum basale

Explanation: Stratum basale is the basal layer of the epidermis, which contains the melanin-producing melanocytes. Layers of the epidermis (superficial to deep) and their components: Stratum Corneum : Keratin and dead keratinocytes. (Option A) Stratum Lucidum : Eleidin (present in areas with thick skin- palms and soles) Stratum Granulosum : Granules of Keratohyalin (Option C) Stratum Spinosum : Dendritic cells (Option B) Stratum Basale / germinativum : Contains cuboidal to columnar mitotically active stem cells; it also contains melanocytes (Option D) Mnemonic : Come Let's Get Sun Burnt

@Neet_pg_bot

Q2: A 35-year-old male presents with a rash on his hands and feet characterised by clusters of small, fluid-filled blisters. Histopathological examination of a skin biopsy reveals intracellular oedema of keratinocytes. Which term best describes this histological finding? (Q845866)

A. Acanthosis

B. Ballooning

C. Spongiosis

D. Parakeratosis

Correct Answer: B. Ballooning

Explanation: The clinical presentation of small, fluid-filled blisters and the biopsy finding of intracellular oedema of keratinocytes are consistent with hydropic swelling, also known as ballooning . This condition is often seen in viral infections. Acanthosis (Option A): Diffuse thickening of the epidermis. Spongiosis (Option C): Intercellular oedema of the epidermis Parakeratosis (Option D): Retention of nuclei in the stratum corneum.

@Neet_pg_bot

Q3: A 10-year-old child exhibits rough, scaly skin on the elbows, knees, and trunk, accompanied by hyperkeratotic plaques. Which skin condition is typically associated with this manifestation of excessive keratin buildup? (Q845867)

A. Freckles

B. Lentigo

C. Nevus

D. Ichthyosis

Correct Answer: D. Ichthyosis

Explanation: Ichthyosis is an inherited skin disorder causing chronic hyperkeratosis, leading to dry, scaly skin due to defective shedding and retention of abnormal scales. Freckles (Option A): Freckles (Ephelides) are small tan-brown spots from increased melanin in basal cells after sun exposure; melanocyte numbers remain normal. Lentigo (Option B): Lentigo is a benign tan-brown spot from increased melanocytes in the basal layer that doesn’t darken with sun exposure. Nevus (Mole) (Option C): Nevi are benign melanocyte tumors caused by RAS pathway mutations, appearing as small, uniform pigmented spots without excess keratin.

@Neet_pg_bot

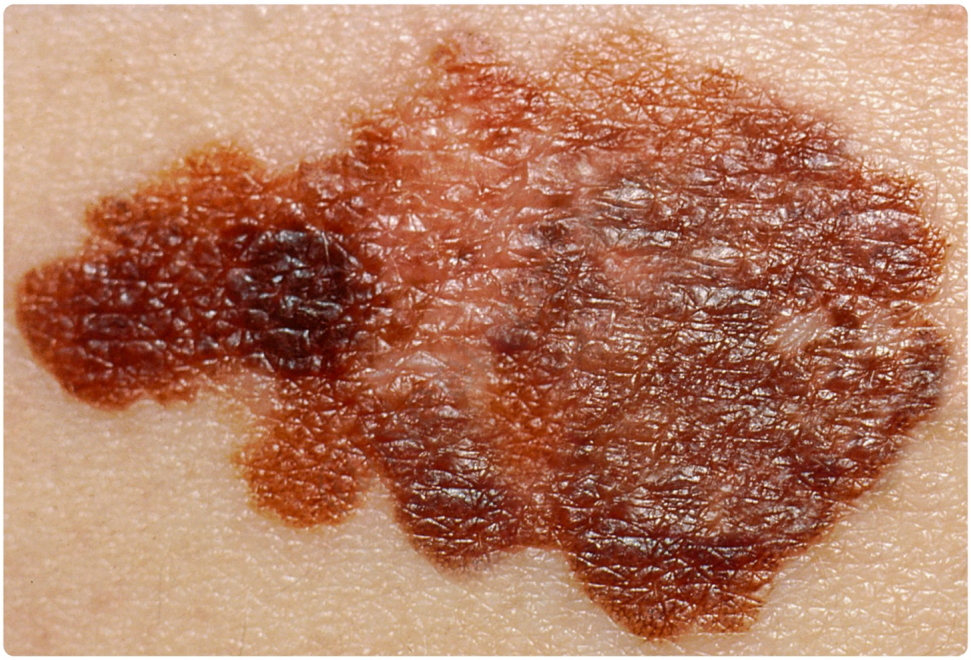
Q4: A 45-year-old woman presents with a dark, irregularly shaped mole on her back that has rapidly increased in size over the past few months. On examination, the lesion has uneven borders and varying shades of colour. Which of the following is true regarding its pathogenesis? (Q845868)

A. Associated with TERT mutations

B. Spreads radially with metastatic potential

C. Spreads vertically with no metastatic potential

D. Associated with mutations that decrease telomerase activity



@Neet_pg_bot

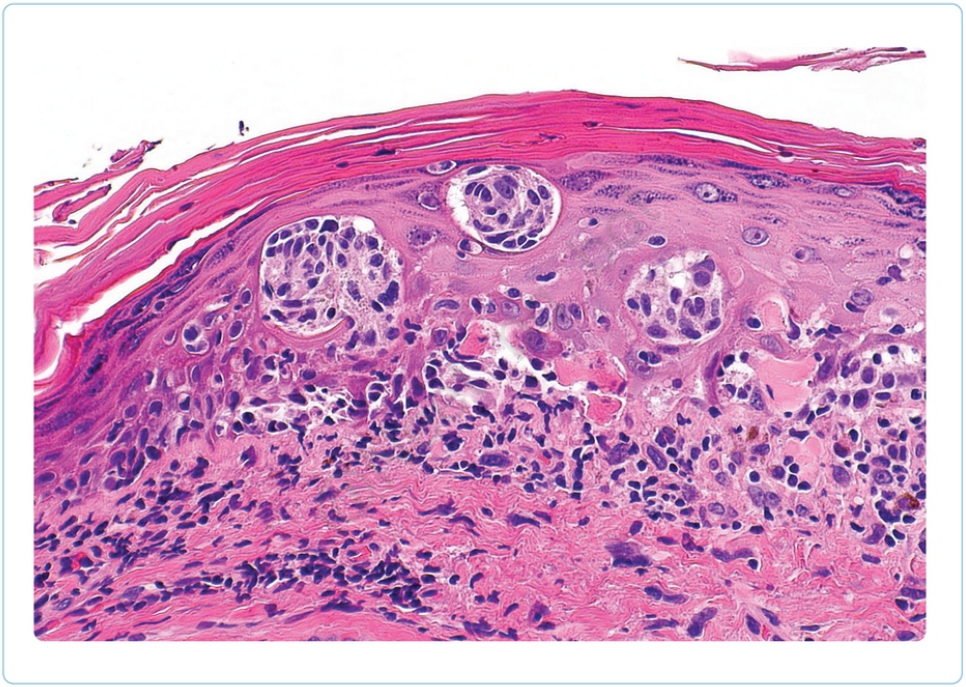
Correct Answer: A. Associated with TERT mutations

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: Malignant melanoma is characterized by the clinical presentation of a rapidly changing mole with irregular borders and varying color. It is often associated with activating mutation in the TERT gene , which is

responsible for increased telomerase activity (Ruled out Option D) . An activating mutation in the TERT gene reactivates telomerase (immortality gene), preventing cell death and leading to increased cell survival. They show two patterns of growth. Radially : Superficial spread on the epidermis and dermis, lack metastatic potential. (Option B) Vertical spread into the deep dermis, characterised by the appearance of a nodule, has metastatic potential. (Option C) ABCDE criteria of Melanoma: A - Asymmetry: One half doesn't match the other half in shape. B - Border: The edges of the mole are irregular rather than smooth and defined. C - Colour: Uneven colour. It may include different shades of brown, black, or tan. D - Diameter: Growns larger (about the size of a pencil eraser). E - Evolving: The mole changes in size, shape, colour, or appearance over time. On microscopy, they have enlarged nuclei and prominent red (eosinophilic) nucleoli with melanin pigment.



@Neet_pg_bot

Q5: A 70-year-old woman presents with a finding as shown in the image. A biopsy confirms basal cell carcinoma. Which molecular pathway is primarily involved? (Q845904)

A. Hippo pathway signaling

B. Hedgehog signaling pathway

C. WNT signaling

D. RAS/MAPK signaling

@Neet_pg_bot

Correct Answer: B. Hedgehog signaling pathway

Explanation: The hedgehog signaling pathway is associated with the pathogenesis of basal cell carcinoma, a locally aggressive cutaneous tumour. Hippo pathway signaling (Option A): It is seen in Neurofibromatosis type 2. WNT signaling pathway (Option C): WNT pathway, disrupted by APC mutations, drives familial polyps and cancers of the stomach, colon, pancreas, and melanomas. RAS/MAPK signaling (Option D): Inhibition of RAS/MAPK signaling is seen in Neurofibromatosis type 1.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q6: A 25-year-old woman presents with multiple basal cell carcinomas (BCCs) on her face, neck, and back. She also has a history of medulloblastoma, diagnosed during childhood. On examination, she has palmar pits and macrocephaly. Which of the following is not true regarding this syndrome? (Q845906)

A. Associated with odontogenic keratocysts.

B. Associated with mutations in the PTCH gene

C. An Autosomal dominant disorder

D. Associated with loss of nucleotide excision repair mechanism

Correct Answer: D. Associated with loss of nucleotide excision repair mechanism

■ *Listen (English)*

■ *Listen (Hindi)*

Explanation: The above clinical scenario is suggestive of Gorlin syndrome which is associated with mutations in the PTCH gene , a tumor suppressor gene. (Option B) The clinical presentation is suggestive of Gorlin syndrome , an autosomal dominant disorder (Option C) characterised by the development of multiple basal cell carcinomas. It also presents with various other tumours like medulloblastomas , bilateral ovarian fibromas , odontogenic keratocysts (Option A) and pits on the palms and soles . Loss of nucleotide excision repair mechanism is associated with Xeroderma pigmentosum and these patients are at increased risk of squamous cell and basal cell skin cancers due to exposure to UV light because of an inability to repair pyrimidine dimers. (Option D)

References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 1147, 315

↑ *Back to this question in Part A*

@Neet_pg_bot

Q7: A 72-year-old man with a history of extensive sun exposure and recent organ transplant presents with a rapidly growing, painless, reddish nodule on his left cheek over two months. Biopsy shows small, round blue cells with salt and pepper chromatin and positivity for neuroendocrine markers. What marker is typically associated with this condition? (Q845908)

A. S-100

B. CK20

C. Melan-A

D. p40

Correct Answer: B. CK20

Explanation: The given clinical scenario points towards the diagnosis of Merkel cell carcinoma, which is an aggressive neuroendocrine skin cancer marked by rapid growth, early metastasis, and high mortality. Risk factors: Immune suppression, sun exposure, and advanced age. It appears as a fast-growing, firm nodule on sun-exposed skin. CK20 with perinuclear dot staining is a key diagnostic marker. S-100 (Option A) and Melan-A (Option C) are more useful in the diagnosis of Melanoma. p40 (Option D) is a marker commonly used in diagnosing squamous cell carcinoma.

@Neet_pg_bot

@Neet_pg_bot

Correct Answer: B. a-2, b-3, c-4, d-1

Listen to Audio 1

Explanation: Psoriasis is an autoimmune chronic inflammatory dermatosis. Clinical manifestations include skin changes such as itchy, silvery scales over salmon-pink plaques, with pinpoint bleeding upon scraping (Auspitz Sign). Histopathology of psoriasis: Parakeratosis: Retention of nuclei in the stratum corneum cells. Munro's microabscess : Collection of neutrophilic infiltrates in the Stratum corneum. Spongiform pustules of Kogoj: Collection of inflammatory cells in the Stratum spinosum. Presence of evenly elongated, thin rete ridges with equally long dermal papillae.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Pages 1157-1158

↑ *Back to this question in Part A*

@Neet_pg_bot

Q9: A 45-year-old female presents to the dermatology clinic with an itchy rash on her wrists and ankles. On examination, small, flat-topped, polygonal, purple papules with fine white lines on their surface are noted. Which of the following is a characteristic histological finding in this condition? (Q845911)

A. Munro microabscesses

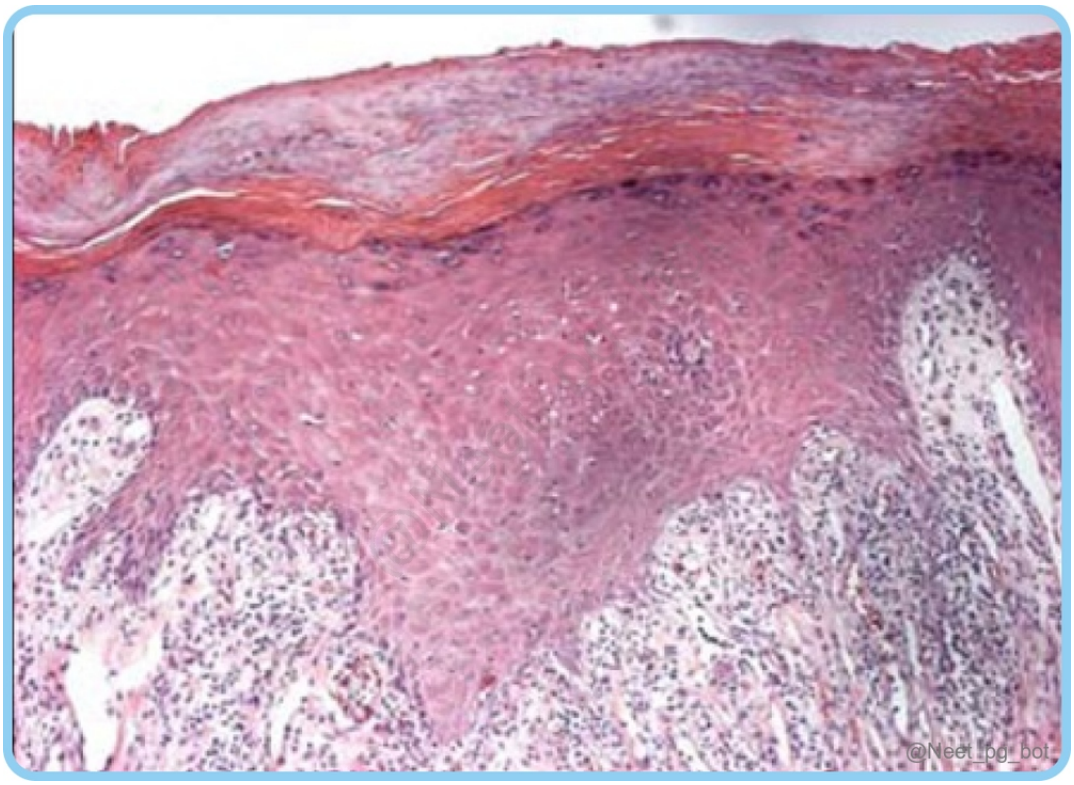
B. Spongiform pustules

C. Sawtoothing of the dermo-epidermal junction

D. Follicular lipping

Correct Answer: C. Sawtoothing of the dermo-epidermal junction

Explanation: The clinical signs and biopsy suggest lichen planus, a skin condition with itchy, purple, flat-topped bumps that may join into plaques, featuring fine white lines called Wickham striae. Lichen planus usually appears symmetrically on wrists, elbows, and limbs, often involving the mouth. Under the microscope, there is a dense lymphocyte layer at the dermo-epidermal junction, creating a sawtooth pattern. Munro microabscesses (Option A) are neutrophil clusters in the outer skin layer, seen in psoriasis. Spongiform pustules (Option B) are neutrophil clusters in the skin’s outermost layer, typical of psoriasis . Follicular lipping (Option D) is neutrophil-rich parakeratosis at hair follicles, seen in seborrheic dermatitis .



References:

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1158

en.wikipedia.org/wiki/Lichen_planus

↑ *Back to this question in Part A*

Q10: A 55-year-old man presents with widespread blistering of the skin and oral mucosa. Skin biopsy reveals acantholysis and intraepidermal blister formation above the basal layer. Which of the following describes the location of the split in this bullous disorder? (Q845912)

A. Subcorneal split

B. Suprabasal split

C. Subepidermal split

D. Intraepidermal split

Correct Answer: B. Suprabasal split

Explanation: The given clinical scenario is consistent with Pemphigus vulgaris, which causes a suprabasal split above the basal layer due to autoantibodies against desmoglein, leading to loss of cell adhesion (acantholysis) and blistering. Subcorneal split (Option A) occurs just below the stratum corneum and is typical of pemphigus foliaceus. Subepidermal split (Option C) is a split in bullous pemphigoid caused by autoantibodies against basement membrane proteins, leading to blistering below the epidermis. Junctional split (Option D) occurs at the lamina lucida in the basement membrane, causing fragile skin blisters in junctional epidermolysis bullosa.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1159

↑ *Back to this question in Part A*

@Neet_pg_bot

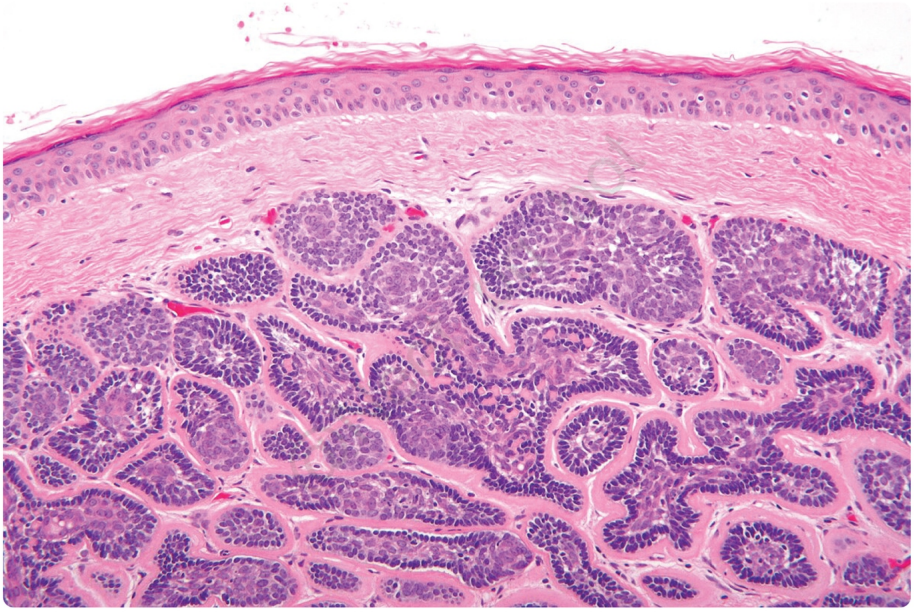
Q11: A 45-year-old woman presents with a slow-growing, painless nodule on her scalp that has recently enlarged. Examination reveals a firm, well-circumscribed nodule. Histopathology shows ductal differentiation with multiple cysts and papillary projections. Which of the following is the most likely diagnosis? (Q845913)

A. Cylindroma

B. Pilomatrixoma

C. Syringoma

D. Trichilemmoma



@Neet_pg_bot

Correct Answer: A. Cylindroma

■ *Listen to Audio 1*

Explanation: The clinical and histological features described in the scenario are consistent with Cylindroma , benign skin tumours that often appear on the head and neck area. They exhibit ductal differentiation and histologically present as basaloid cell islands fitting together like a " jigsaw puzzle " within a fibrous stroma. These tumours can merge over time to form larger, turban-like growths . They may be inherited in an autosomal dominant fashion due to mutations in the CYLD gene . Cylindromas are also associated with Brooke-Spiegler syndrome , characterized by the occurrence of multiple adnexal tumours, including cylindromas, trichoepitheliomas, and spiradenomas. Pilomatrixoma (Option B) are benign tumours derived from hair matrix cells. Histologically, they are characterized by ghost cells . Syringomas (Option C) are benign tumours of eccrine sweat glands. Histologically, syringomas are characterized by comma-shaped or tadpole-like projections when viewed under a microscope. Trichilemmomas (Option D) are benign tumours arising from the outer root sheath of hair follicles and are associated with Cowden syndrome . Histologically, they exhibit clear cells and peripheral palisading, resembling the outer root sheath.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q12: A 38-year-old man complains of severe itching and recurrent skin lesions on his elbows, knees, and upper back. His medical history includes occasional gastrointestinal discomfort. Examination reveals bilateral, symmetric lesions with grouped vesicles. Skin biopsy reveals small microabscesses at the tips of dermal papillae. Which of the following is associated with a disease condition? (Q845916)

A. Associated with Crohn's disease

B. IgA deposits at dermal papilla tips

C. Subendothelial blisters

D. Linear deposits in immunofluorescence

Correct Answer: B. IgA deposits at dermal papilla tips

Explanation: Based on the given scenario and biopsy findings, the likely diagnosis is Dermatitis herpetiformis, characterized by urticaria and grouped vesicles, often presents with bilateral, symmetric lesions involving the extensor surfaces Linear deposits in immunofluorescence (Option D): Direct IF in dermatitis herpetiformis shows granular deposits of IgA, not linear deposits. Associated with Crohn's disease (Option A): Dermatitis herpetiformis is primarily associated with Celiac disease . Subendothelial blisters (Option C): HPE of Dermatitis herpetiformis shows subepidermal blisters with fibrin and neutrophil microabscesses at dermal papillae tips.

Robbins and Cotran Pathologic Basis of Disease, 10th Edition, Page 1163

↑ *Back to this question in Part A*

Q13: A 3-year-old child has a chronic, non-healing scalp rash, showing red-brown papules and plaques with crusting on examination. Electron microscopy reveals tennis racket-like structures in histiocytes cytoplasm, and immunohistochemical staining confirms CD1a and S100 protein presence. Which mutation is likely associated with this condition? (Q845918)

A. TP53 mutation

B. RAS mutation

C. BRAF mutation

D. MET mutation

Correct Answer: C. BRAF mutation

■ *Listen to Audio 1*

Explanation: The clinical presentation and electron microscopy findings suggest the diagnosis of Langerhans cell histiocytosis (LCH) The mutation associated with LCH is the BRAF V600E mutation . Forms of LCH : Letterer–Siwe disease → involves liver and skin . Eosinophilic granuloma → shows eosinophils and

microscopically coffee-bean nuclei . Hand–Schüller–Christian disease → Triad: B, C = Bone Calvarial defects (skull/scalp bone lesions). D = Diabetes insipidus . E = Exophthalmos . Immunohistochemistry (IHC) tests show these cells are positive for CD1a, CD207 (langerin), S100, and HLA-DR . Electron microscopy , considered the gold standard for diagnosis , reveals the characteristic tennis racket appearance of Birbeck granules. TP53 mutation (Option A): This is the "guardian of the genome" and is associated with Li-Fraumeni Syndrome and a vast array of common malignancies, but it is not a primary driver of LCH. RAS mutation (Option B): While part of the same MAPK pathway, RAS mutations are typically associated with melanomas or leukemias rather than the specific histiocytic proliferation seen here. MET mutation (Option D): This is a tyrosine kinase receptor mutation most commonly linked to Papillary Renal Cell Carcinoma (Type 1) or subsets of Non-Small Cell Lung Cancer.

↑ *Back to this question in Part A*

@Neet_pg_bot

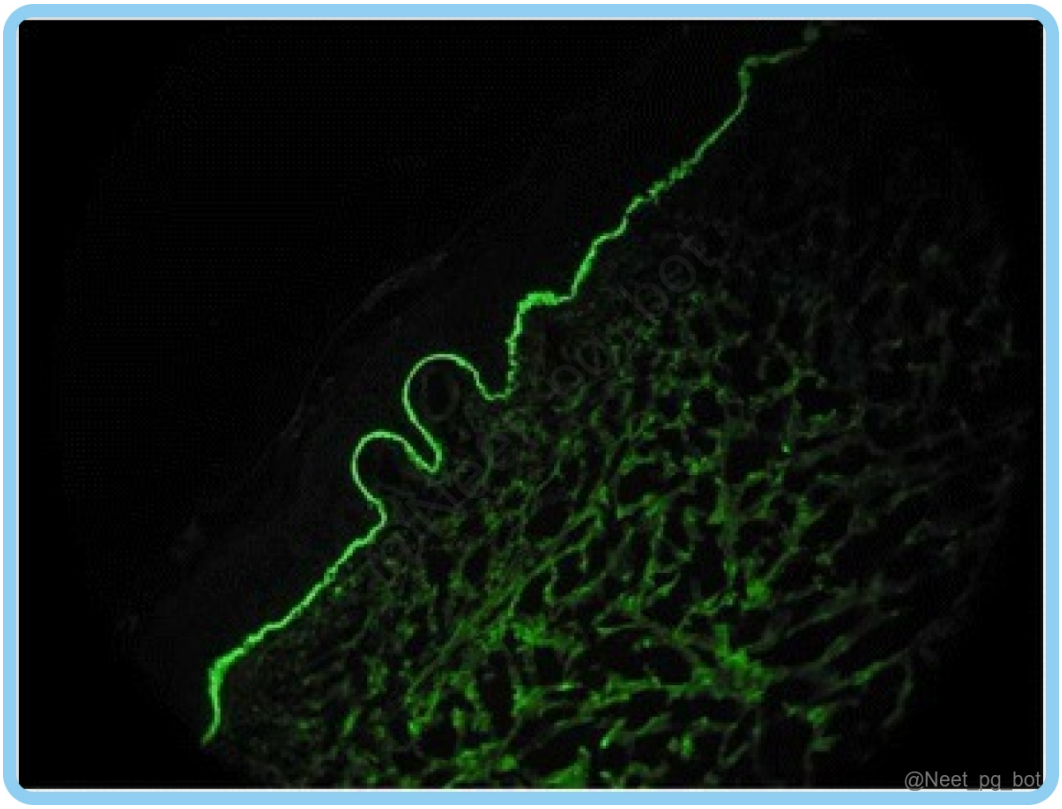
Q14: A 65-year-old male presents with tense blisters on his abdomen and extremities, filled with clear fluid. The skin appears normal between the blisters, which are painful but not itchy. A skin biopsy reveals a subepidermal blister with linear IgG and complement deposition along the basement membrane on direct immunofluorescence as shown in the image. What is the most likely diagnosis? (Q845920)

A. Epidermolysis Bullosa Acquisita

B. Bullous Pemphigoid

C. Pemphigus Vulgaris

D. Dermatitis Herpetiformis



Correct Answer: B. Bullous Pemphigoid

■ *Listen to Audio 1*

Explanation: Bullous pemphigoid: Has subepidermal split Antibodies are against hemidesmosomes , and IgG is deposited linearly along the roof of the bulla . Commonly seen in: Flexor aspect of the forearm, Axilla, and Groin Under Immunofluorescence : Linear Immunofluorescence/ Ribbon candy appearance Epidermolysis Bullosa Acquisita (Option A): It also has subepidermal split but antibodies are against collagen VII , and IgG is deposited along the floor of the bulla . Epidermolysis bullosa acquisita (Option A) : Typical presentation includes trauma-induced blistering, and direct immunofluorescence would show IgG targeting type VII collagen. Direct IMF displaying linear deposition of IgG, IgA, and C3 at the basement membrane zone. Pemphigus Vulgaris (Option C) is an autoimmune blistering disorder characterized by intraepithelial blisters. Dermatitis Herpetiformis (Option D): In dermatitis herpetiformis, the deposited immunoglobulin is IgA , and it tends to deposit in the dermal papillae , forming tip lesions. It is also commonly associated with GI disorders , particularly celiac disease .

Q1: A child presents with skin eruptions upon exposure to sunlight and is diagnosed with a DNA repair defect. Which type of repair defect is most likely responsible? (Q844175)

A. Nucleotide excision repair defect

B. Base excision repair defect

C. Mismatch repair defect

D. Recombination repair defect

Correct Answer: A. Nucleotide excision repair defect

Explanation: Correct Option A - Nucleotide excision repair defect: Xeroderma pigmentosa is caused by a defect in nucleotide excision repair, leading to an inability to repair UV-induced DNA damage, which results in extreme sensitivity to sunlight and a high risk of skin cancers. Incorrect Options: Options B, C, and D do not cause xeroderma pigmentosa.

↑ *Back to this question in Part A*

@Neet_pg_bot

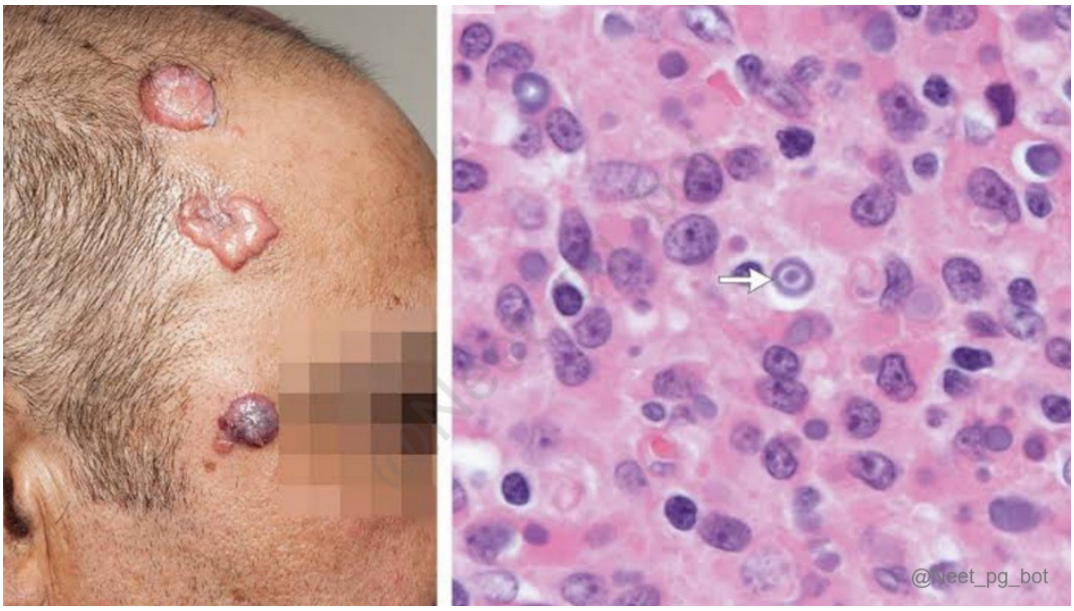
Q2: Identify the diagnosis based on the image provided: (Q844180)

A. Tuberculosis (TB)

B. Malakoplakia

C. Pyoderma gangrenosum

D. Squamous cell carcinoma (SCC)



Correct Answer: B. Malakoplakia

Explanation: Correct Option B – Malakoplakia: The given microscopy image reveals Michaelis Guttman bodies, along with cutaneous malakoplakia on the scalp region. Incorrect Options: Options A, C, and D do not show Michaelis Guttman's bodies.

.

↑ *Back to this question in Part A*

@Neet_pg_bot

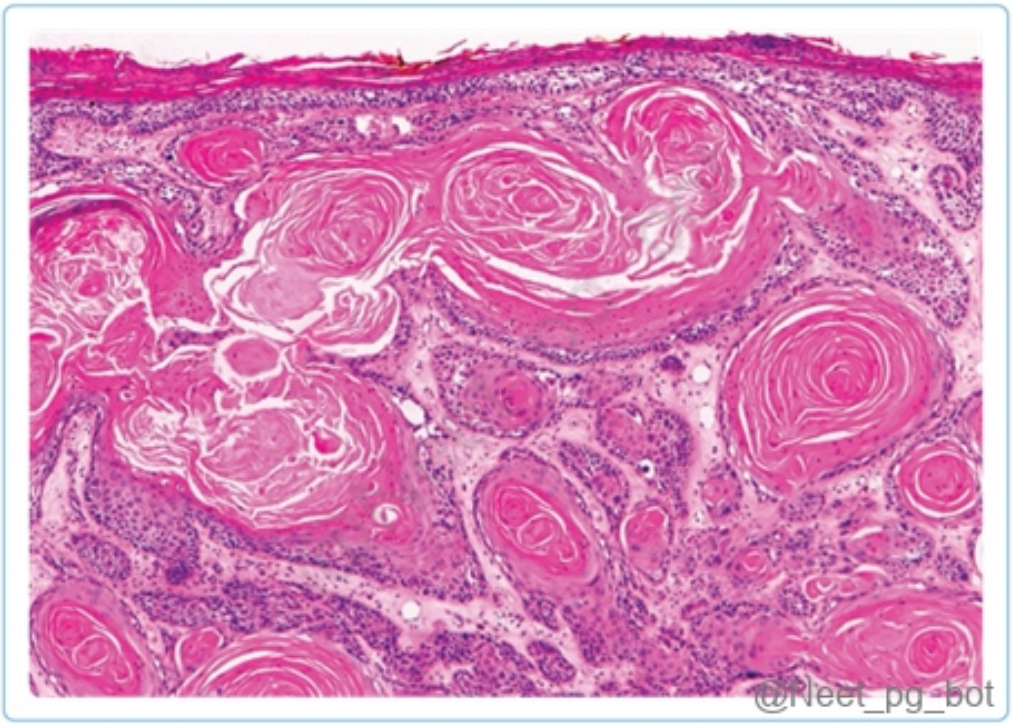
Q3: A farmer has a lesion on the shoulder. What is the most likely diagnosis based on the histopathological image of the lesion given below? (Q860532)

A. SCC

B. BCC

C. Molluscum contagiosum

D. Verrucous carcinoma



Correct Answer: A. SCC

Explanation: The histopathological image showing keratin pearls on histopathology is suggestive of Squamous Cell Carcinoma (SCC) . It is a malignant tumour originating from epidermal keratinocytes. It is the second most common skin tumour after basal cell carcinoma (BCC). SCC is notably the most common skin tumour in immunocompromised individuals . Predisposing factors include UV exposure, immunosuppression, and conditions like xeroderma pigmentosum, albinism, LP, and DLE, which can rarely progress into SCC. Clinical features: It typically exhibits a lower rate of local, regional, and distant spread compared to other skin malignancies. Associated with immunocompromised states such as HIV infection and renal transplant recipients. It presents as papules, nodules, or plaques with induration and signs of photodamage like crusting and scaling. {{caption_text}} Histopathological examination reveals characteristic keratin pearls . {{caption_text}} Treatment: Primary treatment involves wide surgical excision with margins. Advanced cases may require radiation or chemotherapy. BCC (Basal Cell Carcinoma) (Option B) is the most common type of skin cancer , originating from the basal cells in the epidermis. It is typically slow-growing, often appearing as a painless, pearly nodule with telangiectasias on sun-exposed areas like the face. Histologically, BCC is characterised by nests of basaloid cells with a palisading pattern at the periphery, fibrotic stroma, and clefting between the tumour and surrounding tissue. {{caption_text}} Molluscum contagiosum (Option C) is a viral skin infection causing small, flesh-coloured lesions with central umbilication, often in children and immunocompromised individuals. Histologically, it shows epidermal hyperplasia, ballooning keratinocytes, and Henderson-Patterson (HP) bodies in cup-shaped spaces. {{caption_text}} Verrucous carcinoma (Option D) is a rare, low-grade squamous cell carcinoma often found in areas with chronic irritation (e.g., oral cavity, genitals). It presents as a slow-growing, wart-like lesion and is associated with HPV infection. Histopathologically, it shows exophytic growth, thick keratinisation, well-differentiated squamous cells, and pushing borders with minimal atypia. {{caption_text}}

@Neet_pg_bot

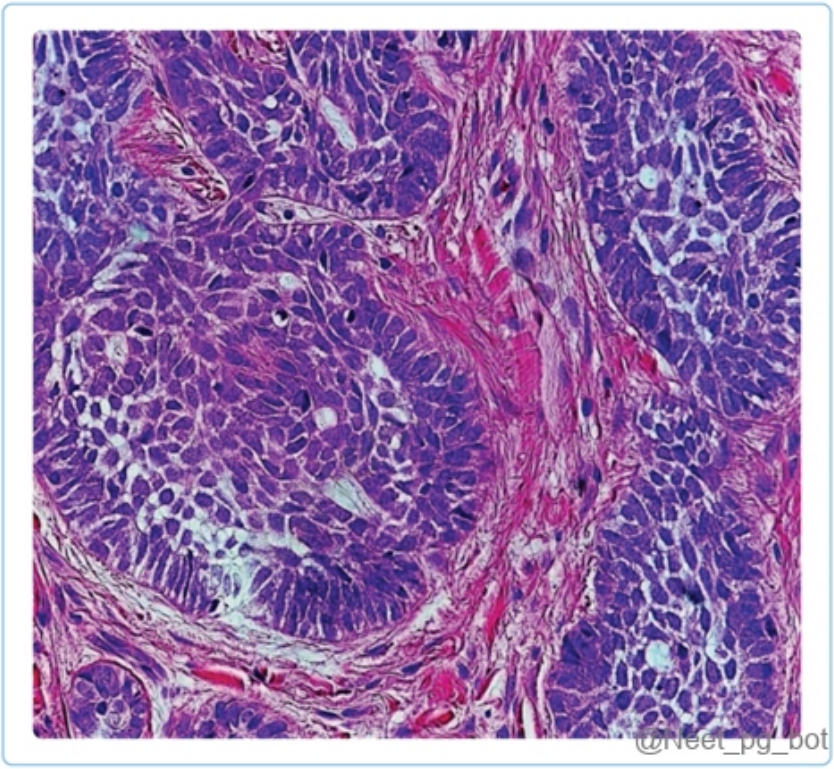
Q4: Identify the histopathological image. (Q860535)

A. Basal cell carcinoma

B. Squamous cell carcinoma

C. Adenocarcinoma

D. Malignant melanoma



Correct Answer: A. Basal cell carcinoma

Explanation: The histopathological image of the skin biopsy reveals nests of basaloid cells with peripheral palisading and a distinctive stromal retraction artefact, characteristic of Basal Cell Carcinoma (BCC), also known as Rodent Ulcer. It is the most common type of skin cancer and is typically seen in sun-exposed areas of the skin. It is a slow-growing, locally invasive tumour, and it rarely metastasises. Origin: Arises from pluripotent cells within the basal layer of the epidermis or follicular structures. Pathogenesis: Site: Face, Around eyes, Nose Clinical Features It presents initially small, scaly plaque. They present as pearly papules containing dilated blood vessels (telangiectasias) They may ulcerate locally and invade the underlying bone or facial sinuses (rodent ulcers). Slow progressive course of peripheral extension. {{caption_text}} Histologically: The tumour cells are basophilic cells with hyperchromatic nuclei (basaloid cells) arranged in clusters with a palisading pattern . The stroma sometimes retracts from the malignant cells. {{caption_text}} Treatment Medical: Imiquimod, 5-FU,Intralesional interferon α-2b Hedgehog pathway inhibitors:(Vismodegib) Surgical: Mohs micrographic surgery, Done in recurrent BCCs. Squamous cell Carcinoma (Option B) typically exhibits keratin pearls and intercellular bridges, features not present in the image provided. Additionally, the cells are generally larger and have more abundant cytoplasm, unlike the smaller basaloid cells seen in BCC. {{caption_text}} Adenocarcinoma (Option C) arises from glandular epithelium and shows glandular structures or mucin production. {{caption_text}} Malignant Melanoma (Option D) is characterised by atypical melanocytes, which can be seen in various configurations, such as nests or single cells within the epidermis and dermis. These cells often contain melanin pigment. {{caption_text}}

@Neet_pg_bot

Q5: An 8-year-old boy presents with progressive muscle weakness and walking difficulties. On examination, pseudohypertrophy of the calf muscles was noted. Which

of the following is true regarding this condition? (Q858113)

A. Abnormal collagen

B. Absent dystrophin

C. Expansions of CAG triplet repeats

D. Defective fibrillin

Correct Answer: B. Absent dystrophin

Explanation: The patient described is likely suffering from Duchenne muscular dystrophy (DMD) , a genetic disorder characterised by progressive muscle weakness, particularly in the lower limbs, with pseudohypertrophy of the calf muscles . This condition is caused by a mutation in the dystrophin gene , resulting in the absence or severe deficiency of dystrophin , a protein that helps anchor the muscle cell membrane. Aspect Duchenne Muscular Dystrophy (DMD) Type of Mutation Frameshift mutations lead to a disrupted reading frame Dystrophin Protein Dystrophin deficient Truncated and unstable (< 3% of normal) Clinical Severity Severe, early onset, rapid progression Inheritance Pattern X-linked recessive. Age of onset Early childhood (Before 5 years) Incorrect Options: Abnormal collagen (Option A) would be more consistent with conditions like Ehlers-Danlos syndrome or osteogenesis imperfecta , which involve defective collagen synthesis. Dystrophinopathies, like DMD, do not primarily involve collagen. Expansion of CAG triplet repeats (Option C) can cause Huntington's disease or fragile X syndrome, but DMD is caused by a mutation in the dystrophin gene , not CAG repeats. Defective fibrillin (Option D) is the cause of Marfan syndrome , which affects connective tissue and is characterized by features like tall stature, long limbs, and aortic dissection, but it is not involved in muscle degeneration like DMD.

@Neet_pg_bot

Q6: A patient underwent surgery for lipoma 5 weeks ago and now presents with a scar at the incision site, which is limited to the original wound boundaries. What is the most likely diagnosis? (Q857162)

A. Keloid

B. Exuberant granulation

C. Hypertrophic scar

D. Granulation tissue

Correct Answer: C. Hypertrophic scar

Explanation: The most likely diagnosis is a hypertrophic scar, characterised by a raised scar confined to the original wound boundaries, unlike keloids that extend beyond the wound. It is marked by excess collagen, rapid growth, and the presence of myofibroblasts. Hypertrophic scars tend to regress over time and recur less frequently than keloids. {{caption_text}} Keloid: (Option A) Scar grows beyond the original wound boundaries and doesn’t regress. More common among African Americans. Develops after deep dermal injuries. {{caption_text}} Exuberant Granulation Tissue: (Option B) {{caption_text}} Excessive granulation tissue above skin level. Blocks reepithelialisation (also called "proud flesh"). Requires cauterisation or surgical excision for healing Contractures: {{caption_text}} Abnormal tightening of the wound and surrounding tissues. Common in palms, soles, and chest. Seen in severe burns, it may impair joint movement.

@Neet_pg_bot

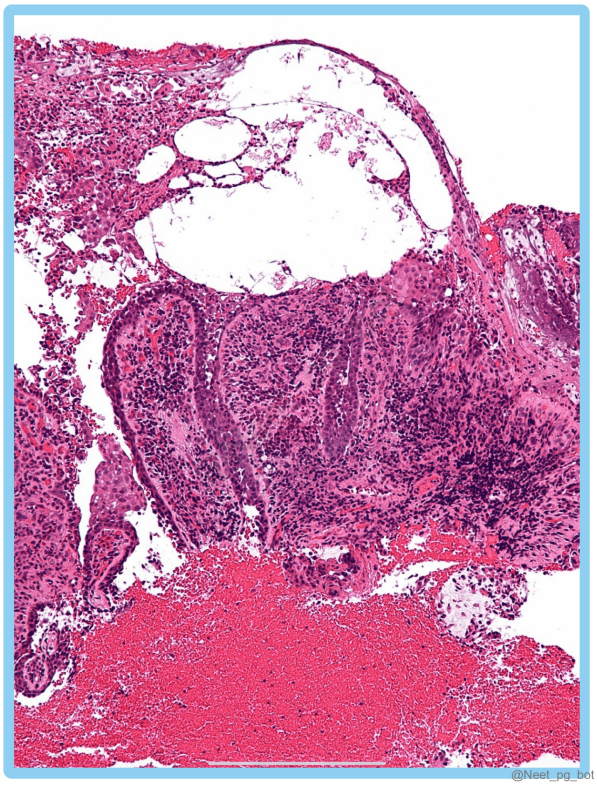
Q7: Identify the given condition. (Q856687)

A. Pemphigus Vulgaris

B. Leprosy

C. Mycosis fungoides

D. Visceral leishmaniasis



Correct Answer: A. Pemphigus Vulgaris

Explanation: The histopathological image shows Pemphigus Vulgaris (PV) , with intraepidermal cleavage and acantholysis in the suprabasal layer, along with a "row of tombstones" appearance due to the separation of basal keratinocytes at the basement membrane zone. It is the most common chronic autoimmune blistering disease caused by antibodies against desmosomal adhesion proteins. The target antigens for PV are most commonly Desmoglein 3 and sometimes Desmoglein 1. Clinical features: Flaccid blisters filled with clear fluid present on normal skin or an erythematous base. The blisters rupture, producing painful erosion. {{caption_text}} Mucosal involvement is a very important and one of the distinguishing features of PV. {{caption_text}} {{caption_text}} Histopathology: Intraepidermal cleavage with acantholysis (detached keratinocytes) primarily localized to the suprabasal region. Separation of basal keratinocytes along the basement membrane zone, resulting in an appearance that resembles a "row of tombstones". {{caption_text}} Leprosy (Option B) , also known as Hansen's disease , is a chronic infection caused by Mycobacterium leprae , affecting the skin, peripheral nerves, and mucous membranes. Tuberculous leprosy shows granulomatous lesions similar to tuberculosis, while lepromatous leprosy features lipid-laden macrophages (lepra cells) containing "globi" of acid-fast bacilli. {{caption_text}} {{caption_text}} Mycosis fungoides (Option C) is the most common type of cutaneous T-cell lymphoma. It presents with a variety of skin lesions, including patches, plaques, and tumours. Histologically, the epidermis and upper dermis are infiltrated by neoplastic T cells, which often have a cerebriform appearance due to marked infolding of the nuclear membrane. {{caption_text}} Visceral leishmaniasis (Option D) , also known as kala-azar, is a systemic parasitic infection caused by Leishmania species. It is characterized by granulomatous inflammation, phagocytosed parasites, hyperplasia of the reticuloendothelial system, necrosis with fibrosis, and hemophagocytosis, where macrophages engulf red blood cells, white blood cells, or platelets. {{caption_text}}

@Neet_pg_bot

Q8: A 5-year-old child who presented with proptosis of one of the eyes was found to have a desmin-positive tumour. What is the probable diagnosis? (Q856705)

A. Ewing’s sarcoma

B. Embryonal rhabdomyosarcoma

C. Leukaemia

D. Retinoblastoma

Correct Answer: B. Embryonal rhabdomyosarcoma

Explanation: The clinical presentation of a 5-year-old child with proptosis and a desmin-positive tumour suggests embryonal rhabdomyosarcoma (RMS). Desmin is a marker for muscle differentiation, and rhabdomyosarcoma, a malignant tumour of skeletal muscle origin, is common in children and can present with proptosis if it involves the orbit. Rhabdomyosarcoma (RMS) Origin A malignant tumour arising from skeletal muscle progenitors Types Embryonal rhabdomyosarcoma. Alveolar rhabdomyosarcoma. Pleomorphic rhabdomyosarcoma. Spindle cell/sclerosing rhabdomyosarcoma Clinical features It is the most common soft tissue sarcoma in children and adolescents. It commonly presents in the extremities. Pediatric rhabdomyosarcomas mostly arise in the sinuses, head and neck, and genitourinary tract. IHC Positive Markers Desmin Myogenin MyoD1 Muscle-specific actin Gross appearance The tumours are often large, soft, and infiltrative, with areas of necrosis and haemorrhage. Microscopy Small, round to spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm, sometimes with a myxoid stroma, are also seen. {{caption_text}} Ewing’s sarcoma (Option A) is a malignant tumour typically affecting bones or soft tissues, often seen in children and adolescents. It is characterized by a specific genetic translocation (t(11;22)) and is usually not associated with desmin positivity, which is more typical of rhabdomyosarcoma. Ewing's sarcoma may cause localized swelling or pain but rarely presents with proptosis unless it involves the orbit or surrounding tissues. It is composed of sheets of uniform, small, round cells with scant cytoplasm that may be clear due to abundant glycogen. Leukaemia (Option C) is a type of cancer that affects the blood and bone marrow, leading to the uncontrolled production of abnormal white blood cells. It typically doesn't present with localized tumours or proptosis. However, in cases of leukemic infiltration of the orbit, proptosis may occur, though it's relatively rare. Retinoblastoma (Option D) is a malignant eye tumour that primarily affects young children, often before the age of 5. While it can cause proptosis due to orbital involvement, it is typically not associated with a desmin-positive tumour. Retinoblastoma usually presents with a white reflex in the pupil (leukocoria) and can cause vision problems or strabismus.

@Neet_pg_bot

Q9: Which connective tissue disorder is not associated with aneurysm formation? (Q840020)

A. Marfan syndrome

B. Scurvy

C. Atherosclerosis

D. Ehler-Danlos syndrome

Correct Answer: B. Scurvy

Explanation: Scurvy is caused by vitamin C deficiency , leading to defective collagen synthesis. Although it causes fragile blood vessels, petechiae, and poor wound healing, it does not typically cause aneurysm formation. The vascular issues are mainly due to impaired collagen cross-linking, not structural weakness severe enough to form aneurysms. Incorrect Options: Option A) Marfan syndrome: Causes cystic medial necrosis of the aorta →

high risk of aortic aneurysm and dissection . Option C) Atherosclerosis: Weakens the arterial media → most common cause of abdominal aortic aneurysm . Option D) Ehlers–Danlos syndrome: Defective type III collagen → predisposes to vascular aneurysms and ruptures

Q1: For testing blood clotting/ coagulation parameters, blood is collected in which color-coded vacutainer tube? (Q866663)

A. Red

B. Green

C. Blue

D. Gray

Correct Answer: C. Blue

Explanation: The light blue Vacutainer contains sodium citrate as an anticoagulant and is specifically used for coagulation studies, such as Prothrombin Time (PT) and Activated Partial Thromboplastin Time (aPTT). The anticoagulant preserves the coagulation factors for accurate testing. Colour Anti-coagulants Uses Purple/Lavender EDTA (Ca2+ chelating anticoagulant) CBC, Peripheral Smear, ESR, HbA1c Light Blue (Option B) Citrate (Ca2+ chelating anticoagulant) ESR, PT, aPTT Red (Option A) No anti-coagulant is added Serum studies (Proteins, enzymes, hormones) Yellow Clot activator/Gel separator Serum studies (Proteins, enzymes, hormones) Grey (Option D) Sodium Fluoride Blood Glucose Green (Option B) Heparin ABG, Osmotic fragility, flow cytometry, immunophenotyping

@Neet_pg_bot

Q2: Basophilic stippling of red blood cells is most characteristically seen in which of the following conditions? (Q866743)

A. Iron deficiency anaemia X

B. Lead poisoning

C. Megaloblastic anemia

D. Hereditary spherocytosis

Correct Answer: B. Lead poisoning

Explanation: Basophilic stippling is a characteristic haematological finding in lead toxicity. Acute lead poisoning It’s rare, and there may be exacerbations of chronic lead poisoning. Symptoms: Astringent or metallic taste, dry throat, thirst, burning abdominal pain, nausea, vomiting, diarrhoea, peripheral circulatory collapse, paraesthesia, depression, coma, and death. Chronic lead poisoning (also known as Plumbism or Saturnism) Clinical manifestations Description Facial pallor It is caused by vasospasm and specifically occurs circumorally , which is the earliest and most specific feature. Anemia Type: Microcytic-hypochromic . Enzymes inhibited: Ferrochelatase

ALA-dehydratase Coproporphyrinogen oxidase Blood picture: Cabot rings in RBCs Microcytic-hypochromic Sideroblasts (nucleated red cells) Anisocytosis Poikilocytosis Polycythemia Basophilic stippling or Punctate basophilia Multiple blue-coloured pinhead dots in RBCs due to the toxic action of lead on porphyrin metabolism (inhibition of enzyme 5- Pyrimidine nucleotidase) (PNN). Accumulation of ribosomes in RBC Lead line or Burtonian lines The stippled blue line observed on the gums, resulting from a subepithelial deposit of granules that develops within one week, is seen in 50-70% of cases and is more common in individuals with carious teeth (bacteria form lead sulfide). Lead osteopathy/Lead line (Bone-line) In children, calcium deposition occurs at the growth plates of bones (specifically the lower end of the femur and the upper end of the tibia), which appears as a radiopaque band and occurs over 4 weeks due to the inhibition of osteoclastic activity. Colic and constipation (Painter's Colic or Devonshire colic) Late presentation occurs in 85% of cases, typically at night, and is characterised by spasmodic pain relieved by pressure. Lead palsy Predominantly motor features include: Dry belly ache Wrist drop (Radial nerve) Foot drop (Common peroneal nerve) Encephalopathy This condition is seen in nearly all cases, is associated with tetraethyl lead exposure, primarily affects children, results in permanent brain damage in 85% of cases, and accounts for 25% of fatalities. Reproductive system Amenorrhea Dysmenorrhea Abortion Sterility derangements (both sexes) Cardiovascular system and Kidneys Hypertension (vascular constriction) Permanent arteriolar degeneration Nephritis Gout Saturnine gout (due to decreased excretion of uric acid) Others These include generalised weakness, anorexia, dyspepsia, emaciation, exhaustion, irritability, foul breath, headache, vertigo, alopecia, and dizziness. Conditions associated with Basophilic stippling: Lead poisoning Thalassemia (Beta-thalassemia) Sideroblastic anemia Arsenic poisoning Alcoholism Pyrimidine 5′-Nucleotidase deficiency Megaloblastic anemia Severe infections (e.g., malaria) Myelodysplastic syndromes Chronic inflammatory conditions Iron deficiency anaemia (Option A): microcytic hypochromic cells, but no basophilic stippling. Megaloblastic anaemia (Option C) : macrocytosis with hypersegmented neutrophils, no stippling. Hereditary spherocytosis (Option D): spherocytes, increased MCHC, but no stippling.

Q3: A chronic smoker presents with a whitish exophytic lesion over the vocal cords, as shown in the image below. During direct laryngoscopy, the ENT surgeon applies a dye to help identify areas of dysplasia and select the most appropriate biopsy site. Which stain is being used? (Q844052)

A. Supravital stain

B. Congo red

C. Hematoxylin and eosin (H&E)

D. Oil red O

Correct Answer: A. Supravital stain

Explanation: The given image shows a laryngeal mass, for which toluidine blue is used for identification, and it is a supravital stain. Commonly used during oral and laryngeal examinations to highlight dysplastic and malignant areas, especially in smokers. It binds strongly to acidic nuclear material (DNA/RNA), which is increased in premalignant and malignant cells due to higher mitotic activity. Thus, abnormal mucosa appears dark blue, while normal mucosa remains unstained. This helps clinicians identify the most suspicious areas and choose the optimal site for biopsy. Biopsy with H&E is still the final diagnostic method, but Toluidine blue is used for identification/screening during the procedure. Incorrect Options: Option B) Congo red : Used for detecting amyloid deposits with apple-green birefringence- unrelated to laryngeal lesions. Option C) Hematoxylin and eosin (H&E): Used for histopathologic diagnosis, not for in vivo identification of dysplastic mucosa. Option D) Oil red O : Stains neutral lipids in frozen sections; not used for mucosal screening or carcinoma detection.

Q4: Which among the following is the least radiosensitive cell? (Q860529)

A. Monocytes

B. Platelets

C. Lymphocytes

D. Neutrophils

Correct Answer: B. Platelets

Explanation: Among the given options, platelets are the least radiosensitive cells. Radiosensitivity refers to the susceptibility of cells or tissues to the effects of radiation. Cells with higher rates of proliferation and less differentiation tend to be more radiosensitive because they are actively dividing and thus more vulnerable to the damaging effects of radiation. Platelets are the least radiosensitive as they do not divide actively. Order of Radiosensitivity: Lymphocytes > neutrophils ~ monocytes > platelets

@Neet_pg_bot

Q5: Which of the following instruments is not used in the colorimetric method for the estimation of hemoglobin? (Q840012)

Correct Answer: Unknown

Explanation: Correct Option: D) The instrument shown in Option D is an RBC pipette, which is used for manual RBC counting in hemocytometry. It is not a part of Sahli’s hemoglobinometer kit and is not required in the colorimetric estimation of hemoglobin. Colorimetric methods rely on comparing the color intensity of acid-hematin with a standard, not on cell dilution. Incorrect Options: The images in Options A, B, and C show a comparator, hemoglobin tube, and a stirrer respectively. They are components of Sahli's hemoglobinometer set. Sahli's method of hemoglobin estimation is a colorimetric method.

Q6: Which of the following is not a part of the criteria for diagnosis of Kawasaki disease? (Q840066)

A. Strawberry tongue

B. Polymorphic rash

C. Purulent conjunctivitis

D. Cervical lymphadenopathy

Correct Answer: C. Purulent conjunctivitis

Explanation: Correct Option C - Purulent conjunctivitis: The diagnostic criteria for Kawasaki disease include non-purulent conjunctivitis rather than purulent conjunctivitis. Incorrect Options: Options A, B & D: Strawberry tongue, Polymorphic rash, and Cervical lymphadenopathy are all features of Kawasaki disease.

Q7: Which of the following disorders presents with repeated catalase-positive infections? (Q840071)

A. X linked hypogammaglobinemia

B. SCID

C. Chronic granulomatous disease

D. Chediak Higashi Syndrome

Correct Answer: C. Chronic granulomatous disease

Explanation: Correct Option C - Chronic granulomatous disease: Chronic Granulomatous Disease is characterized by a defect in the NADPH oxidase enzyme complex. Without a functional NADPH oxidase, the patient is susceptible to recurrent infections caused by catalase-positive organisms. Incorrect Options: Options A, B, and D are not associated with recurrent catalase-positive infections.

Q8: A Diabetic patient's blood sample is kept in the given container. What will be added to the blood sample? (Q860268)

A. Na fluoride

B. EDTA

C. Na citrate

D. Heparin

Correct Answer: A. Na fluoride

Explanation: Grey top containers, used for glucose estimation, contain potassium oxalate as an anticoagulant and sodium fluoride to inhibit glycolysis by blocking enolase. Colour Anti-coagulants Uses {{caption_text}} Purple/Lavender EDTA (Ca2+ chelating anticoagulant) (Option B ruled out) CBC, Peripheral Smear, ESR, HbA1c {{caption_text}} Light Blue Trisodium Citrate (Ca2+ chelating anticoagulant) (Option C ruled out) ESR, PT, aPTT {{caption_text}} Red No anti-coagulant is added. Clot activator without gel Serum studies (Proteins, enzymes, hormones) {{caption_text}} Yellow Clot activator/Gel separator Serum studies (Proteins, enzymes,

hormones) {{caption_text}} Grey Sodium Fluoride (Option A) Blood Glucose Green Heparin (Option D ruled out) ABG, Osmotic fragility, flow cytometry, immunophenotyping

Q9: Which amino acid is necessary for the production of nitric oxide in the blood vessels? (Q859910)

A. Citrulline

B. Arginine

C. Histidine

D. Tryptophan

Correct Answer: B. Arginine

Explanation: Nitric oxide (NO) is a vital signalling molecule involved in vasodilation and various other physiological processes. Nitric oxide synthesis in blood vessels requires the amino acid arginine , which serves as its precursor. Steps in Nitric Oxide Synthesis: Enzyme Involved : Nitric oxide synthase (NOS) converts L-arginine to nitric oxide (NO) and L-citrulline in the presence of oxygen and cofactors like NADPH and tetrahydrobiopterin (BH4). Physiological Role of NO : NO is a potent vasodilator that relaxes vascular smooth muscle cells, thus regulating blood pressure and improving blood flow. It also has roles in neurotransmission and immune response. Citrulline (Option A) is a byproduct of nitric oxide synthesis and can be recycled back into arginine via the urea cycle , but it is not directly used in NO production. Histidine (Option C) is a precursor for histamine and is involved in immune responses, but it does not play a role in NO synthesis. Tryptophan (Option D) is a precursor for serotonin and melatonin but is not involved in nitric oxide production.

Q10: Which of the following is right regarding these stains? (Q879218)

A. Perl’s Prussian blue – stains iron, color red

B. Alizarin Red S – stains calcium, color black

C. Van Gieson – stains elastin, color blue

D. Giemsa – stains mast cells, color purple

Correct Answer: D. Giemsa – stains mast cells, color purple

Explanation: The accurate target structures and associated colors for these stains are: Stain Description Perl's Prussian blue It stains iron (ferric) - Blue Used to detect hemosiderin in tissues. Alizarin Red S Stains calcium deposits orange to red Van Gieson stain It stains collagen (red) and muscle (yellow). Elastic fibers stain black/blue-black only with Verhoeff's elastic stain (Verhoeff–Van Gieson). Giemsa stain Stains mast cell granules purple (metachromatic staining). Also used for blood smears and parasite detection (egmalaria).

@Neet_pg_bot

Q11: Lipid is best visualised on which technique in pathology? (Q879231)

A. Frozen section / Cryostat

B. Paraffin-embedded section

C. Immunohistochemistry

D. Electron microscopy

Correct Answer: A. Frozen section / Cryostat

Explanation: Lipids are best visualised in frozen sections (cryostat technique) because routine paraffin embedding dissolves fats during tissue processing with organic solvents like xylene and alcohol. In frozen sections, the tissue is rapidly frozen and cut without chemical processing , thereby preserving lipids for demonstration with fat stains such as: Oil Red O Sudan III / IV Sudan Black B Incorrect Options: Paraffin-embedded section (Option B): Lipids are dissolved during routine processing, so they are not visualized. Immunohistochemistry (Option C): Detects specific proteins, not lipids. Electron microscopy (Option D): Can show lipid droplets ultrastructurally but is not the standard technique for routine lipid visualization.

« Back to Folder Directory

[25_Platelets and Blood Transfusion] 088 Previous Year Questions — Quick Jump

Q1 (p. 3292) *Q2 (p. 3292)* *Q3 (p. 3293)* *Q4 (p. 3294)* *Q5 (p. 3294)* *Q6 (p. 3295)*
Q7 (p. 3297) *Q8 (p. 3298)* *Q9 (p. 3299)*

Q1: Match the following blood products with their shelf lives. a. 1-Granulocytes A- 5 days b. 2- PRBC B- 24 hours c. 3- SDP C- 42 days d. 4- CRYO D- 1 year (Q840026)

A. 1-A, 2-C, 3D, 4-B

B. 1-B, 2-D, 3-A, 4-C

C. 1-C, 2-A, 3-B, 4-D

D. 1-B, 2-C, 3-A, 4-D

Correct Answer: D. 1-B, 2-C, 3-A, 4-D

Explanation: Correct Option D - 1-B, 2-C, 3-A, 4-D: Granulocyte concentrate : They have a very short shelf life of 24 hours. PRBC (Packed Red Blood Cells) : Packed Red Blood cells have a shelf life of 35 to 42 days, depending on the anti-coagulant used: 21 days (ACD/CPD), 35 days (CPDA) and 42 days (SAGM). SDP (Single Donor Platelets) : Single Donor Platelets have a shelf life of 5 days, CRYO (Cryoprecipitate) : Cryoprecipitate has a shelf life of 1 year. Incorrect Options: Options A, B, and C are incorrectly matched.

@Neet_pg_bot

Q2: Which of the following is used in the treatment of Hemophilia B? (Q840031)

A. Factor 9

B. Cryoprecipitate

C. Factor 8

D. Tranexamic acid

Correct Answer: A. Factor 9

Explanation: Hemophilia B is caused by Factor IX deficiency (Christmas disease). Replacement therapy with Factor IX concentrate restores the intrinsic coagulation pathway and stops bleeding. It can be given prophylactically or during bleeding episodes or surgery. Incorrect Answers: Option B) Cryoprecipitate: Rich in Factor VIII, fibrinogen, and vWF, but contains minimal Factor IX. Not effective for Hemophilia B. Option C) Factor VIII: Used in Hemophilia A (Factor VIII deficiency). Does not correct Factor IX deficiency. Option D) Tranexamic acid : Antifibrinolytic; stabilizes formed clots. Supportive only, does not replace missing Factor IX.

@Neet_pg_bot

Q3: In a trauma patient with an unknown blood group who is unstable and requires urgent blood transfusion, which type of blood should be transfused? (Q840032)

A. A positive

B. AB positive

C. O positive

D. O negative

Correct Answer: D. O negative

Explanation: O-negative red blood cells are called the universal donor for RBC transfusion. O blood group has no A or B antigens, and negative Rh (D) antigen avoids Rh sensitization in Rh-negative recipients. This is critical in trauma or emergency situations when there is no time to determine blood group. Allows rapid transfusion while minimizing risk of acute hemolytic transfusion reactions. After stabilizing the patient and determining the blood group, group-specific blood should be transfused. Incorrect Options: Option A) A positive: May cause hemolytic reaction if the patient is type B or O. Option B) AB positive: Contains A and B antigens; unsafe for most unknown recipients. Option C) O positive: Safe for Rh-positive patients, but can sensitize Rh-negative recipients.

References:

.

↑ *Back to this question in Part A*

@Neet_pg_bot

Q4: Which of the following is not seen in a delayed hemolytic transfusion reaction? (Q840056)

A. Raised LDH

B. Raised indirect bilirubin

C. No improvement in Hb despite transfusion

D. Cola-colored urine after 2 hrs

Correct Answer: D. Cola-colored urine after 2 hrs

Explanation: Correct Option D - Cola-colored urine after 2 hrs Cola-colored urine is not a typical presentation in delayed hemolytic transfusion reactions. Instead, urine color typically ranges from red to brown during hemolysis. Additionally, delayed reactions typically occur after 2-3 days or even a few weeks. Incorrect Options: Options A, B & C: Raised LDH, Raised indirect bilirubin, and No improvement in Hb despite transfusion are all features of delayed hemolytic transfusion reactions.

↑ *Back to this question in Part A*

@Neet_pg_bot

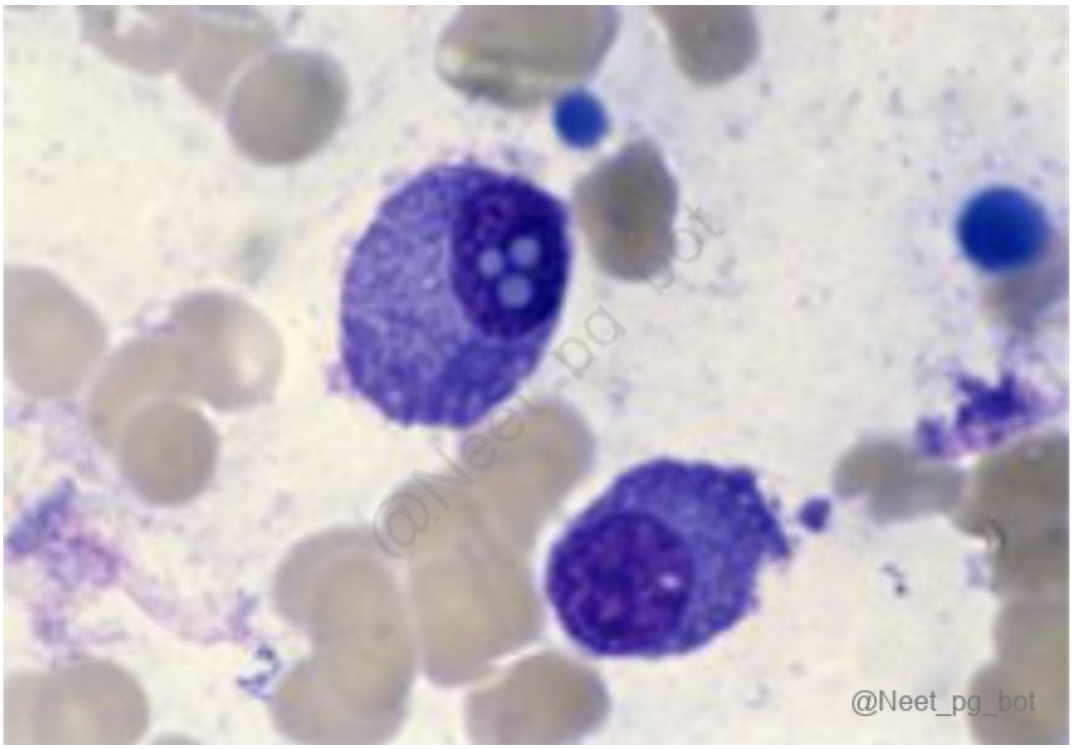
Q5: A patient presents with a tingling sensation in both legs, polyuria, and weight loss. Based on the given bone marrow aspirate findings, what is the most likely diagnosis? (Q844224)

A. Multiple myeloma with renal failure

B. SACD with vitamin B12 deficiency

C. SACD with diabetes

D. Waldenstrom's Macroglobulinemia



Correct Answer: A. Multiple myeloma with renal failure

Explanation: Correct Option A - Multiple myeloma with renal failure: The bone marrow aspirate shows intranuclear inclusions known as Dutcher's bodies, which are characteristic of multiple myeloma. Multiple myeloma often presents with renal failure, polyuria (due to hypercalcemia), and tingling sensations (due to amyloid deposition or hypercalcemia-related neuropathy). Incorrect Options: Options B, C, and D do not show Dutcher bodies on bone marrow biopsy.

@Neet_pg_bot

Q6: A child is brought to the emergency department with a large lesion on his forearm. As a surgery resident, you decide to excise the lesion in the emergency operation theatre. Which of the following investigations will test the entire coagulation pathway? (Q856915)

A. Activated partial thromboplastin time

B. Prothrombin time

C. Thromboelastography

D. Bleeding time

Correct Answer: C. Thromboelastography

Explanation: Thromboelastography (TEG) is a coagulation test that evaluates the entire coagulation pathway, including both the intrinsic and extrinsic pathways and fibrinolysis. It offers a comprehensive assessment of clot formation, clot strength, and clot breakdown. Thromboelastography (TEG) is a diagnostic tool used to evaluate coagulation profiles and guide management with transfusions and hemostatic therapies. Studies show that TEG can reduce blood product usage by up to 40%, decrease postoperative length of stay, and lower the risk of reoperation. TEG measures the viscoelastic properties of blood as clotting occurs. The resulting data is plotted on a graph with time on the x-axis and amplitude (clot strength) on the y-axis. Key values include: Reaction time (R): The time it takes for the clot strength to reach an amplitude of 2 mm. Kinetics (K): The time from R to when the amplitude reaches 20 mm. α-angle: The angle formed by a line from R to the point where K intersects with the 20 mm amplitude mark. Maximum amplitude (MA): The highest amplitude reached. Lysis at 30 minutes (Ly30): The per cent decrease in amplitude 30 minutes after MA (or 60 minutes in some cases). Inference: A prolonged R time may indicate coagulation factor deficiency or anticoagulation. A decreased α-angle can result from hypofibrinogenemia Low MA can be due to thrombocytopenia or platelet dysfunction. Increased Ly30 indicates hyperfibrinolysis, often seen in severe trauma or with thrombolytic therapy. Based on the TEG findings, targeted blood products can be administered to normalize coagulation. For example: Fresh frozen plasma for prolonged R time Cryoprecipitate for decreased α-angle Platelets for decreased MA Tranexamic acid or aminocaproic acid for increased Ly30 Incorrect Options: Activated Partial Thromboplastin Time (aPTT) (Option A) primarily evaluates the intrinsic pathway of the coagulation cascade. Prothrombin Time (PT) (Option B) mainly assesses the extrinsic pathway of the coagulation cascade. Bleeding Time (Option D) measures the duration for bleeding to cease following a standardized skin incision. It primarily evaluates platelet function and primary hemostasis.

@Neet_pg_bot

Q7: How does Total plasma exchange help in the management of TTP (Q857426)

A. TPE removes the Von Willebrand factor

B. TPE removes the Antiplatelet antibodies

C. TPE removes Anti ADAMTS13 autoantibodies and thereby increases the ADAMTS protease activity

D. TPE replenishes the coagulation factor

Correct Answer: C. TPE removes Anti ADAMTS13 autoantibodies and thereby increases the ADAMTS protease activity

Explanation: Total plasma exchange (TPE) is a key treatment for thrombotic thrombocytopenic purpura (TTP); it removes the autoantibodies against ADAMTS13. (Option B ruled out) ADAMTS13 is a protease that cleaves von Willebrand factor, preventing the formation of large, thrombogenic von Willebrand factor multimers. (Option A ruled out) This helps restore normal ADAMTS13 activity and reduces the microvascular clotting that characterizes TTP. Treatment of TTP Plasma exchange (PEX) with high-dose corticosteroid therapy. It is the mainstay of treatment in TTP. Corticosteroids operate by decreasing the activity of the reticuloendothelial system as well as decreasing autoantibody production. Both the ultra-large VWF multimers and the ADAMTS13 autoantibodies are effectively removed from circulation by plasma exchange therapy. The recommended volume of exchange is one estimated plasma volume (usually 40 mL/kg of body weight) with each treatment. The recommended dose for corticosteroids is 1 mg/kg per day of prednisolone. Rituximab An anti-CD20 monoclonal antibody was found to help treat TTP refractory to PEX. It targets B-lymphocytes and has a good response rate in refractory and relapsed TTP. Caplacizumab It has a high potential for TTP. It is a humanized monoclonal antibody fragment (a bivalent, variable-domain-only fragment) that attacks the A1 section of VWF and prevents platelet adhesion. Others Splenectomy, Vincristine, Cyclosporine and Cyclophosphamide. TPE replenishes the coagulation factor (Option D) : TPE does not replenish coagulation factors; instead, it removes harmful substances like autoantibodies against ADAMTS13 in TTP, where clotting issues stem from defective vWF cleavage, not coagulation factor deficiencies.

@Neet_pg_bot

Q8: What is the commonest cause of a hypercoagulable state? (Q857441)

A. Antithrombin III deficiency

B. Protein C deficiency

C. Factor V Leiden mutation

D. G20210A prothrombin gene mutation

Correct Answer: C. Factor V Leiden mutation

Explanation: The most common inherited cause of a hypercoagulable state (predisposing to thrombosis) is the Factor V Leiden mutation . Mutation: Factor V becomes resistant to cleavage and inactivation by protein C, disrupting the antithrombotic pathway. Inheritance: Autosomal dominant. Primary causes of Hypercoagulable states Common causes Factor V mutation (Factor V Leiden) Prothrombin mutation (G20210A) - It is comparatively less common than Factor V mutation (Option D ruled out) Elevated factor levels (VIII, IX, XI, or fibrinogen) Rare causes Antithrombin III deficiency (Option A ruled out) Protein C deficiency (Option B ruled out) Protein S deficiency Very rare causes Fibrinolysis Defects Homozygous Homocystinuria Secondary causes of Hypercoagulable states Major risk factors Myocardial infarction Atrial fibrillation Tissue injury (surgery, fracture, burn) Cancer Prosthetic cardiac valves DIC Heparin-induced thrombocytopenia Prolonged rest or immobilisation

Additional risk factors for thrombosis Cardiomyopathy Nephrotic syndrome Hyperestrogenic states (pregnancy and postpartum) Oral contraceptive use Sickle cell anemia Smoking

@Neet_pg_bot

Q9: Which of the following is the most common inherited bleeding disorder? (Q865368)

A. Von Willebrand Disease

B. Disseminated Intravascular Coagulation

C. Factor V Deficiency

D. Hemophilia

Correct Answer: A. Von Willebrand Disease

Explanation: Von Willebrand Disease (VWD) is the most common inherited bleeding disorder. Types: vWD type 1 vWD Type 2 vWD Type 3 Autosomal dominant. The most common type. Mild to moderate vWF deficiency. Quantitative defect. point substitutions prevent the vWF protein from maturing or cause it to leave the plasma quickly Autosomal dominant. Qualitative defect. Types: 2A, 2B, 2M, 2N 2A (Most common) - Decrease in binding between vWF and Gp1b/9 missense mutations cause faulty multimer formation → the most active forms of vWF, i.e. large- and intermediate-sized multimers are absent. 2B - Increase in binding between vWF and Gp1b/9 2M - VWF dependant platelet adhesion is decreased. There is impairment of VWF binding to platelets. Type 2M VWD typically has mild to moderate mucocutaneous bleeding 2N - There is marked decline in the binding affinity for factor VIII. The level of factor VIII is lower when compared to the VWF:Ag. This led to misdiagnosis as haemophilia A Autosomal recessive . Quantitative defect. produced by frameshift mutations or deletions affecting both alleles (autosomal recessive), which produce little or no vWF. Factor VIII levels are also lowered because vWF stabilizes factor VIII in the blood, and the resulting bleeding condition is severe. Disseminated Intravascular Coagulation (DIC) (Option B) is an acquired (not inherited), secondary condition due to systemic activation of the clotting cascade (e.g., in sepsis, trauma, malignancy). Factor V Deficiency (Option C) is a rare inherited bleeding disorder, also known as parahemophilia. Far less common than vWD. Hemophilia (A or B) (Option D) is an inherited X-linked recessive disorder involving Factor VIII (A) or Factor IX (B) deficiency. More common in males but still less prevalent than von Willebrand disease.
